 2085. C. A. Allison.—From F. P. Stone. Improvements in process of solidifying wood. Complete Specification. Jan. 26.

2195. A. Smart and G. W. Robertson. Improvements in apparatus employed in the manufacture of paving bricks or tiles. Jan. 27.  
 2402. W. D. Cliff. Improvements in glazed bricks and manufacture of the same. Complete Specification. Jan. 29.  
 2794. F. S. Winsor. Improved method of manufacturing stoneware and the like. Feb. 2.

3230. H. Muller and A. B. Hunter. Thin cement. Feb. 6.

3345. C. Lucke. Improvements in presses for forming artificial stones, slabs, tiles, and the like. Complete Specification. Feb. 8.

3574. A. H. van der Vygh, H. van der Vygh, and G. van der Vygh. Improvements in the construction of fire-proof buildings. Complete Specification. Feb. 10.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

3232. J. T. Hanson. A new method of constructing fire-proof floors, flats, partitions, and walls. Feb. 10.

3972. S. Neffgen. Manufacture of artificial stone. Jan. 27.

7866. J. Hamblet and I. Parkes. Apparatus for use in manufacture of coping bricks, terracotta building blocks, and the like. Feb. 17.

- 18,744. J. Junblath. Artificial stone for street pavements, pathways, and like purposes, and method of producing same. Feb. 3.

### X.—METALLURGY, MINING, Etc.

#### APPLICATIONS.

1508. R. Hodgson. Improvements in apparatus for extracting gold from ores. Jan. 19.

1515. C. I. Thorn. Sheet iron and steel castings close annealing heating furnace. Jan. 20.

1593. B. Becker. Improvements in the treatment of gold and silver ores. Jan. 20.

1778. C. Wichmann. Improvements in extracting gold from ores. Jan. 22.

2166. L. Yardley and G. Yardley. A new or improved method of enamelling aluminium articles. Jan. 27.

2204. H. E. Fry and R. H. Everitt. Improvements in the extraction of lead with silver, gold, and other metals from ores. Jan. 27.

2226. T. Doherty and P. D. Crenar. Improvements in or relating to the process of melting iron. Jan. 27.

2256. S. J. Robinson and S. Pope. Improvements in the construction of gas-heated steel-melting furnaces. Jan. 28.

2350. H. Wolff. Method for the preparation of zinc amalgam containing aluminium or magnesium. Jan. 28.

2922. A. Gutensohn. A new or improved process for recovering precious metals from metalliferous ore or sand. Feb. 3.

3037. K. A. May and F. Eldridge. An improved process for the extraction of gold and silver from their ores. Feb. 4.

3303. F. W. Streatfeild. Improvements in extracting metals from their ores or in obtaining solutions of same. Feb. 8.

3609. J. Robson and C. A. Joel. A new and improved aluminium alloy. Feb. 10.

3795. G. G. M. Hardingham.—From T. Huntington and F. Heberlein. Improvements in the treatment of sulphide ores of lead preparatory to smelting the same, and incidentally in obtaining sulphurous acid. Complete Specification. Feb. 12.

3926. H. Newerth. Improvements in the manufacture of iron and steel. Feb. 13.

3932. M. Hinzemann. An improved process for applying leaf metal. Complete Specification. Feb. 13.

## COMPLETE SPECIFICATIONS ACCEPTED.

1896.

2931. J. S. Wallace and J. Castell-Evans. Obtaining metals from refractory ores. Feb. 10.  
 3086. J. B. Torres. Extraction of gold, silver, and other metals from ores and the like. Feb. 17.  
 4122. The Exploring and Gold Mining Association, Ltd.—From S. H. Emmens. A process for recovery of zinc from blende ores. Jan. 27.  
 4667. F. F. Barnes and F. Campbell. Soldering of aluminium or metals alloyed with aluminium. Feb. 17.  
 6572. J. Inray. From M. A. J. Roux. Apparatus for separating volatile metals from their alloys. Feb. 17.  
 7615. R. Farley and E. Tonks. Manufacture of steel and iron sheets. Jan. 27.  
 18,417. C. Phillips. Dry process or method of ore-dressing and gold-separating, and apparatus therefor. Feb. 3.  
 23,958. G. W. Petersson. Process of manufacturing tripettes of iron ore or other iron compounds and briquettes thus made. Jan. 27.  
 25,133. A. Macdonald. See Class XIII.  
 26,066. D. White and T. M. Simpson. Method and apparatus for extracting precious metals from slimes or other finely-divided material containing the same. Feb. 10.

## XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

## APPLICATIONS.

- 25,360a. F. H. Snyder. Improvements relating to the coating or covering of metals and other substances with metals and other materials by the aid of the electric arc. Complete Specification. Filed Feb. 5. Date claimed Nov. 11, 1896.  
 1279. W. Rowbotham and C. Levetus. Improvements in and relating to accumulators or storage batteries. Jan. 18.  
 1369. W. Rowbotham. Improvements in and relating to accumulators or storage batteries. Jan. 19.  
 1430. E. J. Wade. Improvements in and connected with electrical storage batteries. Jan. 19.  
 1535. A. James. Improvements in the electric precipitation of gold and silver from their cyanide solutions. Complete Specification. Jan. 20.  
 1572. H. Leitner. Improvements in electrolytes for the deposition of zinc and for use in secondary batteries. Jan. 20.  
 1595. T. Hamilton. Improvements in electrical accumulators. Jan. 20.  
 1627. A. E. Cook. Certain improvements in apparatus for the electro-deposition of metals. Jan. 21.  
 1657. G. A. Webb and W. A. Thoms. Improvement in the electro-deposition of metals and alloys. Complete Specification. Jan. 21.  
 1714. W. Rowbotham. Improvements in and relating to accumulators or storage batteries. Jan. 22.  
 2207. J. Greenwood. Improvements in and relating to the decomposition of alkaline salts by electrolysis, and in apparatus therefor. Jan. 27.  
 2253. A. L. Porte and J. R. Sykes. Improvements in electrical accumulators. Jan. 28.  
 2272. J. L. Dobell. Improvements in or connected with electric batteries. Jan. 28.  
 2291. M. Engl. Improvements in insulating frames for electrodes. Jan. 28.  
 2378. W. Rowbotham. Improvements in and relating to primary batteries. Jan. 29.  
 2412. H. J. Sheldon. An improved method of depositing aluminium by electricity. Jan. 29.  
 2418. E. W. Benson. An improved form of electrode for galvanic or secondary batteries. Jan. 29.  
 2447. P. W. Northey and The Epstein Electric Accumulator Co., Ltd. Improvements in and relating to accumulators or storage batteries. Jan. 29.

2572. C. R. G. Smythe and M. Crawford. Improvements in and connected with electric accumulator and battery plates. Feb. 1.

2709. W. E. Heys.—From E. Dumoulin. Improvements in and relating to the electro-deposition of copper and other metals. Feb. 2.

2710. W. E. Heys.—From E. Dumoulin. Improvements in the method of and apparatus for the electro-deposition of copper and other metals on rotary mandrels. Feb. 2.

2711. W. E. Heys.—From E. Dumoulin. Improvements in and connected with apparatus employed in the electro-deposition of copper and other metals. Feb. 2.

2712. W. E. Heys.—From E. Dumoulin. Improvements in and connected with apparatus for the electro-deposition of copper and other metals. Feb. 2.

2789. H. S. Lloyd. Improvements in storage batteries. Complete Specification. Feb. 2.

2790. L. Bresson and P. Pacotte. Improvements in electric furnaces for use in the manufacture of calcium carbide, applicable also for obtaining metals from their salts. Filed Feb. 2. Date applied for Sept. 15, 1896, being date of application in France.

2796. P. C. A. Laglenne. Improvements in electric batteries. Feb. 2.

3053. E. S. New. Improved separator for the plates of secondary batteries. Feb. 5.

3113. R. R. von Perks and J. Benger. Improvement in electrical accumulators. Feb. 5.

3235. I. A. Timmis. Improvements in secondary batteries. Feb. 6.

3346. C. Payen. Improvements in secondary batteries. Feb. 8.

3488. E. Schattner. Improvements in secondary batteries. Feb. 10.

3526. J. E. Hordley.—From F. W. Zingsem. Improvements in apparatus for the electro-deposition of metals. Feb. 10.

3831. A. R. Adams. Improvements in or relating to electric batteries. Feb. 12.

## COMPLETE SPECIFICATIONS ACCEPTED.

1896.

4957. E. Clark, W. Clark, and F. King. Plates, grids, or supports for the elements of secondary batteries. Jan. 27.

5673. A. S. Elmore.—From J. O. S. Elmore. Apparatus for refining metals by electrolysis. Feb. 17.

7259. W. P. Thompson.—From J. Julien. Construction of soluble metal electrodes for accumulators. Jan. 27.

12,149. T. J. Holland. Electrolytic apparatus. Jan. 27.

23,663. P. Garuti and R. Pompili. New and useful improvements in the apparatus for the production of oxygen and hydrogen by electrolysis. (System Garuti.) Feb. 17.

25,799. F. W. Schneider. Construction of electrodes for accumulators. Feb. 3.

25,804. Dieffenbach. Electrolytic production of zinc and alkalis. Feb. 17.

29,307. A. Heil. Peroxide of manganese and carbon electrodes, and method of producing the same. Feb. 10.

29,907. C. Brault. Manufacture and production of elements or plates for electrical storage batteries. Feb. 17.

## XII.—FATS, OILS, AND SOAP.

## APPLICATIONS.

1305. T. C. Bryan and B. J. Sharpe. Washing solution. Jan. 18.

1355. E. A. Ruch. Improved method of concentrating glycerin. Complete Specification. Filed Jan. 18. Date applied for July 18, 1896, being date of application in France.

1448. G. Varley and A. Jervis. Improvements in means for deodorising petroleum and like oils. Jan. 19.

1554. J. C. F. Müller. Process and manufacture of a cleaning and caustic agent. Complete Specification. Jan. 20.

2324. J. Twinch. An improved process for the refining of linseed oil and the manufacture thereof. Jan. 28.

2662. W. E. Pearson. Improvements in and connected with the production of prepared tar, mineral, and other oils for pharmaceutical, veterinary, technical, and other purposes. Feb. 1.

3207. E. J. Ellis. Improvements in or relating to soap or detergents. Feb. 6.

3700. J. David. Improvements in the treatment of oleic acid. Feb. 11.

3702. F. J. Billingham. An improvement in the manufacture of soap. Feb. 11.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

799. H. Hinterberger. Apparatus for separating oil and air from water and recovering the oil. Feb. 17.

2511. J. Jack and M. Blake. Extracting and recovering oil from fish, fish refuse, or other oil-producing animal or vegetable matters. Jan. 27.

7379. W. R. Harrison and E. Stephenson. Method and apparatus for extracting oil from seeds or other oleaginous substances. Feb. 10.

25,472. J. Davidson. Manufacture of fatty matter from certain animal tissues. Jan. 27.

#### XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, Etc.

##### APPLICATIONS.

2108. C. L. Barnham. An improved paint for ships' bottoms. Complete Specification. Jan. 26.

2667. A. J. Boulton.—From F. Fritzsche and Co. Improvements in preservative paints, pigments, and the like. Feb. 1.

3116. J. de F. Maunier. Improvements in the manufacture of zinc oxide. Feb. 5.

3576. J. C. Mewburn.—From J. C. Taylor. Improvements in the manufacture of anti-fouling compositions or paints. Feb. 10.

25,133. A. Macdonald. Manufacture of white lead pigment and in the separation of metallic lead from lead sulphide. Feb. 10.

#### XIV.—TANNING, LEATHER, GLUE, AND SIZE.

##### APPLICATIONS.

1442. W. J. J. Hawkins. Improvements in printers' roller composition or the like. Jan. 19.

1587. T. D. Bowman and J. Bowden. Improved manufacture of imitation leather. Jan. 20.

2746. A. J. Boulton.—From C. M. Higgins. Improvements in or relating to adhesive compounds. Complete Specification. Feb. 2.

3073. J. Howden.—From J. Tyciak. Improvements in glue compounds and in applying the same to barrels and the like. Complete Specification. Feb. 5.

3180. S. Millar and C. E. Millar. Improvements in treating hides and skins. Feb. 6.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

3901. F. B. O. Hawes. Treatment of leathers for their better preservation and surface preparation. Feb. 3.

44199. J. Hall. Apparatus for treating skins, hide, leather, and like substances. Feb. 17.

10,263. A. Levinstein. Tanning. Feb. 17.

10,390. A. Levinstein. Tanning apparatus. Feb. 17.

#### XV.—AGRICULTURE AND MANURES, Etc.

##### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

2678. J. G. Wiborgh. Treatment of apatite and other mineral phosphates, and manufacture therefrom of products suitable for fertilising purposes. Feb. 10.

24,776. O. Heymann and A. Nitsch. Process and apparatus for the drying and disintegration of superphosphates. Feb. 3.

#### XVI.—SUGARS, STARCHES, GUMS, Etc.

##### APPLICATIONS.

1338. A. Verley. Improvements in the manufacture of sugar. Jan. 18.

3138. T. E. Forman. Improvements in the manufacture of extracts and preparations to be used in the conversion of starch, gluten, and for other purposes. Feb. 9.

3472. F. L. Calmant. An improved process for the purification of alcohol in general and of raw beetroot sugar and residue by means of carbonic acid and vegetable carbon. Feb. 9.

3900. A. Weickmann. See Class XVII.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

3613. E. Shaw. Boiling sugar and other syrups. Feb. 17.

28,188. A. J. Boulton.—From L. Janssens and Co. Production of sugar. Feb. 10.

#### XVII.—BREWING, WINES, SPIRITS, Etc.

##### APPLICATIONS.

1455. A. Kinder. Improvements in or relating to malt kilns. Complete Specification. Jan. 19.

2287. E. E. M. Payne, T. O. Kent, and E. E. Pullman. Improvements in compositions or mixtures to be used for the preservation of malt liquors such as ale, beer, stout, porter, and other like saccharine liquids, and in the methods of using and applying such compositions or mixtures. Jan. 28.

2434. J. Sinclair. Improved valve fittings for use in fermenting vats or "stone squares." Jan. 29.

2553. J. L. Dewar. A new or improved method of treating beer, ale, stout, and other fermentable liquors for bottling. Jan. 30.

2872. B. Tabrum. Improvements in the process of preserving hops. Feb. 3.

3472. F. L. Calmant. See Class XVI.

3900. A. Weickmann. A process for utilising the solid refuse of breweries, distilleries, starch, sugar, poudrette factories, and the like. Feb. 13.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

2150. R. Cudiffe. See Class I.

21,022. A. E. Feroe. Process and apparatus for treating malt liquors. Feb. 10.

22,403. C. H. McEuen.—From J. T. Bennett. Apparatus and process for removing saccharine and other impurities from wine and spirits. Feb. 17.

28,763. J. Y. Johnson.—From The Electric Rectifying and Refining Co. Apparatus for purifying and decolorising saccharine solutions and other liquids. Feb. 17.

#### XVIII.—FOODS, SANITATION, Etc., AND DISINFECTANTS.

##### APPLICATIONS.

##### A.—Foods.

2670. J. L. W. Thudichum. New and improved modes of producing and treating extracts of flesh or meat and of other parts of animal bodies. Feb. 2.

3810. H. Schowell. Improvements in or relating to the preparation of lupines for yeast manufacture, cattle food, and similar purposes. Feb. 12.

3830. B. Iribarnegaray. An improved process for use in preserving butter and other foodstuffs. Complete Specification. Feb. 12.

##### B.—Sanitation.

1437. W. J. Engledeu. Improvements in the treatment of sewage. Jan. 19.

1722. P. R. Candy. Improvements in apparatus for use in the purification of sewage and polluted waters. Jan. 22.

2228. F. W. Strong. Improvements in tanks and apparatus for use in connection with the same for the purification and treatment of sewage and impure waters. Jan. 27.

2757. E. S. Heaven. Improvements in processes for the treatment of sewage. Feb. 2.

#### C.—Disinfectants.

2774. I. Werber. Improved anti-septic or disinfectant preparation. Feb. 2.

#### COMPLETE SPECIFICATIONS ACCEPTED.

##### A.—Foods.

1896.

5749. D. Finkler. Preparation and extraction of albuminous substances from animal or vegetable mixtures and products. Feb. 17.

6496. W. Nageli. Process for sterilising and preserving food products and beverages. Feb. 17.

25,204. H. D. Perky. Machines for the reduction of cereals and other products to useful, artistic, and convenient forms for food. Jan. 27.

28,708. A. J. C. Rayson. The manufacture of a substitute for coffee. Jan. 20.

##### B.—Sanitation.

1896.

3047. J. B. Petrie. Construction of settling tanks or lodges, used in the purification of sewage and other foul waters, and in the clarification of manufacturers' liquid compositions. Jan. 27.

5955. W. E. Adney and W. K. Parry. The utilisation of by- and waste products from iron and steel industries for the manufacture of improved precipitants for the purification of sewage and other waste liquids. Feb. 17.

##### C.—Disinfectants.

1896.

5381. P. O. Dowd. Composition for utilising and disinfecting sewage matter. Feb. 10.

5705. J. N. Spence. New or improved insecticide. Feb. 3.

5955. W. E. Adney and W. K. Parry. See Class XVIII. B.

14,852. M. Crawford. Manufacture of disinfecting, deodorising, and bleaching agents, and apparatus therefor. Jan. 27.

#### XIX.—PAPER, PASTEBOARD, Etc.

##### APPLICATIONS.

1390. D. Pearson and D. N. Bertram. Improvements in paper-pulp refining engines. Jan. 19.

1550. P. H. Hansen and J. K. Westengaard. Improvements in the manufacture of artificial horn and the like. Jan. 20.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

1556. C. Raymond. Manufacture of gelatinised paper or other fabrics suitable for the reproduction, by printing with fatty inks, of writings, drawings, and the like. Feb. 3.

8309. H. Thame. Manufacture of hollow pulp-ware, particularly applicable to buoyant articles. Feb. 17.

26,464. J. A. Wilkinson, F. C. Wilkinson, and A. T. Wilkinson. Machine for softening paper. Jan. 27.

#### XX.—FINE CHEMICALS, ALKALOIDS,

##### ESSENCES, AND EXTRACTS.

##### APPLICATIONS.

1339. C. Goldschmidt. The application of piperidine for effecting the dissolution of uric acid. Jan. 18.

2472. J. Y. Johnson.—From C. F. Boehringer and Soehne. Improvements in the preparation of hydroxycafeine by the direct methylation of uric acid or of certain mono- and dimethyl derivatives thereof also obtainable in the process. Jan. 29.

2556. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of nitroaliphylpyruvic acids. Jan. 30.

3118. A. Walker. Improvements in the manufacture of malt extract. Feb. 5.

3199. W. Mills. Manufacturing the nitride of carbonyl. Feb. 10.

3500. W. Mills. Improvements in manufacturing nitrides. Feb. 10.

3501. W. Mills. Improvements in manufacturing urea. Feb. 10.

3957. J. Y. Johnson.—From C. F. Boehringer and Soehne. Improvements in the manufacture or preparation of dichloroxypurine. Feb. 13.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

2205. A. J. Boulton.—From C. Schmid. A new benzene sulphonic acid and artificial musk. Feb. 10.

3555. J. C. Richardson. Manufacture of camphors or like compounds. Jan. 27.

15,295. W. E. Heys.—From The Chemische Fabrik vormals Sandoz. The manufacture or production of bis-methoxydiodide-methylgallate. Feb. 10.

28,969. L. Lederer. A process for the preparation of acetyl and lactyl derivatives of aniline and phenitidine. Jan. 27.

#### XXI.—PHOTOGRAPHY.

##### APPLICATIONS.

2269. T. Miller. A mode of developing photographic negatives without the aid of a dark room. Jan. 28.

2305. H. H. Lake.—From H. C. Fairchild. Improvements in methods of producing photographs in relief. Complete Specification. Jan. 28.

3121. G. J. Sersball. Improvements in photographs with coloured effects, and in the method of producing same. Feb. 5.

#### COMPLETE SPECIFICATION ACCEPTED.

1896.

29,437. E. Edwards.—From O. Moh. Process for making photographic negatives. Feb. 17.

#### XXII.—EXPLOSIVES, MATCHES, Etc.

##### APPLICATIONS.

1603. W. G. Newton. Improvements in safety fuses. Jan. 21.

2557. M. Bielefeldt. Improved manufacture of explosives. Jan. 30.

2785. A. J. Fredrikson. Improvements in and relating to the manufacture of matches. Feb. 2.

3002. H. Maxim.—From R. C. Schupphaus. Improvements in smokeless explosives and processes of their manufacture. Feb. 4.

3135. H. R. von Dalmen. Improvements in blasting compositions. Feb. 5.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

4509. W. Greaves and E. M. Hann. Explosives. Feb. 3.

5575. A. Pain. Improvements in ships' signal lights, rockets, and similar fireworks. Jan. 27.

5815. G. Craig. Manufacture of nitrate of ammonium and apparatus therefor. Feb. 10.

6052. G. Schwiemung. Manufacture of igniting compound for matches. Jan. 27.

6937. W. Greaves and E. M. Hann. Explosives. Feb. 3.

25,711. C. Mortier and H. A. Sardon. Manufacture of gunpowder. Feb. 3.

#### XXIII.—ANALYTICAL CHEMISTRY.

##### APPLICATION.

3673. G. S. Newth. Improved means of detecting potassium compounds in analysis. Feb. 11.

# THE JOURNAL

OF THE

# Society of Chemical Industry.

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 3.—VOL. XVI.]

MARCH 31, 1897.

[Non-Members 30 per annum; Members 21 per Set of extra or back numbers; Single Copies (Members only) 2 6.]

## The Society of Chemical Industry.

### Past Presidents:

Sir Henry E. Roscoe, B.A., D.C.L., LL.D., Ph.D., F.R.S.	1881—1882.
Sir Frederick A. Abel, Bart., K.C.B., D.C.L., D.Sc., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, LL.D., Ph.D., F.R.S.	1884—1885.
E. K. Muspratt	1885—1886.
David Howard	1886—1887.
James Dewar, M.A., LL.D., F.R.S.	1887—1888.
Ludwig Mond, Ph.D., F.R.S.	1888—1889.
Sir Lowthian Bell, Bart., F.R.S.	1889—1890.
E. Rider Cook	1890—1891.
J. Emerson Reynolds, M.D., F.R.S.	1891—1892.
Sir John Evans, K.C.B., D.C.L., LL.D., Sc.D., F.R.S.	1892—1893.
E. C. C. Stanford	1893—1894.
T. E. Thorpe, LL.D., Sc.D., Ph.D., F.R.S.	1894—1895.
Thomas Tyrer	1895—1896.

## COUNCIL FOR YEAR ENDING JULY, 1897.

President: Dr. Edward Schnuck, F.R.S.

### Vice-Presidents:

Chas. Dreyfus.	Dr. W. Jay Schieffelin.
Dr. A. Dupre, F.R.S.	E. C. C. Stanford.
Prof. A. K. Huntington.	G. N. Stoker.
Boverton Redwood.	Dr. T. E. Thorpe, F.R.S.
Sir H. E. Roscoe, F.R.S.	Prof. W. A. Tilden, F.R.S.
A. Gordon Salamon.	Thomas Tyrer.

### Ordinary Members of Council:

George Beilby.	C. C. Hutchinson.
R. Forbes Carpenter.	Ivan Levinstein.
R. Le Neve Foster.	J. S. McArthur.
Oscar Guttman.	B. E. R. Newlands.
Douglas Herman.	Sir Robert Pullar.
David Howard.	Wm. Thorp, B.Sc.

With the Chairmen and Secretaries of Sections.

### Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

### Honorary Foreign Secretary:

Dr. Ludwig Mond, F.R.S.

General Secretary: Charles G. Crosswell.

Offices: Palace Chambers, 9, Bridge Street, Westminster, S.W.

## THE JOURNAL.

### Publication Committee:

#### The President.

A. H. Allen.	C. Clarke Hutchinson.
G. H. Bailey, D.Sc., Ph.D.	Wm. Kellner, Ph.D.
Joseph Beruys, M.I.C.E.	J. Lewkowsitch, Ph.D.
H. Brunner.	A. R. Ling.
A. C. Claudet.	Ludwig Mond, F.R.S.
E. Rider Cook.	B. E. R. Newlands.
Chas. Dreyfus.	John Pattinson.
Sir John Evans, K.C.B., F.R.S.	W. H. Perkin, Ph.D., F.R.S.
G. G. Henderson, D.Sc.	II. R. Procter.
John Heron.	Boverton Redwood.
D. B. Hewitt, M.D.	Walter F. Reid.
David Howard.	John Spiller.
Prof. J. J. Hummel.	William Thorp.
Prof. A. K. Huntington.	Thomas Tyrer.
F. Hurter, Ph.D.	Lewis T. Wright.

### Editor:

Watson Smith, 34, Upper Park Road, Haverstock Hill, N.W.

## NOTICES.

### COLLECTIVE INDEX.

In reply to numerous inquiries, the compilation of the Collective Index is in active progress, part of the work being already in the printers' hands. The labour of revision and correction must, however, of necessity, take time; and it is hoped that those members who have already subscribed will extend their indulgence to the Indexer, who is making every effort to complete this vast work.

The prices are as follows:—

To Members (see Rules 25 and 27) and Past Members (see Rule 30): Libraries, Corporations, and Exchanges on the Society's List	Each copy 10s.
To Subscribers .....	12s. 6d.
To others.....	15s.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SPOTTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed. The circulation of the Journal is now more than 3,000 per month.

#### ANNUAL GENERAL MEETING.

The Annual General Meeting will be held in Manchester on the 14th, 15th, and 16th July next. Tickets of Membership will be issued in time for the Meeting, and will form, as heretofore, vouchers for visits to works and excursions.

#### LIST OF MEMBERS ELECTED 23rd MARCH 1897.

Auger, Chas. L., 425, Park Avenue, Paterson, N.J., U.S.A., Silk Dyer.  
 Basu, Atul K., 76—77, Sookan's Street, Calcutta, India, Chemical Analyst.  
 Bird, Chas. S., F. W. Bird and Son, East Walpole, Mass., U.S.A., Paper Maker.  
 Burgess, Geo. E., Thorn Bank, Ellesmere Park, Eccles, Manchester, Dyer.  
 Campbell, Jos., Montezuma G.M. Co., Ltd., Te Aroha, Auckland, N.Z., Consulting Chemist.  
 Coreoran, Jas., 160, Great Portland Street, London, W., Analytical and Manufacturing Chemist.  
 Cunningham, Maxwell, Cairnsmore, Helensburgh, N.B., Student of Chemistry.  
 Dick, John, 14, Bay Street, Toronto, Ont., Canada, Manufacturer.  
 Dolge, Carl B., Westport, Conn., U.S.A., Manufacturer of Instruments and Antiseptics.  
 Farrell, Frank J., Holly Bush, Altrincham, Cheshire, Analytical Chemist.  
 Gronemeyer, Herman H., 731, Giddings Avenue, Cleveland, Ohio, U.S.A., Chemical Superintendent.  
 Harris, Fred. W., Public Analyst's Office, Buruley, Lancashire, Public Analyst.  
 Hart, Wm. Beaumont, Laboratory, 18, Exchange Street, Manchester, Consulting Chemist.  
 Hawkins, Ernest M., 57, Lewin Road, Streatham, S.W., Chemistry and Vinegar Brewer.  
 Heap, Gerald, Lea House, Littleborough, near Manchester, Dyer and Flannel Finisher.  
 Heriot, T. H. P., Fine Ste. Madeleine, Trinidad, W.I., Analytical Chemist.  
 Kearns, Jno. S., Baxenden House, near Accrington, Chemist and Dyer.  
 Kemper, Chas. H., Westport, Conn., U.S.A., Manufacturer.  
 Langdon, Saml. P., Gutta-Percha Manufacturing Co., Parkdale, Toronto, Ont., Canada, Rubber Manufacturer.  
 Lovibond, Mrs. V. A. Frederica, Cannon Brewery, Fulham, S.W., Brewer.  
 Miller, Dr. Edmund H., School of Mines, Columbia University, New York, U.S.A., Chemist.  
 Nelson, Horatio W., 277, Rue St. Urbain, Montreal, Canada, Manufacturer of Electrical Insulators.  
 Nicholson, Harry, Elmore Patent Copper Depositing Co., Pontefract Road, Hunslet, Leeds, Assayer.  
 Quioan, Wm. R., Pinole, Contra Costa Co., Cal., U.S.A., Superintendent (California Powder Works).  
 Skertchley, W. P., Laboratory, 11, Billiter Square, E.C., Analytical Chemist.  
 Snodgrass, Jas., Budhill Chemical Works, Shettleston, near Glasgow, Chemical Manager.  
 Thiel, Dr. C. Walther, 125, Eccles Old Road, Pendleton, Manchester, Chemist.  
 Van Marken, Jacob C., c/o Carbonic Acid Gas Co., Lea Bridge Road, Clapton, N.E., Chemical Engineer.  
 Ward, H. Snowden, 6, Farringdon Avenue, London, E.C., Journalist.  
 Wedge, Uley, Bayonne, N.J., U.S.A., Oil Refiner (Standard Oil Co.'s Chemical Works).

#### CHANGES OF ADDRESS.

SESSION 1896-97.

April, 5th, 1897.—Mr. Oscar Guttman, Assoc. M. Inst. C.E., F.I.C.  
"The Chemical Stability of Nitro-compound Explosives."

Meeting held on Monday, January 18th, 1897.

## THE CHARACTER OF THE LONDON WATER SUPPLY.

BY W. J. DIBDIN, F.I.C., ETC.

(This Journal, 1897, 9.)

### DISCUSSION.

Mr. W. T. BURGESS, having had considerable experience of London water examination in Dr. Frankland's laboratory, was deeply interested in the figures put before the meeting. He had had no experience in working the micro-filter, but looking at the figures before them he thought it at least possible that the results might be influenced by the length of main through which the water passed before examination. For instance, the Southwark Company had to send its water through a very considerable distance of main, and until one had exact information as to the points at which the samples were taken, one could not properly criticise them. Referring to Table IV., which gave percentages of nitrogen in suspended matters and sludges of different origin, he thought it a pity the author had not included some suspended matter or deposit taken from the Welsh rivers. He doubted Mr. Dibdin's correctness in assuming that the improvement in the water supply during the last few years was the result, to a great extent, of the L.C.C. examination made in 1891. If the records of the examinations made by Dr. Frankland for the Local Government Board were examined, it would be seen that the year 1891 was relatively a bad one for the Company's operations. The years immediately in front of 1891 were much better, and the results then obtained compared very favourably with those got in 1893, 1894, and 1895. His own experience of the combustion process led him to think that the author's figures for organic nitrogen were decidedly too high. The author's results showed how well, so far as organic matters were concerned, London filtered water compared with the Welsh river water.

Dr. DUBRE congratulated the author on the admirable working of his micro-filter. He would confine his remarks to the bacteriological aspect of the question. In his opinion, water known to be contaminated by sewage should be rejected entirely for domestic purposes. He thought that the principal danger to London lay in the possibility of an epidemic occurring among the population higher up the river. Instancing the cholera epidemic at Hamburg, Dr. Dupré said that the Hamburg people had drunk the water of the Elbe for many years with impunity, but the cholera infection coming down with the river water had caught the city undefended. Altona—a suburb of Hamburg—it was thought was secure on account of its filter beds, but on one

occasion the filter beds broke down, and the number of deaths that occurred would have been equivalent to 5,000 in the London water area. If such a thing were to occur in London it would occasion a terrible and justifiable outburst of indignation. Dr. Koch had fixed 100 micro organisms per c.c. as a measure of effective filtration which should not be exceeded. It was quite clear from the tables before them that that was a limit which was very frequently exceeded in the London drinking waters. Dr. Koch also urged that whenever, during an epidemic, the number of micro-organisms rose above that limit, consumers should be informed, so that they might take preventive measures; but unfortunately it took at least two days to discover the condition of the water, and therefore that precaution was not all that could be desired. He would admit that, on the whole, filtration of the London water supply was extremely well conducted, but it was susceptible of improvement, especially in the direction of more frequent and careful tests. Every filter ought to be watched daily. If the people of London, knowing the risk they ran, chose to submit to it rather than incur the expense of protection, well and good. But the public ought at least to have the case put fully and clearly before them, so that they might make their choice with their eyes open.

Mr. A. E. FLETCHER considered that Mr. Dibdin had shown clearly that not only an immense improvement had been made by the water companies in the matter of more careful filtration, but that this improvement might be carried still further, and the water supply of London rendered much more suitable for consumption by the adoption of Clarke's process for softening the water. It was difficult to understand how the people of London could submit to use a water notorious for its hardness, and sometimes for its pollution also, when a process for purifying and softening it was available, which process had been proved efficient by the experience of the last 50 years. Using as he did a supply that was so treated he felt the advantage of having a water which did not corrode the supply pipes and kitchen utensils. Even the economy thus effected would compensate to a great extent the necessary outlay. The main point, however, was the benefit to the health of the people that would follow from the more efficient purification of their water supply if so treated; and, taking into account the enormous dividends which the London water companies now realised, he thought that they should not hesitate on the ground of expense to adopt any process which would secure that end. He thought that this Society ought to send forth an emphatic endorsement of Mr. Dibdin's recommendation in this paper of the adoption of some process for softening the London water.

Mr. SHIRLEY MURPHY said his own duty was to consider the effects of the water supply on the health of the inhabitants of London. In former times, when the water for domestic purposes was drawn from the rivers, where they were subject to tidal influence, the effects of these waters was manifested in times of cholera prevalence in the mortality returns; but since the companies had gone above the locks for their supplies, this evidence had been wanting; and, except in 1866, when cholera was undoubtedly spread by water drawn from the Lea, it had not been shown that the river waters had added to the death rate. More recently they had been able to study this subject more minutely, as, owing to the system of notification of cases of infectious disease in force in London, the subject could be considered in the light of cases instead of deaths. He had in a recent report given the figures of notified cases of enteric fever relating to a year in which there had been exceptional floods in the rivers, and these figures raised the question whether the London river water had not on that occasion, although in very much less degree, behaved in a manner similar to that in which Mr. Barry had shown the Tees water had behaved. He agreed with Mr. Dibdin that the water supplied from the rivers was capable of great improvement.

Dr. J. A. VOELCKER had worked according to the author's method, and had found it extremely useful. It seemed to him, however, to fail in one important point, namely, that it did not distinguish between quantity and quality. It was said that suspended matter might be

disregarded if it did not exceed 1 mm. per litre. His own opinion was that if a river were in flood and gave more than that amount of earthy matter, this might be unpleasant, but not dangerous; whereas if it were only  $\frac{1}{2}$  mm. per litre, and that  $\frac{1}{2}$  mm. consisted of dangerous matter, it would make all the difference. Therein lay the whole crux of the question, *viz.*, quality as compared with quantity of suspended matter. With respect to the physiological side of the subject, notwithstanding the great advance made in that department of knowledge, he must confess himself still an unbeliever in its usefulness until we came to know which bacteria were harmful and which were harmless. For his part he was willing to drink a good deal of suspended matter in the form of *débris*, but he would not, if he could help it, take one poisonous bacterium into his system. While admitting the force of the arguments advanced by Dr. Dupré and Mr. Fletcher, he must confess that, knowing what he did of the respective water supplies of London and of the country, he would, on the whole, rather take his chance of life with the London supplies. There was another point, namely, that after all, a greater amount of harmful matter was frequently introduced into our water supply after rather than before the distribution of it commenced. Far more care ought to be taken to keep a water supply free from the contamination to which it was subject in the cisterns of houses. Lastly, as to the suggestion that London water should be softened by means of Clarke's process, that might possibly be necessitated in the case of waters of certain districts but it would be decidedly objectionable from a health point of view in the case of London.

Mr. J. A. R. NEWLANDS endorsed the opinion expressed by Mr. Dibdin and others that it would be highly beneficial to the London water supply to treat it by the Clarke softening process. The question of expense should not be allowed to stand in the way of the public welfare, since the public health was a matter of supreme importance. Even after the application of that process the London supply could hardly be considered a "soft" water.

*Meeting held on Monday, February 15th, 1897.*

#### FURTHER DISCUSSION ON MR. W. J. DIBDIN'S PAPER ON "LONDON WATER SUPPLY."

Mr. BECTRAM BLOUNT said that, notwithstanding the disadvantages of discussing a paper a month after its reading, there was so much of real importance in Mr. Dibdin's production that the interest of the meeting would, he hoped, be sustained. He congratulated the author heartily on having supplied for the purpose of water examination an analytical process which must be reckoned a distinct improvement on existing methods. The criticisms offered had, however, some justification, namely, that a certain assumption had to be made in estimating the quantity of collected precipitate. This precipitate was collected in a tube so small in bore that it was practically capillary; and the diameter of the tube was a factor in the measurement of the quantity of the precipitate. The determination could therefore hardly be made with extreme accuracy, because the tube itself would not always be circular or of known internal diameter. It would be well therefore if tubes could in future be standardised, to save trouble to the users. It seemed to him that the qualitative aspect of the examination was of greater importance than the quantitative, because it would give one some idea of the character of the water supply which had created the precipitate. In this connection he would refer particularly to the very large relative correction made for what the author called unavoidable "rust and dust," which seemed to him to deduct somewhat from the value of the method. Perhaps the author could tell them whether much of the detritus was ascribable to the attrition of packing materials used in the pipes, which would naturally break up in time and be caught on the micro-filter. It was very satisfactory to have it placed on record by so eminent an authority as Mr. Dibdin that London water is not always perfectly clear—that being a fact of which it was very difficult to convince the officials of the water companies. Coming to a more serious consideration *viz.*, the significance of this material,

he must dissent from the view that the small quantities of suspended matter present indicated something seriously wrong in London water. The case had been stated clearly and fairly by Dr. Dupré, who had said that Londoners should clearly recognise that they were running some risk in drinking sewage contaminated water purified by filtration. There were risks in everything, and he for one was well content to accept the present condition of London water as sufficiently satisfactory. He considered that dishonest efforts were being made by irresponsible persons to vilify the character of London water—persons who had not, like Mr. Dibdin, a genuine scientific interest in the matter; and these tactics ought to be clearly condemned. Referring to the character of the Welsh water advocated by such persons, he found that according to Mr. Dibdin's results London water would compare with it by no means unfavourably, and it was to be borne in mind that whereas for the London water they had the figures for the worst as well as for the best parts of the year, the figures relating to the Welsh water dealt with one portion of the year only, when perhaps it was at its best.

Mr. DIBDIN said the figures for the Welsh water were the average of five samples taken from different places in May.

Mr. BLOUNT, resuming, said that was an advantage to the Welsh water, as the average for the whole year would probably yield less favourable results. Then there was that hardly annual, the suggestion of softening London water. No doubt that would suit manufacturers, as it would save their boilers; but as a consumer of water for drinking and ablutionary purposes he would regard the softening process as decidedly objectionable.

Mr. E. GRANT HOOPER cordially endorsed the congratulations offered by Mr. Blount. The author had put before them results not available before; and in his micro-filter had devised a piece of apparatus which would be generally useful. He would have liked to see in the paper a clear statement as to Mr. Dibdin's opinion with reference to the condition of the London water supply so far as it was drawn from the Thames. Did he think the water so bad that it was imperative something further should be done in the way of purification, and, if so, was he satisfied that that something should be the adoption of the suggested softening? For himself the speaker did not think it had been shown that the present condition of London water was by any means a serious one. Dr. Dupré had referred to the risk that must always exist in taking a drinking supply from such a river as the Thames. With that opinion he agreed, for there must always be a danger of pathogenic organisms getting through the filters. But he would like to briefly review what had been shown by the paper, and in the first place he deprecated in a paper of this kind the references to the tons of solid mud in a year's supply of water. Even when to produce this equivalent of mud the total solid matter had been increased by the necessary 90 per cent. of water, he would suggest that if really impressive figures were desired it was unwise to limit the quantity to a mere year's supply. What did this suspended matter really amount to in the quantities with which individuals had to deal? His own observation, which included the summer consumption of thirsty children, would not allow him to rate the demand for actual drinking water at more than a pint per day per person. Mr. Dibdin's results showed that this pint of water contained  $\frac{1}{10000}$  grain of wet mud, or about  $\frac{1}{200000}$  grain of dry solid matter, more than half of which was inorganic matter. This was not a very serious quantity. But that was not all. On such quantities of suspended matter Mr. Dibdin classed 1.0 less than 30 per cent. of the Thames water samples as objectionable. What, then, should they take as a standard of purity? He thought that it was generally admitted that the Kent Company's water would supply such a standard, and that, except for its being somewhat hard, that water was commonly held up as a quality to be much desired. Nevertheless they found that when the Kent Company's water was tested by Mr. Dibdin's micro-filter process, no less than 18 per cent. of the samples were classed as objectionable. That seemed to him ample proof that the condition of the water supplies generally was not very bad. He gathered, however, that Mr. Dibdin

thought some of the companies needed careful watching and keeping up to the mark in the matter of filtration. He agreed that in so important a matter careful watching was necessary. The author had said that though the companies' supplies were constantly examined, nothing ever came of it. He ventured to suggest that that was because they were generally satisfactory. As to the suggested softening, he did not quite agree with Mr. Blount's views, though for personal use he would prefer a water moderately hard—say four or five degrees. There was no doubt that softening would result in a further purification of the water, but with the admitted degree of purity represented by the London water the essence of the matter was the question of cost, and about that the author had said nothing. It had, of course, been gone into again and again in the past. As far back as 1851 a Royal Commission investigated the question and fixed the cost at that time at 1*l.* 7*s.* per 1,000,000 gallons, using the Clarke process. This was calculated as representing an increase to the companies of 10 per cent. on what the water cost them, or 4 per cent. on its selling value. Later experiments had shown a very similar cost, though the figures might be somewhat different now. It was, however, obvious that the cost would be serious, and, unless the reason for incurring it were almost imperative, he thought London ratepayers, upon whom he supposed the cost would ultimately fall, would hardly view the proposal with favour.

Mr. W. THORP would like to know what quantities the author had used in arriving at the given weights of suspended matter, and what method had been employed. The suspended matter in even 100 gall. of water, about 7 mgrms., would be no easy amount to manipulate. He must also object to the author's mode of illustration by multiplying the weight of dry suspended matter by 10 and calling it mud, to which Mr. Hooper had also referred. It seemed not only intended to alarm the unlearned, but it failed to convey any better idea than the actual figures would do. The only satisfactory course was to give the ratio of one number to another: to merely say that 131,000,000 gallons per day would carry down 67 tons of mud, equal to 6½ tons of dry matter, per annum, conveyed nothing to his mind. Again, why was the Fitzroy River, in Queensland, taken for comparison? Unless that river had been as closely studied as London waters, and the figures quoted had been derived from samples taken under similar conditions, the comparison would be misleading. He also considered the "constant" deductions made by the author undesirable. For example, in deducting the amount of suspended matter in the Kent water as a constant, one was met by this difficulty—that the quality of even the Kent water in this respect was not constant. Taking the figures given on page 11, it would be seen that in some months there was only 0.0006 of suspended matter, while in other months the quantity was greater: so that for the year 1895 there was an average of 0.0011. In another year, however, the average might be something quite different, depending on the circumstances of the time. For instance, in December 1892 the quality of the water in this respect was very different from what it was in 1895, and therefore, by taking a constant deduction, one was exposed to the difficulty of dealing with a merely arbitrary figure, which might possibly on some occasions even be greater than the figure from which it was to be deducted. Then again, he would like to ask whether the volatile organic matter from which the proportion of nitrogen was calculated meant "loss on ignition," because that would vary very considerably, according to the way in which it was estimated, and would also include a good deal that was not organic matter. Again the figures given on page 12, fourth column, had perplexed him considerably, and he did not approve of the calculation from which they appeared to have been derived, namely, the multiplication of the percentage number of samples containing objectionable matter by the average weight of the suspended matter contained in the water. Seeing that this "objectionable matter" must vary greatly in character from time to time, it appeared that the author was using two figures to calculate a third, the figures used not being commensurate one with the other. The calculations to which he had referred seemed

to imply an attempt to formulate his analytical results so that they should be understood by those who were not expert. He regarded such a course as quite hopeless in so complicated a matter as water analysis. Figures that meant one thing when associated with certain other figures, would imply something totally different when the circumstances of the case differed.

Mr. W. LAWRENCE desired to point out, with regard to the proposal to soften the London water, that it was quite unnecessary to carry out any such proposal in respect of the whole of the supply, much of it being used for purposes for which a hard water was quite as suitable as a soft water. Even for boiler purposes it was not so much the hardness of London water that rendered it objectionable as the sulphates which it contained, and which could be dealt with more readily in the presence of the carbonates than if the latter were removed.

Mr. E. J. BEVAN endorsed the remarks of Mr. Hooper with respect to the Kent and New River supplies. Mr. Dibdin himself had admitted that those supplies were beyond suspicion; yet he had found that in the case of the Kent Company 18 per cent., West Middlesex Company 24 per cent., and the New River Company 24 per cent. of the samples were rejected as being impure. According to the author's tables New River water in June showed 0.001 grains of suspended matter per gallon, yet the suspended matter observed in the micro-filter was absolutely nothing. Again, the author had called attention to the close concordance between the results obtained by his micro-filter method and those of the chemical and biological processes of examination (page 12). He would like to call attention to figures which to his mind showed that that concordance was not by any means striking. The amount of nitrogen in the suspended matter in the case of the West Middlesex and New River supplies was stated to be 2.86 per cent.; yet, whereas in the case of the former the oxygen absorbed was 0.072, in the case of the New River water it was only half the amount, namely, 0.041. Again, taking the relation of the number of the bacteria found to the amount of suspended matter, in the Grand Junction water the suspended matter was 0.0023 grain per gallon, bacteria 170; in the East London water the suspended matter was practically the same as the Grand Junction, but the bacteria found rose to 277 per c.c., while the Chelsea water, which showed more suspended matter, was found to contain only half the number of bacteria found in the East London water. These criticisms were not intended as suggesting that the paper had no value. On the contrary, he regarded the paper as a monument of industry, care, and application on the part of the author. At the same time he protested against too much reliance being placed on figures, of great value in themselves, but liable to be misinterpreted.

Mr. W. WHITAKER said that he could not treat the subject from the point of view of the chemist, but perhaps it was as well that other views should be heard. As Mr. Dibdin admitted, the water companies had for many years done their best to provide a pure supply. It was certainly to their interest to do so; but he thought that the quality of the water should be considered not only as it was at its source of origin, but as received by the consumer: and the risks of impurities which were met with in its course down the river could not be neglected. The risks to which the water supply was subject could be minimised through careful watching, and he quite agreed with the author that the water companies needed watching, just as probably the London County Council or any other authority would. If the source of supply and the preventive measures of the companies were not constantly and carefully watched, there was always a danger that contamination would come in. The question was whether it was better and cheaper to go on with the present supply, subject to such risks, or to get supplies from another and purer source. That was purely a question of finance. He thought that the water supply of London should be, as far as possible, beyond the risks of contamination, and that if we were to continue to draw our drinking water from the Thames further improvement was necessary. In the first place a more powerful conservancy body was necessary, the present body

being neither strong enough nor rich enough to do what is required. Then there was the question of softening, of which he had had some experience. At Southampton they had the largest water softening works in the country, and the engineer thereof had roughly estimated the cost of the process at a farthing per thousand gallons. That was the presumed cost of reducing a very hard water of about 18 degrees down to about 6 degrees or 8 degrees, and they found that such a course gave satisfactory results. So far, the only softening process that had been referred to was the Clark, but he would be surprised if that were adopted in London, as the plant for it occupied a great deal of ground, which would involve heavy expenses. There were, however, modifications of the process, wherein the plant employed was more manageable. He was sure that any members interested in the subject could obtain valuable information by visiting the works at Southampton.

Dr. BERNARD DYER speaking as one who had to make water analyses, wished to express his admiration for the very neat and useful apparatus devised by Mr. Dibdin as an aid to microscopical examination. It did not matter, practically, whether the apparatus enabled one to estimate exactly the amount of sludge in a given quantity of water, but as a qualitative method showing the kind of impurities absorbable in water it was a most excellent device. He had read not only the paper, but the interesting report lately submitted by Mr. Dibdin to the L.C.C., and while fully recognising the importance of the results embodied in that paper he must admit that he felt regret that the method of examination adopted consisted in drawing from the mains instead of from the filter beds themselves. If Mr. Dibdin had not been able to obtain the consent of the companies to the latter course that would explain matters, but he thought that such a course should have been adopted if possible. The contention put forward was that they did not want to know what came from the filter bed but what the public actually got. He did not agree with that view in a case like this. It was well-known that the Thames was largely fed by surface contaminated water, and that despite all the care of the Conservators impurities containing pathogenic organisms might get in. But was the water so filtered that the total bacteria present in the water as it entered the beds were reduced to a minimum as it left them? If it were true, that, say, 16,000 organisms per c.c. were reduced to 50 or some such small number, most Londoners would be ready to run the very remote risk of their being a pathogenic organism in that number, but they wanted to know also whether the large number of organisms often found by Mr. Dibdin had really eluded the action of the filter or whether they were the result of mere multiplication of the few organisms remaining in well filtered water, or whether they may have had some other origin. It was well known that whatever care might be taken to protect domestic cisterns from dust, &c., it was necessary to thoroughly cleanse them from time to time, when a slimy growth was found on the sides and bottoms of the tanks. Probably something of the same sort existed in the water mains, the growth being no doubt fed by perfectly harmless organisms. Possibly the occasionally large quantities of matter found in the water as drawn from the pipes was due to the disturbance of this slime by adventitious causes, and he thought, therefore, that it was a pity that the author had not made his determinations on lines exactly parallel to those made by Dr. Frankland and other analysts, so that the public might have been in a position to judge as to whether the results recorded by those gentlemen indicative of so high a state of efficiency with regard to filtration were confirmed or not by Mr. Dibdin.

Mr. C. E. GROVES, referring to the fact that the author had taken his samples from the companies' standpipes, observed that special precautions were necessary in collecting water for bacteriological purposes, and would like to know, therefore, what method had been followed. From the report made to the L.C.C., it appeared that some of the samples had been analysed both by Mr. Dibdin and by an independent authority, and it seemed probable that the very great differences in the respective numbers of colonies of bacteria found were due to faults in

the method of collection. With regard to the actual amount of solid matter present that was of slight importance, as in drinking a pint of water, one would imbibe but a minute fraction of a grain, whilst the dust on the drinking glass itself would no doubt be 10 or even 50 times the amount of the solid matter actually present in the water. The nature of that solid matter, however, was far more important. Most people regarded all bacteria as harmful, but this was not the case. By far the larger number of bacteria were non-pathogenic, and they assimilated and decomposed the organic matter dissolved in water which in fact served as food for the bacteria, being converted by them into non-organic matter; therefore the quality of a river water was actually improved by the bacteria present in it. The only way of making a fair comparison between the London supply and the Welsh water would be by running some of the latter through the mains, but of course that was impossible. The severe weather of two years ago had provided many of them with an opportunity of inspecting the interior of the mains which had been destroyed by the frost, and so far as his observation went they were anything but immaculate; it was possible therefore that the extraneous organic matter found by the author had been to a very large extent generated in the mains, but that point could only be settled by comparing samples taken from the mains with others taken from the clear water wells at the filter beds. Mr. Bevan had referred to the variation in the proportion of oxygen absorbed to albuminoid ammonia; the speaker had often observed this to be the case in effluents and had found that it was due to the presence of nitrates.

Mr. BEVAN explained that he had referred to the total nitrogen present.

Mr. GROVES, resuming, said that the question of the advisability of a softening process introduced the engineering question which was a very large one. He might mention, however, that the Royal Commission had advised the construction of large storage reservoirs up the Thames where the water could be collected in time of flood, and he believed that a partial softening of such waters in the reservoirs would greatly accelerate the subsidence of the suspended solid matter.

Dr. S. RIDEAL said that the question resolved itself into one of the suitability of the present supply, and unfortunately many gentlemen who differed from the author on that point were not present. Dr. Dupré had said that it was simply a question of running a risk, but he had not sufficiently pointed out that the method of softening proposed was one by which the risk attaching to the present supply would be reduced, and the suitability of the water would be improved, as the process would remove a large proportion of the pathogenic organisms of all kinds. Dr. Murphy, who spoke at the last meeting, had not brought out as strongly as he might have done the fact that two years ago an outbreak of typhoid in London was obviously due to the flood water distributed by the companies. The area supplied by the Kent water at the same time was free from such sporadic cases. It seemed to him that the proper course was to supply a perfectly sterile water, not generally, but that portion which was actually consumed for drinking purposes, and this could be easily effected by Pasteur filters being included as part of the compulsory water fittings supplied by the companies. The difference in the oxygen consumed and nitrogen found mentioned by Mr. Bevan was often met with. A more important point was the determination of the organic nitrogen in the suspended matter, since it was the condition of the nitrogen in the water that threw a light on its hygienic character. The value of the micro-filter seemed to him to be somewhat discounted by the fact that no close relationship existed between the number of millimetres and the actual weight of deposit when the large quantity of 1,000 gallons was taken. Perhaps that was because only a litre was examined out of the total originally taken. But the figures when working with a larger quantity were very variable as showing the difference between the nitrogen contents. He had occasionally to examine the waters of the Kent, Southwark, and Lambeth Companies, and he found that the oxygen absorption value was the sharpest method for differentiating

between them. Roughly speaking, the waters derived from the Thames contained five times as much organic impurity as waters like the Kent Company's. He attached no importance to the number of organisms present. Any limit must necessarily be an arbitrary number, and after all it was simply a question of whether they were pathogenic or not. What one wanted to know was whether they were organisms which would live at the blood heat. Decided in that way there was a great difference between waters derived from sources like the Thames and the chalk waters of Kent. If one made a plate cultivation and incubated at blood heat, a pure water would show no organisms after 50 hours, whereas the organisms that existed in a polluted water like the Thames or Lea would multiply at that temperature, so that the differences between a good and a bad water were accentuated by such a method, and rightly so. Further he had noticed in the ease of deep well waters with gelatine plate cultures that after some days the number of bacteria were increased as compared with the plates from a polluted water, and even in Kent or other hard water a marked increase in their number would appear after a longer period. That was due to the fact that they contained *Cladothrix dichotoma*, an organism which was very slow in incubating, but would appear in great numbers after five or six days. This might explain the difference found by different examiners. One of the most important points in the paper was the percentages of nitrogen found in the suspended matter, but he thought this information could be ascertained in a simpler way by using a Pasteur filter. Moreover, the yield of such a filter diminished rapidly, and it seemed to him that the diminished yield in a given length of time and with a given head of water might be taken as a measure of the suspended matter in a water. He had no data on the subject, but it was obvious that the rate of diminution must be proportionate to the choking of the filter. One would then take the deposit and subject it to the Kjeldahl method, and so get the percentage of nitrogen. The ratio of the total percentage of nitrogen to the percentage of oxidized nitrogen was a valuable factor in judging whether the water was in a harmless condition. In very pure waters the nitrogen was oxidised to the extent of at least 95 per cent. In the Kent waters the ratio of oxidation was from 95 to 98 per cent., as compared with considerably less in the other London waters. He had not noticed this factor recorded in water analyses and suggested that "the percentage of nitrogen oxidized," or "ratio of oxidation," should always be given as the information was of considerable importance.

Dr. MOIR congratulated Mr. Dibdin on his admirable method of the micro-filter. In perusing the paper he had been struck with the similarity between the deposit in the micro-filter of the unfiltered or the filtered water. Did this arise from a defect of the filter or from the accumulation of the material in the mains? He entirely agreed with the last speaker as to the character of the deposit. Micro-organisms were always with us, and fortunately so, for they played an important part in the economy both of nature and of the human body. There was no question, however, as to the danger of the organisms which got into the water rendered impure by sewage contamination, and there could be no doubt that the Thames was so contaminated. They would not be justified, therefore, in accepting the statement often put forth that a twelve mile run of the water would destroy the typhoid organisms contained in it, and that other bacteria being present in the filter prevented these typhoid ones from going through. He did not think that typhoid was due so much to the impurity of the water as contained in the mains as to the unsanitary arrangements in the consumers houses; and if any new system of water supply would lead to a complete eradication of these unsanitary conditions it would be one of the greatest improvements ever effected by any city. Visitors to Vienna were struck by the splendid water supply possessed by that town, and that was simply due to the fact that owing to an epidemic of cholera the Viennese had changed the source of their water supply and had at the same time got rid of the unsanitary conditions existing in their houses. Liverpool obtained its water from Wales and the results were such as justified the action of the town in taking that course. It

would be of interest to ascertain with the micro filter the number of bacteria in this water. He quite agreed with the remarks of the last speaker on the bacteriological aspect of the question; particularly he advised culture on *Aga Aga* at the temperature of the body.

Mr. W. J. DUDMAN, in reply, said that Mr. Burgess had referred to the amount of deposit in relation to the length of mains traversed, and seemed to think that the longer the main the greater the amount of suspended matter. He had since looked into that matter and could find no ratio. When he commenced his investigations, his ordinary qualitative examination for the suspended matter always showed a considerable quantity to be present which was verified by subsequent measurement. But when it became known that he was taking that course a considerable reduction took place, and at present working under precisely the same conditions he could hardly find any. He mentioned that as a simple fact and did not see that it had anything to do with the mains, many of which had run so long that if they gave merely an infinitesimal quantity of matter to the water they would have been dissolved away long ago. With regard to the Welsh river water he had been anxious to make further examinations but had not had an opportunity. The figures were the average of five samples taken in May. He was not prepared to say that they would not have been better at one time and worse at another; he gave them for what they were worth, merely pointing out that they represented an unfiltered water. He did not say that it was absolutely necessary to soften the London water supply; but he did think that it would be of advantage from the point of view both of comfort and economy. His friend, Mr. Bevan, reminded him of the fact that while lime was worth only 14s. per ton, soap was worth 20s. That was a fact worth reflecting upon. If the course he had suggested was adopted, and London water was softened, the difference between it and Welsh water would be practically nil—a most important matter. With regard to the suspended matter, Dr. Frankland, who was respected by no one more than by himself, used to report occasionally "moving organisms," he seemed to get tired of the phrase; then "bacteria" came into the field, and moving "organisms" moved off. But suspended matter was not even referred to by two eminent authorities who reported on the quality of the London water on behalf of the water companies. That seemed to him to be regrettable. It was perfectly true that the average of suspended matters was so small that it was almost negligible. But the moment of danger came when the water was in its worst condition (just as the strength of a chain was that of its weakest link), and one could only judge the safety of the community by the water supply at its worst, and he maintained that the weakest link in the water supply of London was the amount of suspended matter; for speaking generally the number of bacteria did bear a relation to the quantity of suspended matter. That was in accordance with Dr. P. F. Frankland's results and his own, and reasonably so. If that was the case why was it neglected? he was sorry that men who were looked up to as leaders of the scientific world did neglect such an important fact. They had analyses in official reports giving results to a thousandth part of a grain of carbon and nitrogen; but when they had, not  $\frac{1}{1000}$  grain but  $\frac{1}{100}$  grain of suspended matter loaded with bacteria it was not mentioned. That was not right, and in pointing it out they had done useful work. They had put the companies on their guard against a danger of which they appeared to be unaware. He had no animosity against them; he admitted that the moment they were made aware of certain objectionable things they met the position and remedied the defect. If, however, they got into a comfortable state again they might recur to  $\frac{1}{100}$  grain of suspended matter per gallon again, or even—as it doubtless was in 1892 or thereabouts—about  $\frac{1}{10}$  grain per gallon. Mr. Thorp had inquired as to the quantity used in obtaining the weight in suspended matter. The determinations were made upon samples of about 200 gallons. A stream of water was allowed to run on to a large filter at such a rate that the filter did not overflow. At the end of the day the filter was washed down with a fine jet and the deposit collected in a small bottle, the deposit being sterilised

at once with a little bichloride of mercury. Next day they proceeded in the same way. Thus in 10 days about 2,000 gallons would have passed through, and thus they had a very considerable quantity of deposit to work on. The microscopical examination of some samples was very startling. Some resembled "dne" as if swept up from a floor. This could not have come from the mains, for it was both fresh and decomposed organic matter, as to the method of stating the total suspended matter in terms of tons that might be open to the charge of extravagance; but it had served in calling attention to the fact that these in the aggregate were considerable. It might not matter to Mr. Thorp but to some people it was very important to have facts in the language of everyday life that they could understand. Mr. Thorp had also referred to the Fitzroy river. The fact was that some years since, wishing to get a factor to represent the character of suspended matter in a river absolutely uncontaminated, he had asked a brother living in Queensland to collect some samples, which he did in conjunction with the curator of the local museum, using the precautions laid down by himself, these were properly dried and sent to him direct. Dr. Veecker thought the micro-filter failed to distinguish between quantity and quality. Of course it did. It was simply a useful means for collecting suspended matter for subsequent examination by the microscope. As to the varieties of bacteria, he did not pretend to do more than count the colonies. As to the results obtained in the years 1891-92 and in 1894-95, they were arrived at in exactly the same way. But the numbers of bacteria found at that time were very different, and the Royal Commission came to the conclusion that some of the filters used were very unsatisfactory and required improvement, as much sewage was at that time going into the river. He had answered most of Mr. Blount's points already. As to standardising the micro-filter, when Mr. Blount had done more work with it he would probably abandon the idea of standardising the thickness of the walls of the glass tube. In respect to the correction for rust and dust, however, Mr. Blount had touched upon a point of great importance. The correction made was on the assumption that the suspended matters or "rust and dust" in the Kent Company's waters was accidental. He was by no means sure that it was unavoidable, for at the present time the company was avoiding it, and he had only used the expression because he was anxious to give the companies the benefit of the doubt. As to risk from the existing supply, he did not think there was much to fear as long as the companies kept things up to their present standard; but again it was a question of the strength of the chain at its weakest link, and they must bear in mind what might happen at some future time if matters were not looked after. Things were in a very good condition at present, but he quite agreed with Mr. Whittaker that whoever was in charge of the water supply it was necessary to have the policeman constantly on the beat. He quite admitted the force of Mr. Hooper's remarks about the small quantity of suspended matter consumed per head per day; but the same argument applied equally to the carbon, nitrogen, &c. Again, referring to the deduction for what he had called "unavoidable rust and dust" in the Kent waters, he would ask how it happened that angulicæ occurred in it? Was it from dust in the reservoirs or from dirty mains? There was, in fact, something mysterious at times about the Kent company's water which he could not explain, and had an itching to investigate. As to the loss on ignition there was only one way of determining it, and he thought Mr. Thorp might have given him credit for using that process with the usual care. The solids were dried at 100 C., carefully ignited at a low red heat, and re-carbonated with ammonium carbonate. Then as to the microscopical statements, Mr. Bevan seemed to think that he was pushing matters too far in saying that there was a ratio between the microscopical and the chemical results which fairly agreed. Of course there were isolated cases in which the lines crossed, but it was remarkable how close the agreement was. It must be remembered that this was the first time that the microscopical examination had been put into numerical form, and at the best this could be but an assumption. If the percentage of objectionable samples were calculated into weight

as representing a definite proportion of the total known to be present, and these results formed a fairly uniform curve with the chemical factors, there must be some basis of agreement between them. Doubtless the microscopical examinations would be those most needing revision, as they were not at first made with the intention of working the observations into a numerical statement.

Mr. BEVAN: You cannot average discordant figures.

Mr. DINDIX replied that with reference to the micro-filter it was clear that 1 m.m. deposit in the micro-filter per litre, equalled from 0.002 to 0.005 grain per gallon in the case of the filtered waters, or an average of 0.004. In the case of the unfiltered river water containing a relatively large quantity of mineral matter, sand, &c., the ratio of weight to volume was naturally higher, viz., 0.06 per m.m. than in the case of the lighter organic matter in the filtered water. If the process gave an indication which could not be got otherwise, surely it was a useful one. It was already contended that the difference of a few thousandths of a grain is of no practical importance; why then cavil at such minute differences as these? By it he had been able to point out defects in well waters which he had suspected, but could not be certain about before. Dr. Dyer had objected to the examination of water from the mains instead of the filter beds. Of course he had no power to go to the companies' works for his samples, and questioned whether they would have granted permission. The question was not what came from filter A or B, but what they supplied to the consumer. Some filters might be working well while one might break down entirely. His method tested the average quality of the supply, and that was the main question. As to the collection from the stand pipes, it was made most carefully, the bottles used being thoroughly cleansed.

Mr. GROVES inquired if they were sterilised.

Mr. DINDIX, continuing, said that they were sterilised with strong sulphuric acid, and the samples for bacteriological examination were taken in 2 oz. bottles, sterilised at a temperature of 400°, and many hundred check experiments were made under varying conditions, many plates being inoculated on the spot. As to the amount of suspended matter being unimportant, that was quite true, but where one found a considerable quantity of decomposing matter, hairs, fibres, various infusoria, and colonies of bacteria these were at least objectionable.

## ON A RELATION OF COLOUR TO VALUE IN MALT,

BY JOSEPH W. LOVIBOND.

THE method of estimating the quality of malt to be described is not intended to, nor can it replace the analytical precautions now in use, it is intended to supplement the present methods by providing a means of estimating those subtle properties which, whilst materially influencing the flavour, brilliancy, and keeping properties of ale are yet too subtle in their nature to be isolated, weighed, or even named.

The estimation of malt values does not always receive the attention it merits, considering the large quantity of valuable stock which must accumulate in the brewery between the first purchase of the malt and the final judgment of the finished beer, and in cases where the finished beer is not all that can be desired, the responsibility of placing blame on the malt is not a light one, the whole process of brewing being a succession of conditions each of which has an influence for good or for evil on the final product.

Another difficulty in judging malt arises from experts not yet being fully agreed as to the exact nature and value of some of the malt constituents: for instance, certain soluble substances are sometimes classed as unknown bodies and sometimes as sugars, these substances frequently vary from 4 to 6 per cent. and as their function is undetermined, an element of uncertainty is introduced which tends to confuse the judgment of the practical brewer.

In addition to this a high percentage of diastase is usually considered an index of good value, and this may be

so when a large proportion of starch material is used, requiring for its conversion a great excess of diastatic power in the malt, but in those cases where malt alone, or only a small proportion of starch material is used, the advantage of high diastatic power is not so evident, it is even possible that in some cases a high percentage of diastase may be an index of low value, as affording presumptive evidence of a low temperature on the kiln.

Supposing that all questions of analytical apportionment were settled, there still remain to be dealt with those intangible substances already mentioned.

The method of estimating the effect of these substances on beer is based on a new law, which I call the law of specific colour absorption, the fundamental principle of the law being, that each definite substance has a power of absorbing definite rays from impinging white light, this power being constant so long as the substance itself remains unaltered.

The method of establishing a colour constant is to measure the composition of the light the substance reflects or transmits, and then to obtain the absorbed rays by difference.

A single measurement does not become a colour constant until associated with the density of the substance at which the measurement was made, and then only applies to that particular density. In order to establish the specific rate of absorption which is to be our future factor of value successive measurements must be made at regularly increasing densities, and the results arranged in a table for comparison, or more graphically plotted into curves.

It is evident that the value of the method depends on the definition of the term "white light," and on the accuracy with which the unabsorbed rays can be measured, both these points have been fully demonstrated on several occasions before this Society, and are moreover accepted as valid by those investigators now using the method, I do not therefore purpose going into these details this evening further than to recall one experimental fact, which is this, that any colour no matter how complex can be quantitatively described by means of two colour terms and one light term.

This experimental fact is the outcome of a law which possibly has not received the attention its importance merits, the law being that the colour of a beam of light depends on the one preponderating ray if the colour be pure, and on the two preponderating rays if the colour be complex. That the depth of colour is in proportion to the preponderance of the one or the two rays, and that the tone of the colour is dependent on the quantitative relations of the two preponderating rays towards each other. This holds good in all cases within the power of colour perception by the vision, whether the coloured beam be reflected from a mixture of pigments or whether it be produced by a mixture of coloured lights. Postponing for the present the consideration of the light term, *Yellow* and *Orange* are the two colours which in one proportion or another apply to the description of colour in all malts and malt extracts. It is the varying proportion of these two colours which, when co-related to the beers they produce supply the means of estimating the quality of the malt so far as the unknown constituents are concerned.

The method adopted for preparing the samples for colour measurement is to mash 100 grms. crushed malt in a 500 c.c. flask with 350 grms. of water at 74 c., digest in a water-bath at 63 c. for 48 minutes, cool and make up to 500 with water, filter, and measure, beginning with a 1-in. stratum and progress at 1-in. intervals up to 6-ins., when the colour becomes too dark for reliable reading except in the case of very pale malts, the two colour terms may be tabulated in their numerical values, or plotted into curves, the colour units supplying the ordinates and the densities the abscissæ.

On comparing a number of malt specific colour curves with the ales they produced, it soon became evident that the best results were associated with a high proportion of yellow over orange, and inferior results with a low proportion of yellow over orange, this was so constant that the proportion of yellow to orange is now adopted as an index for valuing pale malts.

The two examples, A and B on Fig. 1, used to illustrate the co-relation of colour differences in the malts, with the differences in quality of their finished ales, were selected from a number of similar instances, because they were the last experiments of a series, and they could also be associated with their chemical analysis by Mr. Heron.

Fig. 1.

Specific Colour Curves of two Samples of Malt (A and B).

The ale brewed from the malt marked A, brightened readily, was fine flavoured, and improved by keeping; that brewed from the malt marked B, brightened with difficulty, was inferior in flavour, and did not improve by keeping; there was nothing in the appearance of the malt to suggest any real difference in quality, nor does the chemical analyses appear to suggest a sufficient explanation of the wide difference between the quality of the ales produced.

On comparing the specific colour curves of A with those of B on chart 1, it will be noted that the initial of yellow for A at 1 in. is 0.5 of a unit more than B, whilst it terminates at the 6-in. stratum 2.6 units more than B, showing a higher rate of increase in the yellow for increasing densities. In the orange curves, A is 0.5 of a unit less than B at the initial inch, and 1.9 units less at the terminal 6 inches, showing a slower rate of increase in the orange for increasing densities, fully bearing out previous experiences as to the co-relation of a high proportion of yellow with fine qualities in ales, and the co-relation of a high proportion of orange with inferior qualities.

In estimating the proportion of the two colours towards each other, the variations in the curves of different malts became somewhat confusing, and it was found more convenient to plot a complementary curve showing the varying colour proportions in a single line. The ordinates for this complementary curve are supplied by the number of times the orange is divisible into the yellow at each measurement, and the abscissæ by the stratum thickness of each measurement, the variations in the curve then exactly represent the

variation of proportion between yellow and orange in the malt extract.

MR. HERON'S ANALYSES OF TWO MALTS.

6 " .....	4.7	+ 32.8	6.6	+ 30.2

The complementary curves of A and B are shown together in Fig. 2: there is an important difference in their type, as they curve in opposite directions, A curving upwards and B downwards.

Fig. 2.

Secondary Curves showing Proportions of Yellow to Orange in A and B Malt Solutions.

A comparison of these two curves show that the measurement of a malt extract at a single density does not give a sufficient basis for a reliable estimation, it may even prove misleading, as in the examples before us, where two malts widely differing in quality give similar proportions of yellow to orange at the 3-in. density where the curves meet, but diverge at all other points.

I am only prepared this evening to deal with the curves of pale ale malts, and for this reason it was found necessary to establish a separate normal for the higher dried malts, as the type of specific absorption curves alters in these malts, appearing to have some relation to the temperature of the kiln, until more work has been devoted to the co-relation of quality to the new specific curve, little more can be said on this part of the subject.

How necessary this co-relation of colour to values is will be realised on examining the collection of nine complementary curves of pale malts on Fig. 3, with the six complementary curves of higher dried malts on Fig. 4; they are arranged and numbered in their order of merit as determined by the rule of yellow proportion over orange already defined.

Fig. 3.

Secondary Curves showing Proportions of Yellow to Orange.

First, dealing with the nine complementary curves of pale malts in Fig. 3, the two extremes are distinctly different in type as they curve in opposite directions, and according to our rule of procedure No. 1 represents the highest type and No. 9 the lowest type. It will be seen that No. 2, the second in quality, is the specific curve of the A malt, which was chosen as an example for illustration, and was known to produce excellent results in the finished ales, in this way confirming the co-relation of fine quality with this particular form of specific absorption curve.

It will be also seen that No. 8 is only one degree better in quality than the worst example No. 9, and was known to produce unsatisfactory results, confirming previous experience as to the co-relation of this type of curve in pale malts of inferior quality. I may say that when these curves were selected as examples there was no previous knowledge as to the position A and B would take in the scale; this was only revealed after the charts were made.

Accepting Nos. 1 and 9 as the result of two distinct methods of malt curing, it is quite easy to suppose that the intermediate curves may be mixtures of these two methods brought about by uneven management on the kiln or, if the kiln had been evenly managed, it is quite as easy to imagine that the intermediate curves are specific for the particular stage of curing where one type was merging into the other. This, however, is pure speculation, the question can only be settled by actual experiment with malt during the process of curing.

Although I do not now propose dealing with the higher dried malts on chart 4, as the co-relation of qualities to curves has not been yet established, it will be observed that there is here also a change of curve character in the highest dried malt; Nos. 13, 14, and 15, and necessarily the intermediate curves are open to the same contingencies of uneven drying. A reference to the table of measurements will show the degree of colour of each malt extract at every density.

Fig. 4.

The consideration of the light factor already spoken of as one of the three terms necessary for quantitatively describing some complex colours, was deferred because this part of the question as applied to malt extracts is still under investigation. The factor itself does not frequently occur in malt extracts, and is sometimes found in malts which are otherwise satisfactory. It is represented by two examples on Fig. 5 by the black line beginning in one instance at the 3-in stratum, and in the other instance at the 5-in. The term used to indicate the presence of this factor is black and the effect of its presence is to dull the brilliancy of the colour according to its proportion.

Fig. 5.

Specific Colour Curves of two Samples of Malt showing Black Absorption Curves.

It is not yet decided whether this black factor causing a decreased brilliancy arising from a slightly less effective filtering, or whether it is an inherent property in some barleys. Should the latter prove to be the case, it would be analogous to the loss of brightness found in wheat flour made from imperfectly ripened wheat.

#### DISCUSSION.

Mr. E. GRANT HOOPER thought that the paper could only be adequately discussed after careful consideration

when in print. There were, however, a few points on which he would like information and on which he might offer something in the nature of criticism. In the first place, had the facts been isolated? They had been told that the beers produced by the two malts of which particulars had been given were in the one case good, and in the other unsatisfactory, and they were asked to conclude that these results were entirely due to those differences in the malt which were indicated by the colour analysis of the wort they respectively yielded. It seemed to him that two classes of malt had been dealt with, which on brewing would result in two distinct classes of wort, each yielding a different proportion of alcohol. The tabular results before the meeting, headed "Analysis of Malts," he understood indicated not the composition of the malt but of the wort or extract yielded by the two samples. Here they found that in one case the maltose was 43 per cent., and in the other 35 per cent., and that the dextrine was in the first instance 9 per cent. as against 14 per cent. in the other. It followed, therefore, that in one case there would be a greater attenuation with the production of a larger proportion of alcohol than in the other, and if up to the end of the primary fermentation other things were equal, two beers so different would exhibit different degrees of stability. It was necessary to bear these facts in mind before speaking of the soundness of a beer derived from such malt. But in connection with the comparison in the matter of soundness he should like to hear from Mr. Lovibond that the precaution had been taken to use the same yeast. If the experiments were made at different times it was quite possible that the instability in the one case was due to the yeast. He would suggest as an explanation of some of the differences found that the orange colour was a product of caramelisation. From the colour curves he judged that different proportions of caramel would be found, and would suggest that the difference in appearance represented the precipitation of a caramel body. So far as he could understand, the curves meant that the lighter the colour of a malt, provided it were completely dried, the better the malt was. Was there evidence that these colour constituents indicated intrinsic soundness, or did this orange colour merely point to the presence of caramel constituents with a tendency to fall out of solution under certain conditions? The more highly coloured a malt was the more the diastase would be affected, and the less complete would be the conversion with a resulting variation in the composition of the beer produced. Had Mr. Lovibond taken care to eliminate the effect of this last difference, and secured such a uniform basis as would permit a reliable comparison?

Mr. BRYAN CORCORAN had had considerable experience in the construction of malt kilns. He also had some acquaintance with the tintometer and quite believed in its tests, but he would like to know what the author meant by the curing of malt, and whether the quality depended on the quality of the barley or upon the way in which it was malted, and also whether the length of steeping had anything to do with it. Some people steeped for 40 hours, others for 60 hours. On the question of drying, Mr. Lovibond had spoken of the temperature in the kiln. He thought that was not a very sound way of estimating the drying, as it was possible to have a kiln at a high temperature with very little draught, or one with a good draught and a low temperature, the latter generally producing the best malt. The colouring of the malt was a very difficult question to understand. Mr. Lovibond had spoken of the highest dried malt. Did he mean the malt with the least moisture in it? He had found that the lower temperature generally produced the best results and therefore gave most satisfaction?

Mr. E. S. BEAVER had found the tintometer of great use in keeping a check on the drying of malts. He was not prepared at that moment to criticise the results, but if they proved to be corroborated by further investigation, they would undoubtedly be of the greatest possible advantage. He would venture to suggest, however, that it would be a great gain if in the place of what was usually known as "Series 52" of Mr. Lovibond's tintometer, the series which was used in recording the tint depth of the caramel colour and of malt extracts, determinations were

made in the standard primary colours. Mr. Lovibond had not that evening referred in any way to that series of standard glasses in which the colour tint of malt extract was usually quoted by analysts. He had standardised that series himself with the red and yellow, giving the orange and yellow curves which Mr. Lovibond had referred to, and he found that as the series progressed upwards the ratio of yellow to orange increased, following in that respect what happened with normally dried malts, and also with different densities of caramel. If, however, it became customary to state and tabulate the colour of malt in terms of the primary standards, it would, he considered, facilitate the elucidation of the colour analysis of malts. The single standard afforded nothing on which to draw any deductions, but a combination of the red and yellow glasses would do so. He had before known of the truth of what Mr. Lovibond had stated, *viz.*, that it was possible to match any transmitted or reflected colour by means of the standard glasses, and it was tolerably evident that irregularities in the drying of the malt were made apparent by the different character of the tints which were revealed. If measurements were taken with those glasses considerable benefit might accrue and the results be further tested.

Mr. J. Huxox had listened with very great interest to the paper, because it opened up a new field in connection with the analysis of malt, caramel, and sugars, the colour of which consisted solely of a combination of red and yellow in varying proportions, its principal use hitherto in a brewer's laboratory appeared to have been exceedingly limited, being employed merely to determine the relative depths of colour of malt extract, sugar solution, &c., but this operation, simple as it was, showed a very great deal about the way in which the malt had been dried and cured on the kiln. The figures so obtained, and compared with the diastatic capacity of the malt, would tend to show the operations to which that malt had been subjected from the time it went on to the kiln to the time it came off, and he claimed that those determinations threw a good deal of light upon the history of a malt from the time it went on the kiln until it came off, but this was as far as they could go at present. Mr. Lovibond drew his attention two years ago to the bearings which the combination of red and yellow had upon the quality of black malts, and it occurred to him afterwards that those observations might be applied to pale and high-dried malts as well. If an analyst carefully examined the colour of malt extracts by the scientific method brought forward by Mr. Lovibond, he would obtain a good deal of information as to the quality of the malt he was dealing with. He had invariably found, and in that he was corroborated by the observations of those brewers who had used the tintometer in the manner indicated, that those malts whose extracts showed a large proportion of orange as compared with yellow, produced beers which did not turn out satisfactory. How did the tintometer values correspond

with the values ascribed by the chemist from an analytical point of view? He was fully convinced that there was some close connection between them, but he should not like to say anything about that just yet, because he did not consider that sufficient experiments had been made in this direction. So far, however, there was a decided connection between the results as revealed by analysis and the results revealed by the tintometer, and he could only hope that it would be Mr. Lovibond's, and perhaps his own, pleasing duty at some future time to give the results of investigations in that direction. He had had nothing to do with the preparation of the paper just read, but there were two or three points in it on which he begged to differ from Mr. Lovibond. He could not agree with him in carrying on his mash at such a high temperature. He had found that a cold water mash and one mashed with hot water under standard conditions (*i.e.*, at 65° C.), provided the extract was not boiled afterwards, would give practically the same results in the tintometer. The colour of the malt was not increased by mashing in water at 65° C., except perhaps, to a point that was negligible. He had no doubt that although the total units of colour obtained by a hot mash were the same as those obtained by a cold mash the relative proportion of orange and yellow might be altered to a slight extent, and he would therefore suggest that whatever be the density used the mash should be carried on with cold water at, say, 60° F. There were a great many small differences which would creep in when making a mash at a high temperature, and which could be avoided by making a mash with cold water. The temperature of 74° C. was a point at which the diastase was considerably crippled, and they might look upon 75° to 80° as the critical temperature. 74° was also very much higher than was usually employed in mashing operations on a commercial scale. He would prefer making a mash at 65° C., equivalent to about 150° F. Mr. Lovibond had referred to the black factor creeping in in the case of certain malts. He had found that with some malts mashed under standard conditions at 65° C. a brilliancy could be obtained in the beer with the greatest ease, while with others it was impossible to eliminate a certain cloudiness which was more easily revealed by examination in the polarimeter than in any other way. This was a very good index as to the brightness of a solution, because although the solution might appear to be absolutely brilliant to the naked eye, yet, when examined in the polarimeter, the slightest degree of cloudiness would be revealed. In a thin strata of liquid this peculiarity would not be perceived, but in a strata of 6 inches or more it would appear, and would indicate certain bad qualities in the malt, but what those bad qualities were it was impossible yet to say. No doubt the lines which Mr. Lovibond had taken up in the paper, and the field of further research thrown open by him, would be productive of great benefit, and when brewers on these lines began to

make a periodical examination of their malts they would find that by a simple operation of mashing and examining the resulting wort in the tintometer, they would after a short time be able to predict what the character of the resulting beer would be like. A great advance in our knowledge of some of the characteristics of malt would then be made, and the thanks of the brewing world generally would be due to Mr. Lovibond for initiating research in what must be regarded as heretofore unbroken ground.

Mr. WILLIAM FAYE said that he gathered from Mr. Heron's remarks that he had considerable faith in the correctness of Mr. Lovibond's theory, *viz.*, that the quality of a malt could be judged by the ratio of yellow to orange. Mr. Lovibond in his paper had told them that he based his theory upon many experiments, and found that the best beers were produced from malts where the tintometer showed a relatively high ratio of yellow to orange. Under these circumstances he wished that brewers' analysts, instead of telling them simply the tintometer reading 4, 5, 6, or whatever it might be, would state the ratio between the yellow and orange, so that brewers might have an opportunity of testing the correctness of the theories enunciated by Mr. Lovibond. The tintometer was becoming a valuable instrument to brewers, who were finding out that the quality of a malt could be judged by the ratio of tintometer reading to diastatic capacity. He himself had found that a malt having a tintometer reading of 3<sup>2</sup>, combined with a diastatic capacity of 42<sup>2</sup>, did not produce so satisfactory a pale ale as a malt having a tintometer reading 4, combined with a diastatic capacity of 37; the former giving a beer more liable to frets and wild yeast attacks in summer, and not fining so readily as beer produced from the latter. Perhaps the gentleman who had previously spoken would say that the condition of his yeast may have had something to do with the difference noted in the quality of the respective beers. But the experience of other brewers led him to believe in the correctness of what he had stated.

Mr. J. W. LOVIBOND, in reply to Mr. Hooper's first question, said that he need hardly assure the members of that Society that every care was taken to have the conditions of the experiments identical; in fact, they were extracts taken from their usual work. This series extended over three months, and embraced twenty times as many examples as had been shown in the charts. Those shown were not selected for any particular reason, except that they were the last of the series, and could be accompanied by the chemical analyses. The colour measurements had nothing to do with Mr. Heron's analysis, and were independent results. With reference to the standards 50 and 52, they were arbitrary standards, and were simply the nearest glasses which, in the early days of the tintometer, he could get in accord with the caramels and malts. They fairly met the case, although they were not scientific, and were not based on the equivalence of the six colour rays in a beam of white light, as the new standards were. He should like to see a change made from the 50 and 52 series. They had answered the purpose up to the present time, but the accumulation of facts showed that they did not meet the requirements of present discoveries. The mash was made as nearly as possible under the conditions obtaining in brewing. The temperature might be high, as Mr. Heron had stated, but in dealing with small quantities there was always a loss of temperature in manipulation. No diastatic destruction took place, because, in fact, the extracts obtained were such as the malts might be expected to yield. In reference to Mr. Corcoran's question as to the quality of barley and malt, and the drying: the malt made by his firm was from barley of good malting quality; the other samples of malt were from good makers, tendered for sale in the ordinary course of business. The drying was a very important problem, however. For his own guidance he had divided the kilning process into two portions: the first he called the drying, and the second curing. The curing was the key to the whole position, and on the care with which it was carried out depended the proportion of yellow and orange, which he had no doubt whatever was an index to high quality.

Mr. FAYE asked how many days it was on the kiln.

Mr. LOVIBOND replied that he had assumed that the malts were fairly made on the floor, and went to the kiln in the usual workmanlike manner; four days was the usual time, but subject to some variations under the exigencies of sudden rise in temperature. With reference to the colour in the high-dried malts, one might get an average colour depth with desperately badly cured malts, burnt in one corner and uncured in another. If mixed together, an average tintometer result may be obtained, and it was not until comparing the proportions of the curve that the true history of the curing was shown. He could take a dried malt and say without hesitation whether the curing had been uneven or not, from the proportion of orange and yellow. Mr. Beaven had spoken of the desirability of replacing the arbitrary standards by the scientific standards. With that he quite agreed, and thought that until it was done it was not possible to compare different results. In reply to Mr. Heron's suggestion of a cold-water mash: it did not matter what process was adopted if the results were similar; and if different, the only difficulty which could arise would be that a separate normal would have to be established for each process. If cold-water extract gave a similar result to the hot-water extract, there would be no necessity for establishing a separate normal. Mr. Fyfe had touched on a most important point when he spoke about unsatisfactory beers. The old tintometer standards would not discriminate between the qualities of the malt, but would simply give the depth of colour; and whether that was arrived at by the quality of the barley or the drying, it would not indicate. If the malt mentioned had passed through his hands, he could have told by the nature of the absorption curve whether the results would be likely to prove unsatisfactory, and whether the malt had been unevenly dried.

## HEHNER'S BROMINE TESTS OF OILS.

BY J. H. E. JENKINS.

THE following comparative results were obtained by the bromo-thermal and bromo-gravimetric tests of oils, the experiments being conducted under the conditions laid down by Hehner and Mitchell in the *Analyst* of March and July 1895. The figures are compared with the iodine-values of the oils as determined by the Hübl process:—

For the bromo-thermal tests a vacuum-jacketed tube was used. The iodine values of the oils are derived by multiplying the rise of temperature in degrees C. by 5.7, the factor for the particular tube, &c. used in the experiments. In the gravimetric process the percentage increase of weight of the oil after bromination, *i.e.* the bromine value, is converted into the iodine value by using the factor 1.587 ( $= \frac{257}{160}$ ).

In the gravimetric experiments the brominated oils were dried first for 5 hours in the water oven, say at 97° C., and afterwards for a further 10 hours in an oil oven regulated to 125° C., successive weighings being taken after each hour's exposure. The deportment of the oils during drying is shown in the following table, in which the weights found after stated intervals have been calculated to iodine values:—

Oil.	Hübl.	Bromo-ther. mal.	Iodine Values.			
			Bromo-gravimetric.			
			Dried at 97° C.	Dried at 125° C.		
			3 hrs.	5 hrs.	5 hrs.	10 hrs.
Rape, .....	100.2	98.6	99.8	99.0	96.8	95.5
Raw linseed, ..	174.3	173.9	171.1	168.8	161.8	156.9
Boiled linseed, ..	166.6	166.7	162.9	162.2	157.5	154.9
Castor, .....	84.1	83.8	88.8	84.9	80.0	77.2

In the bromo-gravimetric estimations, the figures derived from the increase of weight after 3 and 5 hours' drying at 97° C., when the chloroform and excess of bromine may be assumed to have been expelled, agree fairly well with those obtained by the Hübl and thermal processes. The hourly weighings, however, showed a steady decrease of

weight throughout the whole exposure, and even after the 15 hours the loss in the case of the rape oil was 3 mgrms., which, on the 1.5 grm. of sample taken, corresponds to a loss of 0.3 in the iodine value per hourly weighing. The loss in the case of the other oils was somewhat greater. It was difficult, therefore, to ascertain when the oils had approached sufficiently nearly to a constant weight to permit the factor being applied to convert to the iodine value. The brominated oils do not seem to be quite stable at the drying temperatures.

In the following table the thermal iodine values of a series of oils are compared with the Hübl values. The specific temperature reaction figures (derived from the Mauméné tests) are also attached:—

Oil.	Iodine Values.		Specific Temperature Reaction.
	Hübl.	Bromo-thermal.	
Blown rape (sp. gr. 0.9621) . . .	55.3	74.1	153
Blown cotton (sp. gr. 0.9639) . . .	62.2	78.1	164
Nest-foot . . . . .	71.6	72.4	87
Olive . . . . .	80.1	81.5	94
Bottlenose . . . . .	80.6	84.2	105
Castor . . . . .	84.1	85.8	105
Rape . . . . .	100.2	98.6	139
Raisin on rape . . . . .	100.9	114.0	162
Seal . . . . .	135.5	140.5	278
Japanese wood (sp. gr. 0.9585) . . . . .	165.7	133.4	372
Boiled linseed . . . . .	169.6	169.7	248
Raw linseed . . . . .	174.3	173.9	313

It will be seen that there is a general agreement between the Hübl iodine values (column 1) and those calculated from the thermal rise on bromination (column 2). Pronounced exceptions are found, however, in the case of the two blown oils and also in the case of the Japanese wood oil. These oils also form exceptions in the specific temperature reactions, which otherwise generally show increasing values as the iodine values rise. Check determinations of these three oils were made by both the Hübl and thermal methods, but the fresh results tallied closely with the earlier determinations. Thinking that the abnormal calculated iodine values for these oils may really correspond to abnormal bromine values which in these instances may not be comparable with the iodine values, further tests were made with them by the bromo-gravimetric method. The percentage increase of weight, after bromination and drying for 5 hours at 97° C., was calculated to iodine values, and gave for the blown cotton oil 83.6, for the blown rape oil 75.8, and for the Japanese wood oil 189. The figures for the blown oils seem to support the suggestion that the action of bromine is more extensive than the iodine of Hübl solution. The low result obtained by the thermal method for Japanese wood oil remains, however, unexplained, but is probably due to peculiarities of constitution.

It is noteworthy that the differences in the case of Japanese wood oil disappear when the fatty acids are examined. These gave an iodine value by Hübl method of 150.1 and by bromo-thermal method of 148.3.

If an experiment be arranged with the Japanese wood oil as though for applying the thermal test, except that half of the chloroform is replaced by a saturated chloroformic solution of iodine—this being used in place of bromine,—the rise of temperature (only a few degrees) is very slow, but after a couple of minutes the whole solution rapidly thickens to a stiff elastic jelly. This effect with iodine was not noticed in the case of any other of the oils in the list, which all remained clear and perfectly fluid. Bromine has not this thickening effect on the oil in chloroform solution.

In determining the specific temperature reactions, the oils were, when necessary, diluted with a thin mineral oil. The Japanese wood oil acted in a way quite distinct and characteristic: as soon as the first drops of sulphuric acid fell into the oil, a dark, tough clot formed, which so clogged the thermometer that stirring soon became impossible. When one part of the oil was dissolved in four parts of

mineral oil, it became just possible to continue the stirring after the addition of the sulphuric acid, and soon the clotted mass dispersed again and dissolved in the mineral oil.

#### DISCUSSION.

MR. PETER MACEWAN asked Mr. Jenkins what he meant by wood oil. There were several things which went by that name, the best known being Gurjun balsam, an oleo-resin. There was also Chinese wood oil, the identity of which with Japanese wood oil he was not at the moment quite sure of; but it struck him that the difference in the bromine and the iodine absorptions pointed to the presence of an essential oil, seeing that the fatty acids agreed. On the other hand, Mr. Jenkins' description of the oil did not agree with Gurjun balsam.

MR. JENKINS replied that he understood that it was practically the same as Chinese oil.

MR. MACEWAN, continuing, said that the presence of a proportion of essential oil in the wood oil would account for the difference in the iodine-absorbing powers of the oil and fatty acids, as well as the difference between the bromine and iodine absorption numbers, since it was well known that many essential oils absorb bromine much more readily than iodine.

MR. S. HALL had in the course of his work noticed that some oils, such as linseed, rose in temperature very rapidly on treatment with chloroform. It had therefore occurred to him to use carbon tetrachloride instead of chloroform because of its higher boiling point. In some experiments made under those conditions that day the figure for linseed oil was found to be 165, which compared very closely with Mr. Hehner's figure. Another curious fact was that if bromine were added to the tetrachloride by itself, the temperature went down, and this fact had to be taken into account in working out the absorption value.

DR. F. E. POWER had been much struck by the peculiar properties of the so-called Japanese wood oil. He thought it probable that it was a substance bearing some relation to Gurjun oil, commonly known as wood oil, which is obtained from the East Indies, and derived from a species of *Dipterocarpus*. This body was not, chemically speaking, an oil at all, but an oleo-resin, consisting of a resin with an essential oil having the character of a sesquiterpene,  $C_{15}H_{24}$ . When heated to about the boiling point of water, Gurjun oil became perfectly solid; and another peculiarity was the very beautiful reaction which it gave on treatment by nitric acid or other oxidising agent. If Japanese wood oil had a somewhat similar constitution, it would naturally behave towards bromine differently from the fatty acids.

MR. J. H. B. JENKINS feared that he could not throw much light on the origin of Japanese wood oil. It had been proposed to replace linseed oil because of its superior drying properties. With regard to the suggestion that it might contain a considerable quantity of terpenes, the oil on saponification yielded a large proportion of fatty acids—about 96 per cent.—and that fact was inconsistent with the presence of any large proportion of essential oil. He had included all the ordinary data relative to this oil in his second paper, but it was not of sufficient general interest to read to the meeting. He was much interested by what had been said in the discussion; and in connection with the high temperatures attained by the chloroform solution of linseed oil when treated by bromine, he might mention that a friend of his was making experiments with a view to obviate any error likely to be introduced by the temperature approaching too near the boiling point of chloroform. He had not the refraction value of Japanese wood oil, but there was not the slightest danger of its being mistaken for linseed oil, though its iodine value was much the same. Its specific gravity was somewhat higher than that of linseed oil, and its viscosity was many times greater. The melting point of its fatty acids was much higher. The many peculiar properties of the oil as shown in the qualitative tests would also serve to identify it.

MR. S. HALL remarked that some tests he had made with Japanese wood oil entirely bore out the figures given by Mr. Jenkins.

The CHAIRMAN remarked that, in view of the great attention that was being paid to the subject at present by various workers, it would be well that they should agree among themselves on the general conditions of research and particularly work with identical samples.

# JAPANESE WOOD OIL.

BY J. H. B. JENKINS.

THE following further particulars respecting this peculiar oil may be of interest. It is expressed in China and Japan in enormous quantities from the seeds of the *Alnus cordata*, and is used there chiefly as a varnish, and also for lighting (Chem. and Druggist, April 23, 1887). Efforts have been recently made to introduce this oil into Europe, and there are many directions, especially in paint and varnish making, in which it is likely to find an application. The oil was examined over twenty years ago by Cloëz (Bull. Soc. Chim. 26, 286; 28, 23), and more recently by Davies and Holmes (Pharm. J. 1885, 634, 636).

The present sample of the oil was clear and had a golden colour. It gave—

Specific gravity at 60° F. ....	0.835
Solidifying point.....	below -17° C.
Iodine value (Hubl) .....	165.7
Saponification value (mgrms. KHO) .....	191
Helmer value (insoluble fatty acids).....	96.4 per cent.
Unsaponifiable matter .....	0.44 "
Specific temperature reaction .....	372
Free fatty acids (calculated as oleic) .....	3.84 per cent.

The mixed fatty acids gave:—

Melting point .....	37° C.
Solidifying point .....	31° C.
Iodine value (Hubl) .....	150.1

For peculiarities in determination of iodine values and specific temperature reaction, see previous paper.

**Viscosity.**—The viscosity of the oil at 60° F. was determined with Redwood's viscometer. It required 1.433 seconds for 50 c.c. to flow through. Water requires 28 seconds and rape oil 470 seconds to flow through this particular instrument at 60° F.

**Valenta's Test.**—The temperature of turbidity with glacial acetic acid was 47° C.

**Sulphur Chloride Test.**—To 5 grms. of the oil were added 2 c.c. of CS<sub>2</sub> and 2 c.c. of S<sub>2</sub>Cl<sub>2</sub>, and the whole stirred in the cold. In 1½ minutes the oil suddenly stiffened to a thick and sticky jelly. The product was not nearly so hard as that obtained from either castor or linseed oil.

**Drying Properties.**—Four grms. of the oil were exposed in the boiling-water oven in a shallow porcelain dish 7 cm. diam. After ¼ hour's exposure there were evidences of a skin commencing to form round the edges. In two hours the oil would not flow, and was entirely covered by a crinkled skin. The average gain of weight during four hours' exposure was 0.36 per cent. per hour. For comparison, raw linseed oil was exposed in another dish; after four hours there was no evidence of a tendency to "skin," neither was there any sensible increase of weight.

**Elaidin Test.**—By this test a brownish-red product was obtained. An oily layer rested on the lower, nearly solid portion. When stirred up, the whole would slowly flow.

**Beech's Argentie Nitrate Test.**—A quarter-hour's heating with reagents in boiling water produced deep reddish-brown coloration.

**Other Tests.**—Strong sulphuric acid produces a black clot with the oil. Nitric acid (1.4 sp. gr.), after a couple of minutes, converts the oil into a tough mass, which on standing becomes darker and more brittle. When 1 gram. of oil is dissolved in 5 c.c. of chloroform, and 5 c.c. of a saturated chloroformic solution of iodine are added and the solution stirred, after about two minutes the whole is converted into a stiff jelly. If the amount of oil in this test be increased to 2 grms., the jelly formed is so stiff that it can be granulated. Some of the oil was heated, strictly out of contact with air, first for one hour at 150° C., then for

two hours at 200° C., and lastly for a couple of hours at 250° C. At temperatures above 180° C. a very small quantity of gas was given off, but no change in the liquid condition of the oil was noticed until after the last heating to 250° C., when it became converted into a clear, solid, elastic substance. This peculiar product was insoluble in the ordinary oil-solvents, and showed no tendency to melt on being heated again up to the temperature of its formation—about 250° C.

## NOTE ON THE ANALYSIS OF SUPERPHOSPHATES.

BY J. H. COSTE, F.L.C.

THE usual statement of analysis of superphosphates, though sufficient for agricultural purposes, is, from a chemical point of view, rather misleading, as it does not express the true condition of the "soluble" phosphoric acid. A sample of superphosphate which was found to contain 15.79 per cent P<sub>2</sub>O<sub>5</sub> (equal to 34.48 per cent. Ca<sub>3</sub>P<sub>2</sub>O<sub>8</sub>), soluble in water when treated in the usual English method, was, after keeping about a month, analysed in the usual way, and also further determinations made with a view to determining the condition of the soluble phosphoric acid. The composition, according to the general method of stating results, was:—

Moisture (given off at 100° C.).....	15.80
Water of combination, &c. ....	7.51
* Monocalcium phosphate (CaP <sub>2</sub> O <sub>6</sub> ).....	21.86
Insoluble phosphate .....	6.33
Calcium sulphate, &c. ....	46.55
Insoluble siliceous matter.....	1.95
	100.00
* Equal to tricalcium phosphate.....	51.25

The lime in the soluble and the sulphuric acid in the insoluble portion were determined, and the total sulphuric acid, lime, and phosphoric acid also determined in separate portions.

The following results were obtained:—

CaO in solution (same as soluble P <sub>2</sub> O <sub>5</sub> was determined in).....	10.24
SO <sub>3</sub> in insoluble portion .....	19.98
Total CaO .....	25.37
" SO <sub>3</sub> .....	30.01
" P <sub>2</sub> O <sub>5</sub> .....	18.20

On combining these results, the statement of composition of the soluble part became as follows:—

Free phosphoric anhydride (P <sub>2</sub> O <sub>5</sub> ).....	7.53
Monocalcium phosphate (CaP <sub>2</sub> O <sub>6</sub> ) .....	11.38
Sulphate of lime .....	17.45

and the amended analysis—

Moisture.....	15.80
Water of combination, organic matter, &c. ....	5.91
* Soluble { free phosphoric anhydride .....	7.53
{ monocalcium phosphate.....	11.38
+ Insoluble { tricalcium phosphate .....	2.03
{ ferric phosphate.....	4.30
Calcium sulphate.....	51.19
Sand.....	1.95
	100.00

* Equal to phosphoric anhydride .....	15.79
+ " " " .....	2.51

Nearly one half the phosphoric anhydride soluble in water was present as phosphoric acid, and not as monocalcium phosphate.

### SESSION 1896-97.

April 7th, 1897:—

Election of Committee and Officers.

Dr. Hugh Marshall. "The Manufacture and Industrial Uses of Persulphates."

Meeting held on Wednesday, March 3rd, 1897.

DR. C. A. KOHN IN THE CHAIR.

### MICRO-ORGANISMS: THEIR EFFECT AND INFLUENCE IN CERTAIN CHEMICAL INDUSTRIES, MORE PARTICULARLY IN THE MANUFACTURE OF LEATHER, WINE, AND BEER.

BY GUSTAF SCHACK-SOMMER, PH.D.

MICRO-ORGANISMS may be divided into three classes: bacteria, yeasts, and moulds, all of which play a more or less important part in pathology, as well as in many chemical industries. The aim, therefore, of the manufacturer in whose industry these organisms take part, should be directed towards promoting the increase of the beneficial and destruction of the harmful.

One of the subjects I originally intended to include in this paper was brought before this Society by Dr. Voelcker, in London, in November last (this Journal, 1896, 767). I refer to the inoculation of soil with organisms found in nodules on roots of leguminous plants, whereby the assimilation and utilisation of the free nitrogen of the atmosphere by the growing plant is promoted. I therefore omit the subject of artificial manuring through the aid of micro-organisms, and pass at once to the consideration of the first-named industry at the head of my paper, namely, tanning. The importance of the leather industry may be gathered from the fact that it is now said to rank fourth amongst English industries. In the process of tanning, the hides are first soaked for weeks in lime pits, so as to loosen the hair and the fleshy matter which adhere to the skin, and to transform the hide into gelatin with which tannic acid combines to form tannate of gelatin, or leather. As some skins, such as that of the calf, turn black in the tan pit should all the particles of lime not have been previously removed, and since for some purposes the pores, which the lime bath has caused to shrink and close, need opening, the skins or hides, which have been previously swelled by the liming process, require to be brought into a condition which allows of the easy and thorough removal of the lime and lime soap. To obtain a uniform shrinking of the swelled hides, the skins go from the lime pits into dog or pigeon-dung baths. The process consists in treating the hides for some time (sometimes four or five hours) in a vat containing a lye formed of solutions of dog, pigeon, or poultry dung. In some cases the dog-dung acts best, and pigeon or poultry-dung in other cases, but no satisfactory and sound explanation has as yet been given as to the precise kind of action which occurs.

In 1896 Dr. Popp and Dr. Becker, of Frankfort-on-Maine, were granted a patent for a process which resulted from the discovery that the action of these lyes is the result of bacteriological processes, and not, as has been very generally assumed, of the action of phosphoric acid. They examined dog, pigeon, and poultry dung bacteriologically, and showed in the first instance that even after removal of all other constituents which, according to existing views, entered into reaction, the result was the same. Continued research disclosed a second result, viz., that a number of micro-organisms exert considerable influence on the lye, partly beneficial, and partly detrimental. They say that, generally speaking, the non-peptonising bacteria act beneficially, while the peptonising ones generally have a detrimental effect. The specification states that in connection with this discovery, two methods of utilising them have presented themselves (this Journal, 1896, 911).

In the December and January numbers (1896, 910, and 1897, 52) of the Journal there have appeared articles entitled "Fermentation Phenomena in Tan Liquors," by F. Andreasch, to which I beg to call your attention.

In the preparation of tobacco the presence of the right kind of micro-organism has been found to greatly enhance the value of the finished product; it has, therefore, been found advantageous to sprinkle the leaves at the commencement of manipulation with the liquid, which contains pure cultured micro-organisms of the required kind, and the result has been much more satisfactory than if the fermentation had been left to chance.

Although pure cultures have, to the best of my knowledge, not been employed in the manufacture of white lead, the so-called Dutch process is based on the action of bacteria contained in the dung by which the lead plates are surrounded.

Quite a number of chemical compounds, which it has been quite impossible hitherto to produce synthetically, have been brought about by the help of micro-organisms. As an instance, I have only to name lactic acid. Dr. Alfred Koelliker, proprietor of the firm of Dr. L. Marquart, at Beuel, near Bonn, has made use of pure cultivations in manufacturing pharmaceutical preparations. I understand that he ferments sugar solutions at 104° (40° C.) with a pure cultivation lactic ferment. The lactic acid, while being formed, is neutralised by adding lime or chalk during the fermentation. This calcium lactate is purified by frequent re-crystallisation, and is then either sold as such or used for making lactic acid or ferrous lactate. Colours for eatables are now prepared with pure cultures of bacteria on rice, a process which the Chinese have known for ages.

In the preparation of a liquid glue for photography, photolithography, &c. gelatin or other nitrogenous substances are peptonised with bacteria such as *bacillus prodigiosus*.

Thus far the action of the micro-organisms has been considered as the cause of chemical action, but we now come to other industries where they are not only promoters of chemical action, but are of the greatest importance in producing flavours in those substances in which they are allowed to multiply. Take for instance the manufacture of cheese and butter. It is generally known that in butter-making, pure culture bacteria (bacteria of the species producing the desired flavour, and not bacteria which produce unpleasant flavour) are used for inoculating the cream for the purpose of making good butter. The bacteria favourable to this purpose are already in the market, two or three different kinds now being used in this country, the result being that the butter-maker can depend with more certainty upon the product.

For the manufacture of cheese the proper selection of bacteria is of still greater importance than in the case of butter. The curd itself is practically tasteless; it is set to ripen, and it is during the process of fermentation (ripening), which is brought about by micro-organisms, that the taste develops. The different kinds of cheese are mainly due to the growth of different kinds of bacteria in the cheese. Theory in this latter industry is, however, yet ahead of the practice and much good work can still be done in this direction.

The most important industries in which fermentation plays a part are brewing and distilling, and the manufacture of wine. In the first and second fermentation is started artificially by adding yeast, whereas in the third the grape juice ferments without any such addition. Brewers have learnt from experience that with the same raw material they may get products with different flavours, and they have known for a long time that it is advantageous for them to get now and again a fresh supply of yeast from breweries where an avowedly well-flavoured beer is produced. In the same way experience has taught distillers that the yield of alcohol from the same raw material may vary several per cent. The wine manufacturer too found that in certain years his must would not ferment, although by chemical analysis its composition did not differ from that of former years, and so he attributed the failure to the difference in the ferments.

Pasteur, Hansen, Joergensen, and others have shown that these differences are due to the quality and variety of the species of yeast used. They have arranged methods by which the yeast varieties may be distinguished, and by which the most suitable can be picked out. As a consequence certain establishments have adopted the pure cultivation and rearing of special varieties in their works, and the largest and most scientifically and intelligently conducted breweries work now with these pure culture yeasts with the very best results. They find that if they are uniformly careful in the selection of their raw material and in the manner in which they conduct the fermentation, the use of pure culture yeast enables them to have a regular and uniform product of a characteristic similarity of taste. In distilling the same experience has been gained. Preference is now given to those yeast varieties which give an especially high yield of alcohol, and pure cultures are made accordingly. The conditions here, as in brewing, are specially advantageous, as the mash is boiled, and so sterilised, before the addition of the yeast.

Must cannot stand sterilising as it would spoil its flavour, but it is all the better for pasteurising, that is, heating for half an hour in an enamelled or tinned vessel at a temperature of from 130° to 149° F. (60° to 65° C.) and then cooling down to 68° to 72° F. (20° to 22° C.). To that must, which does not contain sufficient nitrogen for the nourishment of the yeast, some should be added. For instance, it is nearly always deficient in cider, perry, and must made of berries, such as elderberry, currant, or gooseberry; to these 15 to 20 grms. of chemically pure chloride of ammonium should be added to every 1,000 to 1,200 litres of must.

Germany has taken the lead in adopting the discoveries of Pasteur, Hansen, and Joergensen in wine manufacture. Messrs. Popp and Becker, to whom I am indebted for much valuable information embodied in this paper and a great many yeast specimens, have the best known institute for the pure cultivation of yeast in Germany. In France, Messrs. Schloesing Frères and Co., Marseilles, are working on similar lines. The former state, and prove their assertion by many examples, that the quality of the wine that has been fermented with pure yeast culture is not only improved, but that the influence on the character of the wine is most telling. The discoveries which were first made in the laboratory, that some varieties of yeast produce more alcohol and glycerine than others, that they have a great influence on the taste, flavour, and bouquet of the wine, and that by the addition to the must of pure culture yeast the fermentation is more rapidly accomplished than if left only to the influence of its natural ferments, have been confirmed on a large scale.

As there are many kinds of fruits and cereals, each of which has its proper name, such as cherry, plum, apple, wheat, and barley, so there are a similar number of varieties of yeast, which will cause a fermentation in sugar containing solutions like must and maltwort. The products of these fermentations, however, differ much from one another. Whilst some produce alcohol and carbonic acid gas, others produce nauseous compounds. Yet even the fermentation of those varieties which produce principally alcohol differ very much both in the energy and speed with which they start fermentation and in the time they require to accomplish their task and in the extent to which they can decom-

pose the sugar. Whilst some start growing and evolve carbonic gas early and stop after several days when the yeast settles at the bottom and leaves the liquid comparatively clear, other varieties start slowly with very little escape of carbonic acid gas, dragging on the fermentation for months, and preventing the liquid from becoming clear. All these varieties of yeast, the good as well as the bad, are generated in and on the soil, and scatter their spores through the wind on to the grapes from which they get into the must. If the beneficent kinds predominate, the wine ferments energetically and quickly and is soon clear, but if the others are in the majority, or even numerous, no matter from what cause, then the must will ferment badly and slowly and will not show signs of becoming bright after months have elapsed.

By using a properly selected pure culture yeast, peculiar to the same kind of grape or one of another particular species, the resulting wine will be of a better quality than if the must had been left to chance fermentation. It would be a mistake to assume that it would be possible to make from any grape juice the choicest wines, for although the influence of pure culture yeast on fermentation is very great, the slower or quicker development of the fermentation and the composition of the finished wine, is amongst others dependent on the quality of the must.

As an instance of the influence which particular varieties of yeast had on the same must, Drs. Popp and Becker send me the following analysis:—

Yeast.	Alcohol.	Glycerine.	Unfermented Sugar.
	Per Cent.	Per Cent.	Per Cent.
A.....	19.00	0.74	0.07
B.....	9.85	0.71	0.12
C.....	8.53	0.54	2.72
D.....	9.17	0.70	1.13
E.....	9.68	0.58	0.13
F.....	7.86	0.50	3.72

In this case yeast A was the best in every respect. It yielded 10 per cent. alcohol, 0.74 per cent. of glycerin, and only left 0.07 per cent. sugar undecomposed, whereas yeast F only produced 7.86 per cent. alcohol and 0.50 per cent. glycerine, and left 3.72 per cent. sugar undecomposed. They add, "naturally we choose yeast 'A' as one of our specimens from which to make pure cultures."

Pure culture yeast has been applied with great advantage in cider and perry manufacture, with the result that these lose their peculiar rough taste and become more winelike. A still more favourable result has been obtained with wines made from berries, especially in the speedier finishing of the product. A wine made from bilberries frequently takes three to four years before it is ready for drinking. This entails a great loss in interest and no small risk. With a suitable pure culture yeast the fermentation will take place much more quickly and much better. Currant and gooseberry wine, which must contain a high percentage of alcohol, should only be fermented with pure culture yeast specially adapted for a thorough fermentation.

The fact is thus established that it is not the geographical position alone and the soil on which the vine grows that accounts for the characteristics of a wine; but that just as great importance should be attached to the kind of yeast used, for not only does the yeast decompose the sugar in solution and so form alcohol and carbonic acid gas, but it assists as well in the decomposition of malic acid and in the formation of succinic acid, glycerine, and various aromatic compounds, to which the flavour of the resulting product is due.

Having arrived at these conclusions, it naturally followed that the chemist went a step further, and tried the effect of the yeast of the choicest wines on other raw products, such as beerwort. Besides the scientific value of these experiments, they promised, if successful, a new field of industry, namely, the manufacture of beverages similar to wine in countries where the grape does not grow, beverages, too, which while containing a larger percentage of nourishing properties, rival in flavour and excellence many of the best known wines of southern climes.

Pasteur was the first to try the fermentation of beerwort with wine yeast. The result as far the aroma went was satisfactory but was very disappointing as regards flavour. M. Jacquemin of Paris, and Dr. Sauer of Schoenberg, near Berlin, picked up the threads where they were dropped by Pasteur, and went to work in the eighties to investigate the same problem. Jacquemin took out a patent in England in 1887 for a process he discovered, but which I understand has never been exploited (this Journal, 1888, 397).

I find in Jacquemin's specification, that he added a suitable quantity of bitartrate of potash to the wort with the object of producing an acidity similar to that of the grape, and thereby obviated the necessity for introducing lactic ferment, one which brewers have great difficulty of avoiding and which he said was detrimental. He then introduced the elliptical ferment of wine yeast. But the above-mentioned addition of bitartrate of potash was not the only addition of a chemical; he introduced tartaric acid into the cane-sugar solution for the purpose of inverting it, and this solution after having been boiled was then added to the wort to accelerate the fermentation and produce a higher percentage of alcohol. He contends that the said inversion of the sugar by an organic acid is essential, as otherwise the fermentation would be too slow to give good results. What Jacquemin said of lactic acid in 1887 was quite right then, for impure lactic acid retards a good and pure alcoholic fermentation, and I suppose the addition of the various chemicals had a good deal to do with the fact that Jacquemin's "Vin d'orge" has never become a popular beverage.

Dr. Sauer some five years ago applied for a patent for a process embodying the results of his discoveries. He succeeded in solving the problem of producing a wine in every way equal in character, flavour, and aroma to similar wines made from must, and moreover, succeeded in freeing this product from all malt taste or smell. He discarded the yeast of the vines of his native country and of those of France, and made pure cultivations from yeasts that have a greater power of fermentation, probably arising from the fact that they are gathered from grapes of southern climes which contain a much higher percentage of sugar. Where however, he had the greatest advantage over Jacquemin, was, that in the meantime, the process of producing pure lactic acid by the pure culture lactic acid ferment had been discovered and it had been ascertained that pure lactic acid had a favourable influence on alcoholic fermentation whilst checking the growth of other micro-organisms. Probably on that account Dr. Sauer was enabled to experiment on the pure malt decoction, generally called wort, without adding any chemicals whatever and only introduced pure cane-sugar into the liquid, as required for raising the alcoholic strength. In his process of fermentation, which I shall describe more fully presently, he produced beverages containing 18.5 volumes per cent. of alcohol.

Dr. Sauer chooses his malt according to the character of wine he wishes to represent and prepares his wort in the copper in the same way as it is done in every brewery. The malt-wort used in brewing beer is as a rule somewhat acid, yet seldom reaches more than 0.1 per cent., and even that quantity is undesirable in the manufacture of beer. In the case of making Dr. Sauer's malt-wine the desired effect is brought about by adding a pure culture of lactic acid ferment. This is allowed to act on the malt-wort heated up to 122° F. (50° C.) for 24 hours in which time it will have changed 0.6 per cent. to 1 per cent. of the wort and produced the lactic acid required. It is then pasteurised, that is, heated quickly to 167° (75° C.) and so the lactic acid ferment is destroyed. At this point it is necessary to cool the hot wort down to the proper temperature, that is, 77° F. (25° C.) and then add a purely raised wine yeast, to induce fermentation. These yeasts are peculiar wine yeasts (*sacch. ellipsoides*) which are specially selected. They are raised from a small quantity, if possible only one cell, on sterilised, acidified malt-wort. The selection of these wine-yeasts should be made in accordance with the particular kind of malt-wine it is desired to produce; in other words, in choosing the yeast one must be guided by the flavour and aroma required.

During fermentation the embryo wine tastes somewhat like "must." The fermentation is accelerated and intensified by the gradual addition of raw sugar, and when this is completed, the preparation must be so treated as to eliminate from it everything that can suggest to the taste or the smell its malt origin. This is done by the action of the oxygen of the air.

The difference between low-fermented liquors which contain under 12—13 volumes per cent. of alcohol (under which head are included all beers, and by far the greater number of the grape wines of Central Europe) and the high fermented alcoholic beverages which contain over 12—13 volumes per cent. of alcohol is that the latter will mature if they are judiciously exposed to the air, whereas the former spoil if the air is not carefully excluded.

The malt-wine is kept for some weeks in contact with constantly renewed outer air, at a temperature of 122° F. (50° C.) or over. The higher temperature not only hastens the maturing process, but, at the same time nullifies the baneful influence of micro-organisms in conjunction with the acidity and alcohol present in these beverages. While beer is invariably shut off from all contact with the atmosphere, at a very low temperature, and matured entirely by after-fermentation, malt-wine is, on the other hand, matured as above stated, after its fermentation is completed.

A peculiar odour arises from the aromatic properties of the malt and the alcoholic contents, the exact composition of which has not yet been determined. Whether this odour, which is also present in the very best old selected Tokay, is acetal as discovered by Von Liebig, must be left for future investigation. Certain it is, however, that the malt aroma disappears entirely, and is replaced by a very agreeable one.

After the precipitate of albumin has settled, the liquid is put into casks and left to ripen. After this the malt-wine is ready to be bottled and will keep for any length of time.

The wine, to begin with, is akin to beer with which its mode of manufacture is practically identical. Its ingredients are also of such a nature as to allow of malt-wine being classed for excise purposes among the beers. It differs from them in the relative proportions of the ingredients, and especially in containing a large proportion of alcohol, in which property it compares with the high-fermented genuine wines. It also differs from the known beers in appearance and taste, in both of which it resembles the proper grape product, justifying the assumption that it may take the place of genuine grape wine, although the chemical composition is not the same.

The analyses by Fresenius show the following results:—

Character of the Wine.	Sherry.	Ma-deira.	Malaga.	Tokay.
Specific gravity .....	1.0203	1.0327	1.0594	1.0909
Polarisation in 220-mm. tube direct.	+17.75°	+18.3°	+31.9°	+29.48°
Polarisation in 220-mm. tube after inversion.	+17.75°	+18.0°	+32.8°	+21.12°
Alcohol (percentage in weight) ..	Grms. 14.78	Grms. 14.22	Grms. 12.13	Grms. 11.41
Alcohol (percentage in volume) ..	18.62	17.91	15.28	14.37
Extract .....	11.27	14.24	20.50	25.50
Mineral substances .....	0.24	0.23	0.35	0.37
Free acid (calculated as lactic acid).	0.64	0.75	0.73	0.82
Volatile acid (calculated as acetic acid).	0.062	0.077	0.064	0.061
Non-volatile acid (calculated as lactic acid).	0.55	0.64	0.063	0.73
Glycerine .....	0.31	0.34	0.20	0.19
Nitrogen .....	0.062	0.059	0.190	0.101
Corresponding to albumen .....	0.387	0.369	1.188	0.631
Phosphates .....	0.0654	0.0690	0.1515	0.1371
Raw sugar .....	5.00	7.37	10.25	5.86
Reducing sugar (invert sugar, dextrose, maltose) expressed as dextrose).	5.00	7.37	10.25	13.14
Dextrine .....	2.86	2.12	5.00	2.17

The tests for salicylic, tartaric, citric, and malic acids gave negative results. The acids present may, therefore, be assumed to result from fermentation, and consist of

lactic and succinic acids. The above analyses indicate that these preparations are beverages of a sweet-wine character, and with respect to the amount of alcohol and sugar they contain, are absolutely identical with sweet wines. They are distinguishable from the latter in containing a not inconsiderable quantity of dextrin, and of extractives peculiar to malt, whereas the extractives of the genuine grape sweet-wines are absent. With regard to their nutritive qualities, they are on a par with extract of malt beers, but their stimulating powers are fully equal to those of sweet wines.

Owing to the presence of the nourishing extractives of malt (which include nitrogenous substances, dextrin, as well as phosphates), they should replace the so-called medicinal wines now in use. One of the advantages claimed for these wines is that they are free from sulphates, which are present in sherry and similar southern wines, owing to these having been clarified with gypsum.

#### DISCUSSION.

The CHAIRMAN asked whether the use of specially cultured germs for tanning had been tried on the large scale, and if so, whether the difficulty of getting even results with the different kinds of hides employed had been overcome by thus adjusting the tanning materials? In regard to tobacco also, had any practical application really followed the investigations referred to by Dr. Schack-Sommer.

Respecting the wines made from malt he (Dr. Kohn) felt that Dr. Schack-Sommer had laid too much stress on the value of the chemical analyses. Did the percentage of alcohol really mean anything in regard to the nature of the wine? The difference between pure brandy and that adulterated with potato spirit was not recognisable, he believed, by chemical tests although very evident by taste to a connoisseur.

Dr. Schack-Sommer had also referred to the oxidation of the must as a part of the process described by him. Was that not a process likely to destroy the most characteristic properties of good wine? Some time ago one heard of maturing wines by means of oxygen, and he (Dr. Kohn) had experimented with Italian wines with this object. The result was certainly to do away with the harsh taste of the wine, but the original bouquet was entirely destroyed. He was therefore inclined to think that this portion of the process was likely to prevent the preparation of any of the better qualities of wine from malt.

Mr. E. K. MUSPRATT remarked that Dr. Schack-Sommer had spoken of pure cultivations of yeast that were used for the manufacture of cider. Did that explain why large quantities of apples were taken from Normandy by rail to Frankfort, converted into cider, and the cider exported? He thought it quite possible owing to the excellent quality of the cider produced by these methods.

Dr. SCHACK-SOMMER replied that it was curious that it was at Frankfort where those improvements took place. They certainly delivered pure wine cultures, and so far as he knew that had not been done in England.

Mr. MUSPRATT said there was no doubt they got very excellent cider in England, which could be improved by the adoption of scientific methods of manufacture.

Dr. HURTER asked whether the amount of sugar which must be produced in one way or the other by the soil could be raised in this country at such a cost that it could really compete with the great quantity of cheap wines now imported; and was there really any prospect of making wine materially cheaper, taking into account the amount of the excise duty which would have to be paid on home produce just as much as on wines imported from abroad.

Dr. SCHACK-SOMMER in reply to the Chairman's question as to whether bacteria had been used practically in tanning and in the curing of tobacco on a large scale, answered in the affirmative. Amongst others, a large firm in London, having tanneries in England and America, had worked very successfully with this new departure; and further, the curing of tobacco by micro-organisms had long ceased to be in the experimental stage, and been very generally adopted by the trade.

To those who criticised the wine-like beverages brought before them from the standpoint of wine connoisseurs, who would pay 10s. or more for a bottle of port, sherry, or Tokay, he submitted that such a high standard was not aimed at. The object had been to produce a wholesome, nourishing, palatable, wine-like beverage at a low price that would compare favourably with the average quality of the wines usually sold of the kinds mentioned above.

The less said the better as to the power of chemists to distinguish the differences between high class and ordinary wines and spirits of the same kind. All those who had studied the Blue Books containing the report of Lord Playfair's Commission on wines and spirits would agree to their inability to achieve this. The analysis by Professor Fresenius showed that there were no sulphuric acid or sulphates present, and these were always to be found in sherries. The analysis showed the composition of the wine, and from this the medical profession on the Continent concluded that the beverages under consideration must be nutritive as well as stimulating.

It was suggested that forcing air through the finished product might remove the bouquet; he proposed to the audience to use their olfactory organs and so convince themselves from the samples submitted to them, that this was not the case. He wished to draw their attention to the fact that these samples were rather sweet, for the reason that they were made in Germany for German tastes. The wines could be prepared just as well dry, so as to suit English tastes.

To Dr. Hurter, who had asked if it were possible to get sugar cheap enough to justify the starting of this industry, he would reply that there was no country where sugar was as cheap as in England, nor could a better place be found for manufactures in which it was an important raw material. When in Hamburg last spring, he was surprised to find in the large "Muster Lager" (Sample Exhibition), the whole collection of sweets and fancy confectionery goods were from England or Scotland, and when he asked how that was, as they had such large works in Germany, he was told that they could not compete in price for export with British produce. If this was true for sweets, it would be equally so in the manufacture of wine. The question of the duty to be paid to the excise authorities had been submitted to the officials at Somerset House, and they were of opinion that the tax would have to be levied in the same way and to the same amount as in an ordinary brewery, there being practically no difference in the processes.

### MICRO-CHEMICAL EXAMINATION OF LEAD-ANTIMONY, TIN-ANTIMONY, TIN-ARSENIC ALLOYS, &c.

BY JOHN E. TEAD, F.I.C.

THE microscopic study of metals was instituted and successfully carried out by Dr. Sorby, of Sheffield, and his first paper on the subject was read before the Sheffield Literary and Philosophical Society in February 1864, or 33 years ago, but his studies were confined almost exclusively to iron and steel. For many years little or no notice was taken of this pioneer's researches, and practically nothing has been done in this country until quite recently, although the microscopic structures of iron and steel have been more or less studied by our friends in America and on the Continent. Prof. Martens and Dr. Wedding, in Germany; H. Behrens, in Holland; F. Osmond, in France; L. Garrison and A. Sauvour, in America, have all communicated valuable articles on the structures of irons, spiegel-eisens, and steels; and quite recently, within the last few years, Messrs. Guillemin and Charpy, and Prof. J. O. Arnold have made most important microscopic researches on the structures of alloys.

Prof. H. Behrens (Das Mikroskopische Gefüge der Metalle und Legierungen) is, I believe, the only gentleman who has written a book solely dealing with the micro-structures of metals and alloys. This book is most instructive, and we can only regret that it has not yet been translated into the English language from the German.

In this work, Prof. Behrens describes the micro-structures of a very large number of alloys such as are commercially in use.

The valuable researches of Mons. F. Osmond, which are to be found in the Transactions of the Société d'Encouragement pour l'Industrie Nationale of Paris, have enabled us to determine, with a fair amount of precision, by the microscope alone, the heat treatment to which steel has been subjected; and we are now able, on the examination of very small pieces of structural steel, to determine whether or not it has been properly dealt with by the workmen during its manipulation. It is not my intention to dwell upon or discuss the structure of iron and steel, but rather to describe briefly researches which have recently been made upon alloys, and afterwards to put before you my own work.

One of the most valuable articles on the micro-structure of gold and copper, to which had been alloyed small quantities of other metals, was published in *Engineering*, February 7, 1896, by Prof. Arnold, of Sheffield. In this article it was clearly proved that the reason why bismuth, to the extent of only 0.2 per cent., in gold and copper made the whole mass so brittle and weak, was that the

bismuth, or a compound of bismuth with gold or copper, separated out from the metals when solidifying, in such a way that every grain or primary crystal of the pure metals which had freed themselves from the impurity became enveloped, more or less completely, with a brittle "cement" of low melting point.

A polished and etched specimen of gold containing 0.2 per cent. of bismuth, presents the appearance of polygonal grains or crystals of yellow gold, cemented together with a red-brown substance, which Prof. Arnold has provisionally called bismuthide of gold. The thickness of this red-brown track or cement is out of all proportion in volume to the quantity of bismuth added, and Prof. Arnold is no doubt correct in assuming that the bismuth combines with a proportion of the gold, forming a fusible alloy. According to the same authority, tellurium and lead, when alloyed with gold, give very similar micro-structures to that produced by bismuth.

The bismuth in copper appears to separate out in a free state, and is found between and surrounding the grains of copper.

Prof. Arnold has also studied the micro-structure of copper after melting it with small quantities of cuprous oxide, cuprous sulphide, silicon, arsenic, and antimony, and in each case it was found that the impurity was found between the grains. This paper, in my opinion, is one of the most valuable ever communicated on the micro-structure of metals.

It will have been observed that Prof. Arnold has assumed, probably most correctly, that the bismuth and some of the other impurities actually form chemical compounds, but at present I do not believe that he has actually separated them and verified this hypothesis.

Prof. Martens, in his most valuable paper on the micro-structure of ingot iron in cast ingots, read at Chicago, before the International Engineering Congress, in August 1893, pertinently points out "that the true aim to be steadily and earnestly kept in view, is first to develop the methods for the microscopic resolution of the elements of structure, and to determine their chemical composition"; and then continues: "Micro-chemistry proper should set itself the task of isolating a certain element of the structure, and determining its composition by micro-chemical means, such as crystallising the element out of solution and determining the crystals or chemical reactions in a microscopic field"; and he appeals to all friends of microscopic metallography that they should pursue their labours along the course indicated.

Prof. Behrens, in his work on micro-chemical analysis, gives us some hope that to a certain extent the chemical reactions may be developed on the various structures in metals and alloys in the microscopic field; but the more certain method, and the one I have adopted, following the example of Sir F. Abel and Dr. Muller, is the employment of some reagent which will preferentially dissolve away one constituent before another, and then to make chemical analyses of the residues and solutions. It was in this way that the gentlemen just named determined the constitution of the hard carbide of iron.

Mons. Charpy, in a most valuable paper on the alloys of copper and zinc, read before the Société d'Encouragement pour l'Industrie Nationale, February 1896, after a most painstaking research on the mechanical, physical, and microscopic properties of brasses, sums up his microscopic researches by the following conclusions:—

"It" (*i.e.*, the microscope) "allows us to classify the alloys in three categories, corresponding to well-defined mechanical properties: the first category corresponds to alloys very malleable in the cold; the second to alloys of great resistance, less malleable than those of the first category, but forgeable when hot; the third category includes the very various alloys of which the common characteristic is brittleness, which is enough to make them rejected for commercial application." "Again, the study of the structure allows us to determine approximately the mechanical treatment undergone by the metal—above all, in the case of alloys of the first category."

"We shall be able to determine if the metal has been cast, and, according to the dimensions of the grain, to know

almost in what conditions (high or low temperature, moulded in sand or cases); if it has been hardened; if it has been annealed, at a high or low temperature; finally, if it has been burnt."

"The study of the structure perhaps may furnish many other indications; it really appears to us already capable of useful application, not to replace chemical analysis, but to complete this operation by information which chemistry is powerless to furnish."

In an admirable paper by Mons. Osmond, read before the International Congress at Chicago, upon Microscopic Metallography, he briefly gives the observations of Mr. Guillemin, and as this clearly shows to what extent the examination of metals and alloys have been pursued in France, I introduce it here.

Mr. Guillemin says: "Micrographic examination permits the direct classification of the usual alloys in a few categories." "Thus, the bronze and brasses are distinguished as—

Tin-bronzes.  
Phosphor-bronzes.  
Brasses containing less than 37 per cent. of zinc.  
Muntz metal and analogous alloys containing more than 37 per cent. of zinc.  
Aluminium-bronze.  
Aluminium brasses.  
Delta metal.  
Roma bronze, &c.

"In the white 'anti-friction' alloys containing tin, antimony, and copper, it is easy to recognise the presence, and even, with a little practice, to make a close estimate of the proportion of lead.

"By examining the ingots of rose-copper composing different casts from the same smelting of ore, those which have been perfectly refined can be distinguished, and the rest can be classified according to the degree in which they have been refined."

"It is known that the mechanical qualities of brasses and bronzes are profoundly modified by the addition of small quantities of aluminium and of phosphorus." "The presence of these two elements can be detected with certainty by micrographic examination. Thus, the tracings assume invariably the form of veins in marble when the alloy contains aluminium, even in proportions so minute as to be detected with difficulty by chemical analysis." "In like manner, phosphorus produces in tin-bronzes an absolutely characteristic image, recalling a fern-leaf. This reaction, however, may be masked by the presence of zinc, in amount exceeding 4 per cent."

"Finally, for a known alloy, the microgram indicates also the conditions of casting, as well as the nature of the mechanical work subsequently performed upon the specimen. Thus, the image shows whether bronze has been cast too hot or too cold; whether it has been stamped or rolled; and, in the latter case, the direction of the rolling is distinctly marked."

"In a word, micrographical analysis enables us to determine quickly and summarily the nature of a bronze or an industrial alloy by the simple inspection of a polished and etched surface, and to recognise whether the alloy has been simply cast, or has been rolled or stamped."

Prof. Roberts-Austen, who has perhaps done more investigation into the physical and mechanical properties of alloys than anybody else in this country—his results being embodied in four consecutive reports to the Alloys Research Committee of the Institution of Mechanical Engineers—in his fourth report on compounds of copper and zinc, states that in his next report he will deal with the micro-structure of metals and alloys.

When the ternary and other more complex alloys are studied, I anticipate that it will require the combined assistance of the recording pyrometer, the microscope, chemical analysis, and the mechanical methods of investigation in order to obtain a correct knowledge of their properties, constitution, and structure; and I also anticipate that it will require the work of careful investigators for very many years to come before we have obtained the truth about them all.

During the past year I have devoted most of my leisure-time in repeating the researches of Osmond, Arnold, and others, and have obtained results which practically confirm their work. It has, however, been beyond the resources of a private laboratory to experiment with gold; but as Prof. Roberts-Austen's pyrometrical observations agree with the microscopic work of Prof. Arnold, we may consider that the researches of the latter are beyond dispute.

The micrographic study of metals is of such a fascinating character, it appears to me, considering that the unexplored field is so extensive, and the results of research so interesting, it is difficult for anyone interested in true science, who once commences this kind of research to abandon it.

The whole operation of making the alloys, cutting them up, polishing, etching, and examining them, is of such a simple and inexpensive character, almost anyone with a little practice can do important research and obtain most valuable information.

It would not appear, after reading all the available literature on the micro-structure of alloys, that the compounds of lead and antimony have been studied; I therefore prepared a series of lead-antimony alloys, and the following description of my work will, I hope, be of interest to the members of this institution:—

#### *Lead and Antimony.*

As the object was to ascertain the micro-structure of alloys which are commercially produced, virgin lead and best "star" antimony, such as are regularly used in commerce, were employed in this research. Fifteen mixtures were made, in which the proportion of lead and antimony varied between 1 per cent. of antimony and 99 per cent. of lead, and 95 per cent. antimony and 5 per cent. lead. The carefully weighed metals were introduced into plumbago crucibles containing fluid cyanide of potassium, which were then placed in a Fletcher's gas crucible furnace. The lead in each case was first added, and when it was fluid and red hot, the antimony was dropped in, and as it immediately sunk below the surface of the molten cyanide practically no volatilisation of antimony took place. The crucible with the contents was then vigorously shaken, to effect thorough admixture, and was allowed to slowly cool in the crucible in the open air. When cold, the cyanide was washed away by a running stream of water, and the solid metal or alloy was then removed by striking the mouth of the crucible upon an iron slab. Of course, the same crucibles were used over and over again, as it was not necessary to use a new one for each trial. The pieces of alloy weighed about 100 grms., and measured about  $1\frac{1}{2}$  in. at the top, and were about 1 in. deep. Each sample was sawn vertically through the centre, and a complete section was then taken by cutting out a piece about  $\frac{1}{8}$  in. in thickness.

#### *Grinding and Polishing the Specimens.*

After many trials, it was found that the best way to obtain a perfectly flat face was to hold the section between the first finger and thumb, and to draw it downwards over the face of a smooth-cut file held vertically by the left hand, the tang resting upon a hard board or support. Having obtained a smooth surface, the next operation was to grind it upon a flat surface of Turkey stone, such as joiners use for sharpening their tools; but instead of using oil, the stone was kept continually wet by the application of clear water. In a very few minutes of rubbing backwards and forwards, the file marks were obliterated.

The following stage consisted in rubbing the specimen, with the application of practically no pressure, over a sheet of French emery paper No. 0000.

It is important that no pressure, or at least practically no pressure, should be applied; otherwise the softer parts of the metal will be forcibly dragged or torn, and will overlap the harder parts of the structure.

The final stage consisted in rubbing the specimen over smooth cloth, free from ribs, upon which had been previously placed a small quantity of diamondine powder—a most valuable preparation, made in Switzerland, for the purpose of polishing steel, and which can be obtained from almost any jeweller; a bottle costing 1s. 6d. will serve to polish more than 100 specimens. It is important that this block should

be kept continually moist, otherwise the softer metal will be torn by the friction and the specimen spoiled. It is also important that the pressure applied to the metal should be excessively light. The surface should be examined from time to time, and the polishing stopped as soon as the fine scratches left by the emery are obliterated. If the polishing is carried beyond this point, the softer constituents will be carried away, and the crystals or grains harder in character will stand in great relief, and be more or less rounded, and their true shapes rendered difficult to determine.

#### *Etching the Polished Specimens.*

After leaving the polishing block, each specimen was thoroughly washed in water, and was at once, without drying, placed in a solution consisting of 99.5 c.c. of water and  $\frac{1}{2}$  c.c. of nitric acid of 1.42 sp. gr. In about one minute the structure was usually sufficiently developed for a preliminary examination. It was then removed from the acid, thoroughly washed with water, and afterwards soaked in rectified spirit, after which it was removed, the excess of alcohol shaken off by swinging the specimen backward and forward, and was finally placed on a hot plate to dry, when it was ready for microscopic examination.

#### *Description of Micro-Structures.*

In the specimens containing between 1 and 13 per cent. of antimony, the structure appeared to be almost amorphous, and it was difficult to determine the character of the crystals; but in the alloy containing 15 per cent. antimony there was found to be a distinct layer, clearly visible without magnification, of harder metal at the upper surface, that is to say, on that part of the metal which was uppermost when it solidified. In proportion as the antimony was increased, this hard and silvery white layer increased in thickness, until when 50 per cent. antimony was present, the whole mass appeared to be bright. On examining these white layers with an objective magnifying about 50 diameters, it was noticed that they were not by any means homogeneous, but consisted of more or less well-formed crystals, apparently of cubical form, imbedded in a substance exceedingly dark in colour.

Fig. 1 clearly indicates the appearance of the various

Fig. 1.

Sb = 50, 40, 30, 20, 15, 12, 10, 8, 6, 4, 2, 1 per cent.  
Pb = 50, 40, 30, 20, 15, 12, 10, 8, 6, 4, 2, 1 per cent.

sections, whilst Fig. 2 is a magnification of 50 diameters of the white layer in the 80 per cent. antimony alloy.

Fig. 2.

(One-sixth of actual size.)

Having now crystallised out a definite structure, the next question which arose was whether or not the alloy

had separated into two fluid layers, one lighter than the other, previous to solidification, or whether the crystals had formed throughout the alloy, and afterwards floated up to the surface in a manner analogous but the reverse of that which occurs in crystallising salt.

Messrs. C. R. Alder Wright and C. Thompson communicated a most important paper to the Royal Society, in 1889, on certain ternary alloys, in which the metals lead, tin, and zinc in varying proportions were melted together, and the resulting mixtures, after slow cooling, were examined. It was found that if the tin is less than  $\frac{2}{3}$ ths of the whole mass, the alloy divides itself into two different ternary alloys, lead preponderating in the heavier one; and they point out that this phenomenon is entirely distinct from the segregation of alloys during solidification, in consequence of the formation of other differently fusible alloys, and they also point out that the alloys separate as fluids, and then crystallise afterwards. In order to compare the micro-structure of such alloys with that I had obtained, a mixture of tin, lead, and zinc was prepared in the manner described by those gentlemen. A section of the mass was then made and was examined under the microscope. The appearance clearly showed that the alloys had separated when in a liquid condition, for there was a clearly defined line between the upper and lower alloy, which was perfectly horizontal, the alloy above having an entirely different structure from that below the line of demarcation. In the lead-antimony alloys no such clearly cut line was present: in fact, as a rule, the upper layer was not horizontal, but curved downward on each side, and the matrix which constituted the lower part of the alloy could be traced continuously between the crystals to the very top of the mass. It was also noticed that several of the white bright crystals were present at the very bottom of the alloy, and it appeared that these had attached themselves to the bottom of the crucible, and were not, therefore, free to float through the mass. Although such considerations would lead to the assumption that the crystals formed in the matrix at a temperature considerably above its melting point, and then, in virtue of its less gravity, floated to the top, it was considered unsafe to form any conclusions without more practical demonstration. In order to settle the question beyond doubt, a considerable amount of an alloy containing 30 per cent. of antimony and 70 per cent. of lead, was melted and afterward poured into a mould which had been previously heated, and which was provided with rigid shelves, attached to one side of the mould only, and which projected half way across, and which were fixed at an angle of about 30 degrees in an upward direction.

The following, Fig. 3, will make the matter more clear:—

Fig. 3.

( $\times 50 \times$ .)

Lead = 20 per cent. Antimony = 80 per cent.

It may be assumed that if the lighter mass was in a fluid condition before it reached the surface, the shelves would not impede its progress. A liquid ascending would of course flow readily up the inclined planes and escape to

the surface, whereas if it crystallised in the body of the mass, on ascending to the under sides of the shelves the friction would be too great to allow the crystals to travel upwards, and on making a section of the cold alloy, from top to bottom, we should then find layers of crystals under each shelf.

After pouring the alloy into the mould, it was allowed to cool very slowly, and when cold it was sawn from top to bottom, cutting it at right angles through the shelves. The whole mass was then polished and etched, and it was found, as was naturally predicted, that the crystals on one half of the mould, where the shelves existed, were equally divided between the under sides of the three shelves and the surface. The above diagram is a graphic representation of the results obtained.

The next point of interest to determine was the composition of the hard white crystals. For this purpose a considerable quantity of the 30 per cent. antimony alloy was melted, and cooled somewhat rapidly in a shallow iron mould, the object being to obtain the crystals unattached one to the other and suspended in the eutectic compound. This bar, measuring 6 ins. by 2 ins. by  $\frac{1}{4}$  in., was then filed bright, and was immersed in a 10 per cent. nitric acid solution in water, and it was allowed to remain there several days in the cold. On removing the bar from the acid, it was found to be coated with a soft, slimy material, in which the granular crystals were retained in position. By brushing off this deposit and washing with water, the dark-coloured slime was removed, and the apparently pure white crystals separated as a heavy granular deposit. In order to thoroughly eliminate all adherent matter, these crystals were boiled with dilute nitric acid, but previous to doing this they were thoroughly well rubbed with the finger and thumb to separate adhering crystals, which might possibly enclose a portion of the eutectic alloy. After digestion with acid, they were thoroughly well washed in running water, and were afterwards dried. On examination under the microscope, it was found that they consisted of more or less perfectly formed crystals of cubical form, and it was also observed that the angles had been but slightly acted upon by the acid, and as their surfaces were bright and continuous, we may be justified in assuming that the acid had not acted in any way upon the interior of their mass. The specific gravity of these crystals proved to be 6.5, which approximates to that of pure antimony, which is 6.7. An analysis showed them to contain 99.8 per cent. of antimony and 0.2 per cent. of lead; in other words, they consisted of practically pure antimony. On examining the alloys containing more than 50 per cent. of antimony, the crystals increased in volume until, when 95 per cent. antimony was reached, practically the whole field under the microscope appeared to consist of antimony, but even in this alloy, a small quantity of the eutectic compound was most distinctly visible, surrounding more or less completely the square masses of antimony. As it was impossible to separate the crystals from the alloys containing a very large proportion of antimony, I am not in a position to state from actual trial that they do not contain some lead. The relatively small areas of the dark eutectic compound would lead us to believe that the white crystals in the 80 per cent. and the 90 per cent. alloys were not pure antimony.

The next question to determine was the character and composition of the eutectic or most fusible compound.

This was done by two different methods: first, by synthesis, and second, by analysis. It had been observed that there were hard crystals in the 15 per cent. alloy, but none in that containing 10 per cent. antimony. Several mixtures were made, containing between 15 per cent. and 12 per cent. antimony, and, after melting under cyanide and allowing them to cool slowly, they were cut up and examined. As the antimony was reduced, the hard upper layer decreased, until on arriving at a mixture containing 12.5 per cent. antimony, and 87.5 per cent. lead, no separation of crystals could be detected, although they were clearly present in the alloy containing 13 per cent. of antimony. If we take the atomic weights of lead and antimony to be 207 and 120 respectively, we find that a chemical compound having the formula  $Pb_3Sb$  would contain 12.66 per cent. antimony and 87.34 per cent.

lead. On now melting the metals together in that proportion and allowing to cool slowly, we obtained an apparently homogeneous mass, free from separated crystals.

There was no difficulty in obtaining this material in a perfectly pure state, as it was only necessary to cut off the upper portion containing the free antimony of any of the alloys containing above 13 per cent. of antimony, and to use the lower portion for analysis. Two carefully conducted determinations gave 12.8 per cent. and 12.7 per cent. of antimony and 87.2 per cent. of lead, and this corresponds nearly with the formula  $Pb_3Sb$ . Although it was an easy matter to obtain the eutectic alloy from the alloys containing under 50 per cent., it was impossible to separate this material from those containing 50 per cent. and over of antimony. Recourse was therefore made to another method of research, namely, the determination of the freezing or critical points in cooling the liquid alloys. Each alloy was therefore carefully melted in a small charcoal crucible to a point considerably above the fusing point, and by means of the Le Chatelier pyrometer a careful determination of the critical points was obtained. In applying the couple to the molten mass, the two twisted wires were first of all covered very carefully with moist asbestos paper, in which condition it could be most readily moulded, so as to completely protect them from actual contact with the fluid metal. Previous to the introduction of the couple into the metal, the asbestos enclosing the couple was heated to bright redness in a Bunsen flame, by which means the asbestos assumed a fair amount of rigidity. The actual thickness of this coating did not much exceed  $\frac{1}{16}$ th of an inch, and was so strong as to last for more than 20 determinations of temperature without breaking. The pyrometer having been previously most carefully calibrated according to the method given by Prof. Roberts-Austen and others, and the alloys having been melted, it was only necessary to lower the asbestos couple into the molten mass, and to pack loose fibrous asbestos all round it, over the surface of the liquid in the crucible, and then to carefully observe the points at which the speck of light became stationary or moved very slowly. The eutectic alloy had only one freezing point—at about 247° C. The melting point of lead being 325°, and that of antimony 630°, the mean of the two metals is 388°. It will be seen that the eutectic alloy had a solidifying point of  $388 - 247 = 141^\circ$  below that of the mean of the two metals in the mixture, and 78° below that of lead. The alloy containing 95 per cent. of antimony had a first critical point of about 615° C., and another of very short duration at 217° C., and all of the alloys had this one common critical point of 247° C., showing most clearly that the eutectic alloy in the 95 per cent. alloy was of the same composition as that containing about 13 per cent.

The specific gravity of the eutectic or lighter alloy was 10.48. Theoretically, the mean of the lead and antimony should have given a specific gravity of 10.77.

It is not surprising that the antimony crystals floated up to the top of the mass, considering that they were so much lighter than the eutectic alloy; in fact, the latter was more than  $1\frac{1}{2}$  times as heavy as the antimony.

Attempts were made to determine the crystalline structure of this eutectic alloy, but, as before stated, I failed to determine it by the usual method of polishing and etching. When, however, a sufficient quantity of the material was allowed to cool or solidify very slowly, the surface of the bright alloy presented a frosted appearance, and on examining this under high power, crystals of an hexagonal form were clearly detected.

When the proportion of lead is increased above 87 per cent., the pyrometrical results indicate two melting points; the higher, or first freezing point increasing with the increase of lead, until, when the whole of the antimony is eliminated, the melting point is that of lead, or 325° C. Until that point is reached, however, there is a clear retardation at 247° C., showing that in this case the same eutectic alloy remains, as is the case in the alloys containing less than 87 per cent. lead.

In one case lead is dissolved in excess of the eutectic alloy and in the other case antimony is in excess in the same mother liquor.

That antimony and lead should combine in atomic proportions in the eutectic alloy is not contrary to the conclusions of Dr. Guthrie, who has thoroughly investigated eutectic compounds, his results having been communicated

Fig. 4.

( $\times 300 \text{ V.}$ )

Eutectic Alloy of Lead-Antimony Compound (Pb,Sb).

to the Royal Society in 1884 (*Philosophical Magazine*, Vol. 17, 1884, page 462), for that gentleman, although pointing out that such eutectic metals do not as a rule exist in atomic proportions, makes the following statement:—

"When we are dealing with metals, which, like antimony and arsenic, on the one hand, are themselves halogenous, or with such strongly chemico-positive metals as sodium, on the other, we may and do get alloys of atomic composition," "Metallo-metallic salts." It would not appear that Dr. Guthrie had studied antimony and lead compounds; in fact, all his communicated results dealt with the compounds with bismuth, zinc, tin, lead, and cadmium, and with mixed salts; and he clearly demonstrated that the eutectic, or most fusible constituent of each alloy did not have the metals in any simple atomic proportion. To use his own words, "The constitution of eutectic alloys is not in the ratio of any simple multiple of their chemical equivalents, but their composition is not on that account less fixed, nor are their properties less definite."

The same gentleman showed that there was a close relation between the eutectic compound metals, and the cryohydrates of common salts in water, and states, "For as a salt may unite with water, as when anhydrous chloride of calcium does so, to fix the water as crystalline water, and also may unite with water as a cryohydrate, so two metals may unite in one proportion, while they form a definite eutectic alloy in another."

Henri Gautier (*Compt. rend.* 1896, 123, 109—113) makes the following interesting statement with reference to the fusibility of metallic alloys:—"Fused alloys, on solidification, behave in a similar manner to fused mixtures of salts, and hence may be divided into three classes corresponding with the three classes of saline mixtures recognised by Le Chatelier."

"(1.) The metals do not combine in any fixed proportions, and the two constituents crystallise quite distinctly; for example, alloys of tin with zinc, bismuth, or lead."

"(2.) A definite compound of the two metals crystallises out, but these crystals are scattered in a crystalline matrix of the metal which is in excess; for example, copper with tin or antimony."

"(3.) Alloys corresponding with isomorphous mixtures of salts; for example, gold and silver."

"The fusibility curve of an alloy at once indicates to which of these three classes the alloy belongs."

In concluding this section it is necessary to point out that various chemical and metallurgical text books contain most erroneous statements with regard to the melting point and equivalent of antimony.

The chemical equivalent is given in many books as 123 instead of 120, and the melting point as  $430^{\circ} \text{C.}$  instead of  $630^{\circ} \text{C.}$ ; in fact, my own observation proves that antimony and aluminium have practically the same melting point, namely, about  $630^{\circ}$ , and Henri Gautier gives the melting point as  $632^{\circ}$ .

#### *Antimony and Tin.*

It was not my intention to deal in this paper with other than the lead-antimony alloys, but as I have done much work with the antimony and tin compounds, although the investigations are far from complete, the results are of such interest that I am sure I will be pardoned if I introduce a brief account of the work as far as it has been carried out.

The same method of procedure was followed in making these alloys as was adopted in making those previously described, and the specimens were polished and etched in the same manner. Up to a point when the antimony did not exceed 7.5 per cent. there was no apparent separation of well-formed crystals in the mass, but the bright surface of the alloy rapidly clouded over, leaving a dark deposit upon the surface, showing clearly that at the solidifying point some of the antimony had been retained in combination, or solution in the tin, and white meshes of a harder constituent were found more or less irregularly distributed between the joints of the crystals, indicating clearly the presence of some compound which had crystallised out at the moment when the mass was solidifying.

With 8 per cent. of antimony, the matrix presented the same appearance as the 7 per cent. alloy, with this difference, a few cubical crystals, very hard, and little acted upon by dilute acid, were observed on the upper surface of the solidified alloy, when the cooling was done very slowly. When, however, the fluid mass was cast in an ordinary mould, the crystals were distributed evenly throughout the mass. With 9 per cent. the number of crystals were relatively increased; with 10 per cent. a still larger proportion of cubical masses were found distributed throughout the mass, in the moderately rapidly cooled alloy, and each addition of 5 per cent. of antimony was accompanied with a corresponding increase in the proportion of the separated crystals, until 40 per cent. of antimony and 60 per cent. of lead were present. The alloy with 25 per cent. of antimony and 75 per cent. of tin gave a really unique and beautiful section, the crystals embedded in the matrix being of the most perfect form and shape, and indicated beyond all doubt that they were perfect, or almost perfect cubes. The following Figures, 5 (omitted) and 6, clearly prove this statement.

Fig. 6.

( $\times 50 \text{ V.}$ )

Tin = 75 %. Antimony = 25 %.

When the amount of antimony was increased to 45 per cent. and the tin 55 per cent. the structure no longer presented the same appearance, for, instead of cubical masses, the crystalline mass evidently consisted of plates

(Fig. 6a), crossing in almost every conceivable angle, the whole surface of the mass, the dark matrix clearly

Fig. 6a.

( $\times 50$  V.)

Tin = 50%, Antimony = 50%

showing itself between the crystals. In proportion as the antimony was still further increased, until it reached about 54 per cent., the structure appeared to have the same character; but on continuing the action of the acid it appeared that the centre of the plates was harder in character than the exterior portion, and less acted upon by nitric acid. With 53 per cent. of antimony there still remained the dark coloured matrix. When the antimony was increased to 55 per cent. this dark matrix had entirely disappeared, and after the action of very dilute nitric acid, for a time quite sufficient to develop the dark matrix in the alloys just described, the field remained perfectly bright, and apparently homogeneous; but on acting for a few seconds on the bright surface with nitric acid of 1.42 sp. gr., a well-defined structure was developed, and it was clear that it consisted of two different constituents, one relatively more easily attacked by the strong acid than the other. The constituent least acted upon had every appearance of the crystalline forms which antimony assumes when crystallising out of the lead-antimony alloys; and although I have not yet actually separated them, we may be fairly safe tentatively in assuming that they actually do consist of antimony, for in proportion as more antimony was added to the alloys this harder constituent increased in proportion, until when 90 per cent. of antimony and 10 per cent. of tin were present, it occupied the greater part of the microscopic field. As the crystals in the 25 per cent. antimony alloy were so perfectly formed, and were sufficiently distributed through the matrix, a successful attempt was made to effect their isolation. This was most readily and perfectly effected by a long-continued action of comparatively strong nitric acid (1 part of acid to about 9 parts of water). The bar, after the action had been continued for several days, had much the same appearance as the lead-antimony alloys when similarly treated, and the dark-coloured slime containing the crystals was removed, and the turbid liquid decanted from the residue. The latter was rubbed up on the bottom of a mortar with an india-rubber pestle to detach the pulverulent apparently amorphous grey powder. It was then washed several times with water, and finally with dilute hydrochloric acid, to remove any mechanically adherent tin and its oxide, which was found to be present in more or less quantity. In this way a most perfect crop of crystals was obtained, and these, after drying, had their specific gravity and analysis determined. The specific gravity was 6.96; the specific gravity of tin being 7.29 and that of antimony being 6.71. If the antimony and tin were present in equal atomic proportion, and had not suffered any alteration in volume when combining, the specific gravity should have been 7.00.

Several portions were then tested for antimony and tin, using two different methods for their determination. The mean results obtained were as follows:—

	Per Cent.
Antimony .....	50.54
Tin .....	49.46

If the elements had combined in simple atomic proportions of one equivalent of tin and one equivalent of antimony, the calculated composition would have been—

	Per Cent.
Antimony .....	50.21
Tin .....	49.79

which shows most conclusively that the compound approximated to the composition of  $\text{SnSb}$ , and may be described as tin antimonide, a "metallo-metallic salt," as it would be called by Dr. Guthrie.

The following photograph (Fig. 7) was taken of one of the crystals after separation from the 25 per cent

Fig. 7.

( $\times 200$  O.)

Separated Crystal of  $\text{SnSb}$  (Antimonide of Tin).

alloy, and clearly indicates that it is cubical, but that as it has one corner absent, it may be considered to belong to a system between the octahedron and cube.

An attempt was made to produce an homogeneous mass of the above composition by melting the two metals in the proportions indicated, but, as before stated, such a simple compound could not be produced by this process; no cubical crystals were present, but the peculiar plates surrounded by the dark matrix were invariably the result.

A large quantity of the crystals themselves were then melted under cyanide of potassium, but with no better result, we are therefore forced to conclude that this peculiar chemical compound  $\text{SnSb}$  can only exist in presence of a large excess of an alloy containing a preponderating quantity of tin. An analogous case is well known in pig iron, or in compounds of carbon and iron, for it is now recognised that the exceedingly hard bright constituent of the most highly carburised white iron and steels consists of a definite compound  $\text{Fe}_3\text{C}$ , which can be readily separated as such from the matrix by suitable means, and that if the carbide so separated is melted in a crucible, it is instantly decomposed into a compound containing about 4.5 per cent. of carbon and 95.5 per cent. of iron, and into free graphite, which rises to the surface of the mass and is eliminated.

I have not fully completed the pyrometrical records of this series, but one point has been determined, and that is, that in all the compounds containing between 7.5 per cent. and 50 per cent. of antimony, there is a common freezing point of  $236^\circ \text{C}$ , which it will be noticed is close to that of

NOTE.—Prof. H. Behrens described an alloy of 90 per cent. of tin and 10 per cent. of antimony (Das Mikroskopische Gefüge der Metalle und Legierungen), but he does not appear to have examined a complete series.

the eutectic compound of the lead-antimony series. This is an exception to the general rule, that binary alloys fuse more readily than the less fusible constituent, for tin has a melting point of 231, antimony 630, the mean of the melting points of the constituents of the eutectic compound of about 92.5 per cent. tin and 7.5 per cent. of antimony is 261 °C., therefore the actual melting point is 5 degrees below this, but is 25 degrees above that of the most fusible constituent, tin. An analogous case to this has been found by Henri Gautier with antimony-aluminium alloys containing more than 2 per cent. of antimony, which are less fusible than aluminium.

This subject is receiving further investigation, and it is hoped that before long it will be completed.

#### *Tin and Phosphorus.*

Phosphor tin is a compound well known in commerce, and is extensively used for the production of phosphor bronze. It is characterised by its extreme brittleness and its spiegel-like fracture. A section of this compound polished in the manner previously described is a beautiful object under the microscope. It has the appearance of brilliant lines, perfectly straight, which pass in every conceivable angle over the whole object, and the matrix between is of exceedingly soft character, and as is the case with all similarly constituted alloys by polishing alone, the structure is well developed. On acting on the surface with dilute acid, the matrix is slightly darkened, leaving in brilliant relief the harder constituent. A series of compounds containing between 0.04 per cent. of phosphorus and 5 per cent. was carefully prepared, and each of them

Fig. 8.

(× 50 V.)

Tin = 97.5 % . Phosphorus = 2.5 %.

Fig. 9.

(× 70 V.)

Tin = 99.53 % . Phosphorus = 0.47 %.

was subjected to microscopic examination. It was found, as one would naturally expect, that as the phosphorus was reduced, the hard constituent also decreases, until when only 0.04 per cent. phosphorus was present a few hard specks remained in between the junction of the crystals. The diagrams shown fully illustrate these structures (Figs. 8 and 9).

It was found that just in the same way that antimony and antimonide of tin could be separated from alloys by the action of dilute nitric acid, so the hard constituent in phosphor tin could be similarly isolated. Obtained in this way, it presented the appearance of brilliant white plates, very similar to graphite, but of course much brighter. Several analyses of this compound demonstrated that it consisted of a chemical compound of the composition  $\text{Sn}_3\text{P}_2$ . Fearing lest nitric acid might have acted upon one of the constituents more than on the other, an attempt was made to dissolve out the tin with mercury, as it was found that the phosphide was quite insoluble in that solvent, and that after heating comparatively large pieces of the phosphor tin with that solvent for some hours, the scales floated to the surface, and could be removed more or less mechanically contaminated with mercury, which appeared to have the property of wetting the surface of the plates without actually combining with them. By strong pressure, the greater part of the mercury could be removed. The mass so obtained was then subjected to an analysis, with results sufficiently near to those first obtained to justify the conclusion that the phosphide obtained by the first method had been unaltered in the process of separating it. This phosphide, on heating in a stream of hydrogen gas, was decomposed, free phosphorus passing off, and a compound of phosphide of tin and free tin remaining behind. On treating any of the compounds containing phosphorus, with strong hydrochloric acid phosphine gas was liberated, which burst into flame on coming into contact with the air. In cooling the fluid compounds, the phosphide of tin crystallises out before the tin, and if the quantity of phosphorus in the compound is comparatively small, and the cooling very gradual and slow, the crystallisation invariably commences at the outer portion of the alloy, and travels in straight lines towards the centre. In fact, the structure is such that the slowly-cooled alloy resembled the appearance of a section of a pan of soda crystals, the mother-liquor remaining in the centre, the crystals radiating from the exterior of the pan to the centre. If the phosphor-tin compounds are allowed to cool sufficiently slowly to a point a few degrees above the melting point of tin, the latter may be most readily pressed out from the solidified crystals of phosphide; but of course the latter cannot be obtained in a very pure state by this means. In cooling a 3 per cent. phosphorus and 97 per cent. tin compound, the following critical points were obtained:—500° and 235° C., the higher being the point at which the phosphide began to crystallise, the lower being the freezing point of the tin.

The plates, after careful separation, were examined carefully under the microscope, and the two following diagrams, Figs. 11 and 12, indicate clearly that they crystallise in hexagonal plates.

#### *Tin and Arsenic.*

Arsenic is frequently met with in commercial tin, and the microscope is a valuable means of detecting its presence. It behaves in a similar way to phosphorus, the only difference being that the plates of arsenide of tin are a little more rough on their sides than those of the phosphide, and judging from the fact that the matrix is sensibly darkened by dilute nitric acid, we may assume that, at the point of setting, the tin still contains a minute quantity of arsenic. The arsenide crystals are quite as readily obtained as those of the phosphide, and an analysis of them after separation gave a compound containing—

	Per Cent.
Tin.....	69.45
Arsenic.....	30.55

As it was found, however, that the action of acid removes a portion of the tin, leaving the arsenic still in the form of

Fig. 11.

( $\times 50 \text{ V.}$ )

Tin Phosphide ( $\text{Sn}_3\text{P}_2$ ). Separated from Alloy.

Fig. 12.

Tin Phosphide ( $\text{Sn}_3\text{P}_2$ ). End of a separated Plate showing how the Crystals grow.

plates, I should not like to say definitely, at present, that the arsenide has that composition. It is most likely to have a corresponding composition to that of phosphide of tin, or  $\text{Sn}_3\text{As}_2$ , which would contain—

	Per Cent.
Tin.....	70.42
Arsenic.....	29.58

Further trials are in progress to definitely determine its true composition.

Unlike phosphor tin, it is possible to obtain fusible compounds of tin and arsenic, containing as much as 43 per cent. of arsenic; and I have obtained such a compound by simply dropping metallic arsenic into tin heated to bright redness. The compound was perfectly fluid at a red heat, but gave off copious fumes of arsenic when being poured into the mould, and solidified, or began to solidify, when still dull red.

The critical points of a tin-arsenic alloy with 20 per cent. of arsenic are at  $530^\circ$  and  $235^\circ \text{C.}$

Both arsenic and phosphorus lower the melting point of steel and iron, but evidently have precisely the opposite effect with tin; at least, the first freezing point is many degrees above the melting point of tin itself.

Several photographs which were shown on the screen represent the micro-structure of tin containing varying and decreasing quantities of arsenic, and they were all prepared in exactly the same way, the same weight being made of each, and the conditions of cooling were identical. In reality, the total compound in each case was only 10 grms., and as the small crucibles were taken from the fire and placed on a metal block to cool, the time taken to set must

have been of very short duration. With the higher percentages of arsenic, the plates of arsenide pass right through the section, whereas with smaller quantities, although apparently distributed at fairly equable distances apart, differ as the proportion of arsenic is reduced in their length and thickness. The plates freeze out at a very much higher temperature than the matrix, and it is quite possible to squeeze out the fusible mother-liquor, if we may so call it, leaving a mass of impure arsenide behind.

This compound crystallises in the same system and manner as the corresponding compound of phosphorus.

#### *Bismuth and Tellurium.*

Some observers have found that 0.2 per cent. tellurium in pure bismuth results in a perfect change of structure, from that of a coarse spiegel-like fracture of pure bismuth to one of fine grain.

On experimenting with small quantities of the bismuth, such as is sold as pure by chemical dealers, there was practically no difference between the pure bismuth and that containing 0.2 per cent. tellurium when they were cooled very slowly. The fractured surfaces were almost identical. The micro-structures were similar, the essential difference being that the alloy contained hard irregular shaped crystals, distributed between the grains of bismuth.

With 3 per cent. of tellurium, cubical crystals were distributed throughout the matrix on the upper portion of the alloy, and the secondary crystals below in the matrix were not so well formed as those in pure bismuth.

The results do not disprove those of others, probably the conditions of cooling are responsible for differences observed. The subject is receiving further investigation.

#### *Nitro-Cyanide of Titanium in Spiegeleisen.*

My investigations have fully confirmed those of Mr. T. W. Hogg, that this compound is present in spiegeleisen, but I found it not always necessary to dissolve the material, in order to obtain the cubic crystals. They can most readily be detected on the surfaces of the bright thin tabular plates, which are to be found in the hollow portions of the pigs. These plates are interesting objects themselves without any treatment, and the cyanide crystals are easily detected in widely separated aggregations.

#### *Micro-Mechanical Examination of Alloys.*

During my investigations, I have found it of great value, after having examined sections under the microscope, to determine by mechanical means, which part of the structure, if any, reduced the strength of the whole mass. The device employed is exceedingly simple, and yet is of the most invaluable character. The section after careful examination is placed, polished surface downwards, into a small V-shaped opening cut out of a solid square bar of steel. A round piece of steel is placed on the back of the specimen, and either slow or percussive pressure is then applied, until the specimen is distinctly curved. It is then without further treatment placed under the microscope, and if there is any brittle element present, it will be at once detected, as a microscopic fracture will have been effected at that place. If the first application of pressure does not develop any fissures, it is further pressed, or struck until if necessary, the sample is bent over right upon itself, when it is examined, and the appearance carefully noted.

The micro photographs, Figs. 14 and 15, of the samples which have been treated in the way described, fully demonstrate the great importance of this method of examination.

The following are examples of the value of this method of testing:—

1. Vertical sections from the worn surfaces of steel rails, tyres, &c. almost always show weakness at the extreme surface, this part breaking first, and the crack thus developed, then traverses downward into the sound physically unaltered material.

2. Micro-sections of structural steel, on being bent, first across the piece, and the direction of rolling, and second at right angles to that direction, almost always show the greater weakness in the latter case. The microscopic structure, as a rule, most clearly indicating the direction in which the rolling has been done.

Fig. 14.

(× 50 V.)

Copper = 89  $\frac{1}{2}$ %. Bismuth = 1  $\frac{1}{2}$ %. (After bending in V-block.)  
(Dark lines are fissures.)

Fig. 15.

Surface of a small Ingot of an Alloy of 80% Tin and 20% Arsenic, showing Arsenide Crystals and fracture made in V-block.

3. Steel castings which show microscopic intergranular foreign matter, such as has been described by Prof. Arnold and Mr. T. Andrews, of Sheffield, always break away at the joints of the grains where the deposit exists.

4. Inter-crystalline weakness is always detected in copper, especially when the element bismuth is present.

5. All the weak parts of white metal alloys are clearly revealed by this method. Straight lines, or plates of a brittle constituent, in a softer alloy, are split down their centres, and the complex fracture traverses these brittle tracks, which constitute lines of least resistance.

Small or great quantities of arsenic, phosphorus, and copper, in tin, give good examples of this when tested by this method.

It is not all the metals and alloys, although they contain relatively strong and weak structures, which break away when tested by this simple process, it is therefore important to find another method for testing, to meet such cases.

In conclusion, I must apologise for the great length of this paper. My excuse is that it is not nearly as great as the importance that this somewhat neglected branch of science is almost certain to attain to. More workers are wanted; the field is unbounded. The work appeals both to the analyst and to the engineer. The results which will be obtained by systematic research are certain to add to our scientific knowledge, and practical applications are sure to follow.

### SCHEME OF ANALYSIS FOR PHOSPHATES.

BY R. M. CAVEN, B.Sc., F.I.C.

THE following table for the qualitative separation of metals whose phosphates are precipitated from acid solution by

#### TABLE FOR ANALYSIS OF PHOSPHATES.

If  $\text{PO}_4$  is found to be present in the filtrate from Group II, after boiling off  $\text{H}_2\text{S}$  and adding a little  $\text{HNO}_3$ , and a precipitate forms on adding to the solution  $\text{NH}_4\text{Cl}$  aq. and  $\text{NH}_4\text{HO}$  aq., redissolve this precipitate in the least possible quantity of  $\text{HCl}$  aq., then add a few drops of  $\text{H}_2\text{A}$  aq. and a considerable quantity of  $(\text{NH}_4)_2\text{A}$  aq. If a precipitate forms, filter.

Precipitate may be—

$\text{FePO}_4$

$\text{AlPO}_4$

$\text{CrPO}_4$

If no precipitate forms, Fe, Al, Cr may still be present. Add to the solution or filtrate a few drops of  $(\text{NH}_4)_2\text{HPO}_4$  aq., and if a precipitate forms continue adding this reagent until no further precipitation takes place. Filter if necessary, pouring the turbid liquid through the same filter as before, if one was used.

*Residue*.—Dry the precipitate on the paper and fuse it with solid  $\text{KHO}$ , free from Al, on Pt foil. Boil the mass with water, and filter.

*Filtrate or solution* may contain Cr, which is not completely precipitated by  $\text{NH}_4\text{A}$  aq. in presence of  $\text{H}_2\text{A}$  aq. Add  $\text{FeCl}_3$  aq. carefully until the precipitate first formed remains reddish-brown in colour; boil for several minutes and filter.

*Residue* consists of  $\text{Fe}_2\text{O}_3$ . Dissolve in  $\text{HCl}$  and add  $\text{KCys}$ . A red colour shows Fe.

*Filtrate*.—Divide into 2 parts.

If yellow shows Cr, a trace of Mn may appear here and colour the solution green. In this case add  $\text{H}_2\text{A}$  aq. and  $\text{PbA}_2$  aq. If the precipitate formed is yellow, the presence of Cr is proved.

Add  $\text{NH}_4\text{Cl}$  aq. in excess and allow to stand. A white gelatinous precipitate shows Al.

*Residue* consists of  $\text{FePO}_4$  and basic ferric acetate, and may contain a little Cr. It may be neglected unless Cr has not already been found, and traces are to be looked for, when a fusion with  $\text{KHO}$  must again be performed.

*Filtrate* should be free from Fe and  $\text{PO}_4$ . Add  $\text{NH}_4\text{Cl}$  aq. and  $\text{NH}_4\text{HO}$  aq., and examine by general table for groups III, B., IV., and V.

ammonium hydrate, is the outcome of some recent experiments on the subject; and although much originality cannot be claimed for the general method adopted, the table differs in some important particulars from any scheme which has previously been published. When ammonium acetate is added to a solution containing Fe, Al, and Cr, and in which free mineral acids have been replaced by a very small excess of HFA;  $\text{FePO}_4$  and  $\text{AlPO}_4$  are entirely, and  $\text{CrPO}_4$  is partially precipitated in the cold, provided excess of  $\text{PO}_4$  is present. If only a small amount of  $\text{PO}_4$  is present, the phosphates formed remain partly, or even entirely, in solution in the corresponding acetates, and the solution is not easily freed from  $\text{PO}_4$  by boiling. Additional phosphate is therefore added, if necessary, in the form of ammonium phosphate, to complete the precipitation in presence of ammonium acetate.

$\text{PO}_4$  will now be in excess, and ferric chloride is added and the solution boiled, by which means all the  $\text{PO}_4$  is removed from solution and the slight excess of iron precipitated in the form of basic acetate. If any chromium remained in solution before the addition of ferric chloride, it will be precipitated during the subsequent boiling.

The method adopted for the detection of Fe, Al, and Cr in the precipitate by ammonium acetate has been described in a former paper (this Journal, 1897, 29).

The table has given good results in the hands of several experimenters. It is susceptible of some simplification at the expense of accuracy.

#### DISCUSSION.

Dr. F. CLOWES said that the paper was principally interesting to him as leading up to the improved phosphate table prepared by Mr. Caven. In his old student days they had a phosphate table which they admired largely because they could not understand it, and that table survived, with some emendations, to the present time. Mr. Caven's scheme was a simplification of that table, and he thought that any elementary student would easily understand the principles involved. He should be very glad, with Mr. Caven's permission, to make use of it in future text-books with which he was concerned. There was only one point which he should be inclined to criticise. Chromium, if present, might apparently be divided into two portions; accordingly, if only a trace of the metal had to be detected, there might be risk of its detection being missed when the small amount had been thus divided. He did not see, however, any way out of this difficulty. Mr. Caven had certainly effected a very great improvement on the old method of analysis.

Mr. L. MEGGITT added a few remarks on the quantitative estimation of aluminium and iron phosphates which occur in the mineral phosphates of commerce.

Dr. J. D. GRANGER wished to remark that it was not stated which metals were present as phosphates and which were not, in the results obtained by this table. In the old tables they were supposed to ascertain which metals were present as phosphates and which were in combination with other acid radicles. Apparently Mr. Caven's method could be carried out much more quickly than the old method. Mr. Meggitt gave them a number of methods which, for quantitative work, were very accurate, but which were too lengthy for qualitative analysis. At present, when time was of so much value, they strove for the quickest method which would give satisfactory results, and Mr. Caven's scheme appeared to comply with these conditions.

Mr. G. J. WARD asked whether the table could be used for quantitative analysis as well as for qualitative.

Mr. CAVEN, in reply to Dr. Clowes, said that the ease of chromium presented a difficulty because of the partial solubility of chromium phosphate in acetic acid, even in presence of ammonium acetate. But it would very seldom happen in practice that chromium need be looked for twice, though, in the case of small quantities of the metal having to be looked for, the possibility of division into two portions was an undoubted disadvantage. He was very glad that Dr. Granger had remarked about the older tables professing to find certain metals present as phosphates. When once a mixture containing phosphates had been dissolved in an acid

it was impossible to say how the  $\text{PO}_4$  had been originally distributed in the solid substance; it was more than doubtful whether the identity of the original substances was in any way preserved in the state of solution. So that the use of the term "present as phosphate" was purposely avoided in this table. In reply to Mr. Ward's question, the table was intended for qualitative work only, and the author was not prepared to say how far it might be used for a quantitative separation of the metals.

#### THE EXPLOSIBILITY OF LIQUID ACETYLENE.

BY PROF. FRANK CLOWES, D.Sc.

THE author, after referring to a former paper communicated by him to the Section, stated that Mons. Pictet now prepared acetylene gas in a dry state, and in an absolutely pure condition. Mons. Pictet maintained that in this state the gas might be safely liquefied by compression, and then stored, transported, and used for illumination.

The pure gas possesses a distinct but not unpleasant smell, and produces no chemical action upon metals. It appears to give rise to no danger from explosion.

According to the researches of Prof. Dixon and of MM. Berthelot and Vieille, a local source of energy, such as an electric spark, an explosion of fulminate, or a source of heat of sufficient intensity, when applied to acetylene gas under atmospheric pressure, does not produce explosion throughout the whole volume of gas, but only an explosion immediately around the source of energy. An illustrative experiment made by the author when communicating the paper, however, proved that an explosion caused by the firing of fulminate in a small quantity of acetylene gas would develop very great energy; a glass vessel being shattered, and the glass fragments being driven through a metal screen.

On the other hand, the researches just referred to prove that acetylene gas, when compressed to two or more atmospheres, is exploded throughout its mass by the local means stated, and under these conditions a very dangerous pressure may be developed.

Liquefied acetylene is a substance of considerable scientific interest. It exerts a pressure of about 30 atmospheres at ordinary temperatures. It is the lightest liquid known, and has the greatest coefficient of expansion of any known liquid or solid. It is also possessed of less refrangibility than any known liquid or solid. It furnishes about 300 times its volume of gas by evaporation.

As regards the explosibility of liquid acetylene, it is conceded that, under suitable conditions, it explodes *en masse*. Unfortunately, numerous serious and fatal explosions have occurred from liquid acetylene, but their extraordinarily destructive effect has led to considerable difficulty in tracing the precise cause of the explosion. In a recent explosion in Mons. Pictet's own laboratory the origin has been attributed to the fact that workmen neglected to pump out the acetylene from a steel cylinder before its cap was unscrewed, and the use of a spanner on the cap appeared to develop sufficient heat to explode the acetylene. In a more recent explosion in Berlin the explosion was said to be started by friction. Until the possible causes of explosion are more fully known, it seems impossible to feel that the liquid is safe for ordinary purposes.

Mons. Pictet describes the precautions which he has taken in order to avoid risks of explosion during the preparation and liquefaction of the gas. The gas must be pure and must be cooled during the process of compression. In order to obtain the gas with safety in a pure state, the lumps of calcium carbide are allowed to fall into cooled water, so as to be at once entirely immersed, and the gas is then purified by passage through dilute sulphuric acid, calcium chloride solution, solution of a lead salt, and solid calcium chloride. All these purifying substances must be kept cool. The impurities thus removed are mainly ammonia, arsine, phosphine, hydrogen sulphide, hydrocarbons, and moisture. The dry, pure gas is then stored over heavy petroleum oil.

Mons. Pictet attributes the intense light of the flame of acetylene to the same cause as the explosibility of the gas, namely, its dissociation into its elements with production of

a temperature exceeding that of the electric arc. This dissociation occurs very near the base of the flame, and only after the elements have cooled can they subsequently undergo ordinary combustion in the higher part of the flame.

Dr. J. D. Granger, Mr. J. Golding, and the Chairman took part in the discussion, and Dr. Clowes, in reply to questions from these gentlemen, stated that the intense heat near the jet from which the gas was burnt did not appear to injure the jet, whilst the heating and contamination of the atmosphere by an acetylene flame was considerably less than that arising from the equivalent illumination produced by coal-gas. He believed that no experimental proof had been furnished that acetylene could be exploded by a distant detonation.

#### DISCUSSION.

Dr. J. D. GRANGER, who had just returned from Berlin, referred to the extensive character of M. Pictet's work in this matter. Unfortunately two most serious explosions had taken place in Pictet's own laboratory in Berlin. It had been found that friction was more likely to explode acetylene than any other cause, especially when it was in a liquid state. In that condition the friction caused by opening the valve was enough to cause an explosion. That the acetylene was split up into its component parts, hydrogen and carbon, during the explosion was proved by the large quantity of carbon found subsequently in the cylinder. M. Pictet had succeeded in removing most of the impurities, but there was one, and that a very dangerous one, which he had not yet proved to be removed, *viz.*, phosphoretted hydrogen. M. Pictet had passed the acetylene through a solution of lead acetate or lead nitrate, and that would probably remove much of this impurity. It was necessary, however, to remove every trace of it, or there was great liability to explosion. One thing that was most lamentable was that they did not know exactly what had caused most of the explosions. In some cases they seemed to have happened without any apparent cause. It had been stated several times that acetylene acted on copper, but that was chiefly owing to impurity; and copper could be replaced by some other metal, such as nickel, in order to avoid this danger. From all that was known there could be no doubt that in the near future acetylene would replace in many places, or supplement the use of ordinary gas, but there were many things which it could not do. At the present time it had one great competitor, and that was the incandescent light. The insurance companies on the Continent were beginning to issue policies under which provision was made for lighting houses with acetylene, but the restrictions were so great that scarcely anybody availed themselves of them. Until more experiments had been made on the explosiveness of acetylene, it was hardly likely to come into general use.

Mr. GOLDING asked whether the heat of its combustion was not an objection to the domestic use of acetylene. Again, if the burner were tilted on one side so that a part of the flame impinged against it, would not the extreme heat of the interior of the flame fuse its orifice?

Mr. H. FORTH said he believed English insurance companies had absolutely refused to allow the gas to be used. They would have nothing whatever to do with it.

Mr. F. J. R. CARULLA asked in what proximity it was necessary to have the fulminate in order to produce an explosion.

Dr. CLOWES, replying to the questions asked, said he could not give any information on the last one. With regard to Mr. Golding's questions, they had tried the flames and had found, as a matter of fact, that they could hold their hands much closer to the acetylene flame than to the ordinary gas flame, for the heat disseminated in the air was much less. They had never had the difficulty of the burner being sealed up; but supposing the jet was tilted one way or another, he did not think it would play upon the jet, since the flame was a stiff one on account of the high pressure under which the gas issued. He knew as a matter of fact that there had been no trouble arising from this cause.

#### AN APPARATUS FOR COLLECTING THE GASES DISSOLVED IN WATER OR OTHER LIQUIDS.

BY PROF. FRANK CLOWES, D.S.C.

Dr. CLOWES then exhibited an apparatus devised by Dr. Truman for expelling and collecting the gases contained in solution in water, or in any other liquid.

The apparatus is represented in the accompanying figure:—

The flask B which receives the measured volume of liquid is connected by a jacketed rubber joint with the condensing vessel A, over which is spread a piece of fabric which is constantly moistened by a stream of water. The flask A is connected with the vessel C, into which the liquid may be introduced in measured quantity, and from which it is then allowed to flow through A into B. The liquid is poured into C and is drawn into A and B, which are vacuous, by opening the tap at the bottom of C.

The vessel A is connected also with two tubes provided with stop cocks and with a mercury gauge.

The apparatus is connected by tube E with a mercury Sprengel pump, and by the tube to the left of E with a high-pressure water-exhauster. And the process is commenced by exhausting the air from the interior of the apparatus as far as possible by the water-pump, then completing the exhaustion by the mercury pump. The measured

volume of water is then introduced into B from C, and is allowed to stand exposed to vacuum for several hours; the gas thus liberated is removed by the Sprengel pump and measured and analysed. The remainder of the gas which is in solution may then be removed by heating the liquid in B, and may be separately collected, measured, and analysed.

The apparatus is supported on a specially designed stand and since the support is mainly by suspension the risk of breakage is extremely small. There is sufficient play and freedom of movement to prevent the jar of a sudden shock from proving dangerous to the fragile glass.

MR. THOS. FAIRLEY IN THE CHAIR.

## THE MANUFACTURE OF AMMONIUM NITRATE BY DOUBLE DECOMPOSITION.

BY T. FAIRLEY, F.R.S.E.

WITHIN the last ten years ammonium nitrate, formerly only used in the laboratory, or in the production of nitrous oxide, has been employed in considerable quantity in the manufacture of "safety explosives."

A "safety explosive" for use in mines must leave no solid residue after explosion, and should not be capable of being fired by any ordinary means or mechanical violence, but only by a detonator. Ordinary explosives containing fixed solid substances may send out sparks of red or white-hot material when they are fired in blasting. This should not be possible with any safety explosive since it requires much higher temperatures to make gases red-hot, especially when they are allowed to expand.

Sprengel in 1873 (*Jour. Chem. Soc.* 796) showed that mixtures of nitric acid with other nitro-compounds give rise to very powerful explosives when fired by a detonator, but these Sprengel explosives have not come into general use. Sprengel also mentions the use of ammonium nitrate (*Jour. Chem. Soc.* 1873, p. 804) in place of nitric acid—his only objection to it being its hygroscopic nature. He found that this salt added to ordinary powder increased its explosive power.

The use of  $\text{NH}_4\text{NO}_3$  for explosives is mentioned in patent of 1872, No. 2766, Norrbom and Ohlsen, but there is no mention made of it in Sprengel's patents of 1871.

Ammonium nitrate is an endo-thermic compound—80 grms. of the salt may be exploded so as to give nitrogen, oxygen, and steam, with an evolution of 64,000 heat units or gram-degrees. The heat evolved is probably increased in presence of a small percentage of such substances as nitro-benzene or nitronaphthalene, used in the safety explosives.

An important point in the increased use of these explosives is their relative cost, and as many of them contain from 50 to over 90 per cent. of ammonium nitrate, the question hinges largely on the cheap production of this

salt. Generally it has been made by neutralising nitric acid by means of ammonia, and usually the liquid acid is saturated with ammonia gas, but in Blake's patent (this *Journal*, 1889, p. 706) both the constituents are mixed in the state of vapour. Very pure salt may be obtained by such processes—but more costly than if the salt could be obtained by double decomposition of the cheapest nitrate—sodium nitrate.

Little difficulty has been found in carrying out the manufacture of the corresponding potassium salt by the reaction of potassium chloride, carbonate, or hydrate on sodium nitrate.

The very great solubility of ammonium nitrate in water has, however, hitherto proved a difficulty in its manufacture by similar means—especially as the presence of 1 or 2 per cent. of fixed impurity renders the salt unfit for a "safety explosive."

The development of the ammonia-soda process suggested its application to sodium nitrate instead of sodium chloride.

Thus ammonia and carbon dioxide, or ammonium bicarbonate, would react on sodium nitrate to give sodium bicarbonate and ammonium nitrate—

In 1875, Gerlach patented processes based on this reaction in England (Wirth, No. 2174) and in Germany having special reference to the purification of gas liquor. *Ding. Polyt. Journal*, cccxiii., p. 82. *J. Chem. Soc.* xxxii., p. 236. Lesage and Co. in 1877, and Chance, in this country, in 1885, also took out patents for the application of the ammonia-soda process to sodium nitrate (this *Journal*, 1886, p. 325).

If the above reaction could be carried out to completeness, one would obtain only sodium bicarbonate insoluble and ammonium nitrate in solution, and the latter would be pure except from a small quantity of sodium bicarbonate corresponding to the sparing solubility of this salt.

It is now, however, well understood that such reactions are not complete under any conditions hitherto obtained. When the salts are present in molecular proportions, only about two-thirds of the quantities react—one-third remaining unaltered. If either salt exceeds the molecular proportion—the excess remains also and does not materially reduce the proportion of the other salt unaffected.

If one reverses the process, the salts—sodium bicarbonate and ammonium nitrate can react on each other so as to give a mixture of ammonium and sodium nitrates.

Though there is no doubt that variations of conditions such as temperature and pressure do slightly modify the proportions of the salts reacting, yet I have found a tolerable constancy in the results of experiments carried out in the laboratory.

Neglecting the small proportions of ammonium and sodium bicarbonates, the following numbers represent the proportions I have obtained:—

Application of the ammonia soda process to sodium nitrate.

Mixed salts obtained. $\text{NH}_4\text{NO}_3$ and $\text{NaNO}_3$ .	$\text{NaNO}_3$ .	Per Cent.
59.10 containing 19.75 corresponding to 39.80		
58.06 "	19.44 "	33.48
56.70 "	18.76 "	33.08
56.14 "	17.12 "	30.49
51.34 "	19.50 "	35.75

Further treatment of the product from these experiments made practically no difference in the proportions of the salts, and the lowest proportion of sodium nitrate remained as above about 30 per cent.

Other processes depending on the solubility of ammonium nitrate in alcohol and the use of this solvent to extract the salt from the products of double decomposition have been proposed by:—

1889. Roth, Eng. Pat. No. 1885, Ger. Pat. 48,705.

1889. Wahlenberg, Eng. Pat. 12,451 (this *Journal*, 1889, 293).

1892. Groendahl and Landin, Eng. Pat. No. 1868 (this *Journal*, 1893, 263).

In these processes the ammonium salts (generally sulphate) are treated with sodium nitrate (Roth also names potassium nitrate) in various ways and the product extracted with alcohol.

Roth and Wahlenberg assume that the reactions between the materials mixed in molecular proportions are complete, while Groendahl and Landin state that a certain amount of sodium nitrate remains with the ammonium nitrate dissolved in the alcohol and a certain amount of ammonium sulphate remains with the sodium sulphate. According to this, the reaction is not complete, and alcohol containing ammonium nitrate can dissolve sodium nitrate in appreciable quantity.

The incompleteness of the reaction of ammonium sulphate with sodium nitrate and the solubility of sodium nitrate in an alcoholic solution of ammonium nitrate I had previously proved conclusively, and I find that Watson Smith, in a paper read before the London Section found that "well dried absolute alcohol" extracted after two or three hours heating, ammonium nitrate containing some sodium nitrate (this Journal, 1893, 10).

Seeing the differences, in what ought to be simple matters of fact, in these patented processes, I have made a detailed examination of the processes described in each of them.

Roth's processes, Eng. Pat. 1885 of 1889 and Ger. Pat. 48,705 are best described in the latter. He heats the salts taken in molecular proportions, say, ammonium sulphate

or chloride with sodium or potassium nitrate, in three different ways:—

(a.) With three the weight of the mixed salts of 95 per cent. alcohol in a suitable vessel furnished with a reversed condenser, during 8 to 10 hours to (77° C.) the boiling point of the alcohol; then he separates the hot alcoholic solution containing the ammonium nitrate from the undissolved alkaline sulphate or chloride.

(b.) Ammonium sulphate, chloride, or carbonate are heated in an autoclave with similar proportions of sodium or potassium nitrate and of 95 per cent. alcohol during 4 to 5 hours to a temperature of from 120° to 140° C.

(c.) The same mixtures of salts are heated in the dry state to 140° to 160° C. for some time. With ammonium carbonate, closed vessels are used. The resulting mass is then treated with alcohol stronger or weaker, according to the purity of the salt required.

Where the reactions were carried out in the open, ammonia was given off and the materials became more or less acid, so as to act freely on ordinary metals. This does not apply to the ammonium carbonate experiments which were necessarily carried out in closed vessels.

The results show that in each case the ammonium nitrate contained about 10 per cent. of sodium nitrate. The reactions with potassium nitrate were very incomplete, only about 25 per cent. of the salts being converted.

Percentage of Sodium or Potassium Nitrates found in the Ammonium Nitrate Obtained after Completion of the Process.

Salts Treated in Molecular Proportions by Processes stated in Roth and Wahlenberg's Patents.	Percentage of Sodium or Potassium Nitrates found in the Ammonium Nitrate Obtained after Completion of the Process.		
	(a.) 95° Alcohol boiled Ten hours (77° C.).	(b.) Autoclave Heated to about 140° C. Five Hours.	(c.) Dry Salts Heated to 160° C. One Hour.
1. Ammonium sulphate and sodium nitrate.....	NaNO <sub>3</sub> % 11.35	NaNO <sub>3</sub> % { 11.04 } { 10.69 }	NaNO <sub>3</sub> % 10.30
2. " chloride " " .....	NaNO <sub>3</sub> % 11.15	NaNO <sub>3</sub> % 10.29	NaNO <sub>3</sub> % 11.45
3. " carbonate " " .....	KNO <sub>3</sub> % 10.29	KNO <sub>3</sub> % 8.44	..
4. " sulphate and potassium nitrate.....	KNO <sub>3</sub> % { 4.65 } { 4.00 }	..	..
5. " chloride " " .....	KNO <sub>3</sub> % { 4.90 } { 4.35 }	..	..
6. " sulphate and sodium nitrate.....	NaNO <sub>3</sub> % { 31.20 } { 33.80 } { 31.30 }	..	..

The experiments under 3, 4, and 5 were very incomplete at the end of the time stated, as the greater part of the salts were unaltered.

I also find that boiling alcohol of various strengths dissolves appreciable quantities of sodium nitrate, and that after the alcohol is saturated with ammonium nitrate, the amount of sodium nitrate then dissolved is so great as to render alcohol useless as a means of separating these salts.

Thus 100 c.c. of alcohol (measured at 15° C.) dissolve:—

	92 per Cent. (Sp. Gr. 0.817).	95 per Cent. (Sp. Gr. 0.809).	100 per Cent. (Sp. Gr. 0.794).*	Methyl Alcohol (95 per Cent.)
Sodium nitrate.....	Grms. 1.25	Grms. 0.56	Grms. 0.27	Grms. 3.86
Ammonium nitrate..	20.00	16.00	9.10	49.00
Sodium nitrate after ammonium nitrate	3.37	1.81	0.76	9.00

Calculating the sodium nitrate as a percentage on the mixed ammonium and sodium nitrates, we have—

	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Sodium nitrate.....	11.16	10.16	7.7	15.6

\* NOTE.—This alcohol was carefully rectified by treatment with sodium and distilling.

In some experiments with cold ethylic alcohol, I found that it dissolved from one-fifth to one-sixth of the above quantities, and that in each case sodium nitrate was dissolved along with the ammonium nitrate when both salts were present, as in the reaction of ammonium sulphate on sodium nitrate.

On testing the undissolved residues after removal of the alcoholic solution of ammonium nitrate, quantities of ammonium sulphate or the other ammonium salt used were found, equivalent to the unchanged sodium nitrate.

The reaction is therefore an incomplete one throughout the varied conditions of these experiments, and the same remark applies to the conditions as prescribed by Wahlenberg. Thus, the statements of Groendahl and Landin apply to each of the processes in which alcohol is used by Roth and Wahlenberg.

Groendahl and Landin state that if the ammonium sulphate be in excess of the molecular proportion, a less amount of sodium nitrate is found in the alcoholic solution with the ammonium nitrate.

To eliminate the sodium nitrate, they propose filtering the alcoholic solution through granulated ammonium sulphate. If the sodium nitrate be not eliminated by this treatment, then they recommend filtering through ammonium chloride.

The following experiments have been made on this proposed process.

With an excess of ammonium sulphate in the mixed salts, the following results were obtained.

Percentage of Sodium Nitrate found in the Ammonium Nitrate.

Molecular proportions of ammonium sulphate and sodium nitrate.	12.07
Same + 25 per cent. ammonium sulphate mixed and heated together before treatment.	10.69
Same + 50 per cent. ammonium sulphate.	10.39
Same + 100 per cent. ammonium sulphate.	10.26

Also the alcoholic solution of the impure ammonium nitrate was filtered through layers of ammonium sulphate.

Percentage of sodium nitrate found in the ammonium nitrate..... 8.52 and 9.5

It is therefore exceedingly difficult to purify the ammonium salt by treatment with excess of ammonium sulphate, either at the temperature of the boiling alcohol or at ordinary temperatures.

Incomplete reactions are generally reversible, so that in this case— $(\text{NH}_4)_2\text{SO}_4 + 2\text{NaNO}_3 = 2\text{NH}_4\text{NO}_3 + \text{Na}_2\text{SO}_4$ —one ought to obtain similar results, whether one starts with the substances on the left or right of the equation. I find that on heating pure ammonium nitrate and sodium sulphate in molecular proportions, and then extracting with alcohol, that the ammonium nitrate contains from 8 to 10 per cent. of sodium nitrate.

These experiments may be taken to prove that under the prescribed conditions ammonium nitrate containing under 1 per cent. of fixed impurity cannot be obtained by treatment with strong or even absolute alcohol of the mass resulting from the reaction of ammonium sulphate, chloride, or carbonate on sodium or potassium nitrates; with weaker alcohol the proportion of impurity is greatly increased.

I hope to give an account of the other processes proposed for this manufacture during the session.

#### DISCUSSION.

In reply to Mr. B. Watmough, Mr. Fairley stated that he had also experimented with absolute alcohol, but found that it acted similarly to that which he had used in the experiments described.

In reply to Mr. N. Farrant, who asked whether the loss of alcohol in separating sodium nitrate from ammonium nitrate is great, Mr. Fairley said he was unable from laboratory experiments to state exactly how much loss there might be on the large scale, but he thought that if it could be kept under 1 per cent. of the ammonium nitrate produced, the process could be made to pay.

DR. A. P. AITKEN IN THE CHAIR.

### EXPERIMENTS ON THE COMPOSITION OF TURNIPS AND THE EFFECTS OF MANURES THEREON, WITH A METHOD OF ANALYSIS.

BY JAMES HENDRICK, B.Sc., F.L.C.

THE cultivation of the turnip crop has long occupied a most important position in the agriculture of this country. To this crop it has been customary, under the most various systems of farming, to apply a very great part of all the manure which the farmer uses. One often finds, indeed, that all the manures, both the dung of the farm and the purchased or artificial manures, used in the rotation are applied to this crop, and the other crops get nothing but the residues left in the soil after the turnip break. More artificial manure is probably used in this country for the turnip crop alone than for all the others put together. The question of the manuring of this crop then is of great importance, not only in its purely agricultural aspects, but in its relations to the manure industry.

The profound changes, brought about by the great modern development of our commercial and industrial conditions, which our agriculture is at present undergoing, most seriously affect the position and manuring of the turnip crop. This is the most expensive and troublesome crop in our ordinary agricultural practice, and it may almost be said that it continues to occupy its present position more for its collateral advantages than for its intrinsic worth. With the improvements of knowledge and instruments, the old turnip culture must be gradually superseded by better and more economic methods. Already the manuring practice with regard to this crop, and, as a consequence, with regard to all the other crops of the rotation, is being greatly modified, and even the position and acreage of the crop is undergoing much alteration at the hands of many enterprising farmers.

As might be expected, this crop has always been a favourite one with agricultural investigators. The late Prof. Anderson published numerous papers on the composition of turnips (Trans. Highland and Agric. Soc. of Scotland, 1851 to 1868); Lawes and Gilbert investigated the same subject at Rothamsted (Rothamsted Memoirs); and the late Prof. Voelcker also published papers on this subject (J. Roy. Agric. Soc. of England, 1877). Though there are some foreign investigations on the same subject, foreign investigators have paid far more attention to the closely related subject of the composition of the sugar beet, which has been worked out by Geriaun and French workers with a thoroughness which nothing which has yet been done on the turnip can approach. In more recent times we have had investigations on the composition of turnips by Dr. Aitken (Trans. Highland Soc. of Scotland, 1884), and by Mr. Wilson, of Carbeth (Trans. Highland Soc. of Scotland, 1884 and 1886), and simultaneously with my own I find that Dr. Somerville and Mr. Smith, of Newcastle, have been carrying on investigations, which were published in the Journal of this Society, January, 1897. In the last four years, too, an enormous number of experiments have been done. The great majority of these are purely agricultural, and can hardly be said to have any real scientific value. When properly carried out these manorial trials are, no doubt, useful object lessons of considerable educational value, but it is absurd to talk of them, as is too often done, in high sounding phrase as research work comparable with that of foreign research stations. The difficulties surrounding the subject and the labour involved in any large investigations into the composition of root crops are so great that few agricultural chemists in this country have the means of doing any such thorough investigations, as have been carried out abroad, on the composition and improvement of the beet, for instance.

The experiments dealt with in this paper were carried out in the years 1894 and 1895. In 1894 the work was mainly

this dried material. Nitrogen was determined by the Kjeldahl method. Crude fibre is the insoluble matter which is left after extracting fresh pulp with water for the sugar determination, less the albuminoids and ash which it contains. Albuminoids were determined in the dried material by Church's phenol method. As repeated experiments, both with roots and with such other plant products as contain much non-albuminoid nitrogen, have convinced me of the unsatisfactory nature of this method; Stutzer's method was used in 1895 and found much more satisfactory.

Little importance can be attached to the crops per acre given in Table I., except as showing that whereas the unmanured plot gave practically no crop, the manured ones were capable of giving a very fair crop. Disease developed in certain parts of the plots late in the season, and certain plots, such as V., had their produce very seriously diminished from this cause.

All the turnips in this experiment gave an amount of dry matter above the average. The smallest turnips give the highest percentage of dry matter, and the largest the lowest percentage. This effect of size on composition is strikingly brought out by the difference between the large and small roots from IX. and XI. Not only do the small roots contain 3 per cent. more dry matter, but there is a higher percentage of each individual constituent determined. The dry matter, too, is, weight for weight, of better composition as a food. This is shown by Table II., which gives the composition of the dry matter.

TABLE II.

*Cleghorn Experiment. Composition of Dry Matter.*

Plot .....	I.	II.	IV.	V.
Sugar (as cane-sugar) ..	49.11	57.51	57.24	51.53
Crude fibre .....	23.98	25.67	25.55	28.58
Nitrogen, total .....	1.41	1.63	1.46	1.40
" albuminoid ..	1.02	0.76	0.92	0.90
Ash .....	8.55	7.14	6.25	7.50

Plots IX. and XI.

	Plots IX. and XI.		Plot XII.
	Large.	Small.	
Sugar (as cane-sugar) ..	58.24	50.68	58.12
Crude fibre .....	28.43	24.71	27.23
Nitrogen, total .....	0.92	1.43	2.03
" albuminoid ..	0.60	0.81	1.18
Ash .....	7.50	8.51	7.37

We must expect, then, that this difference in size will be felt all through the table, so that the differences in composition obtained in the other columns are not merely a result of the manuring, but of the average size as well.

This effect of size on composition is further illustrated in Table III., which gives the composition of two samples of "Achilles" turnips taken from analyses made at the same time, but in connection with some experiments on quite a different subject:—

TABLE III.

	A.	B.
Average weight .....	5 lb. 1 oz.	2 lb. 14 oz.
Moisture .....	92.770	91.340
Dry matter .....	7.230	8.660
Sugar (as cane-sugar) ..	3.930	4.620
Total nitrogen .....	0.192	0.148
Albuminoid nitrogen ..	0.108	0.076
Ash .....	0.560	0.640
Percentage of the total nitrogen which is non-albuminoid ..	43.750	48.650

In this case the amount of dry matter in both samples is considerably below the average. This may be due partly to the different variety of seed, and partly to differences in soil, climate, and manuring. These roots were liberally

manured. It is noticeable that both in Tables I. and III. the smaller roots have the larger percentage of their nitrogen non-albuminoid.

The nitrate of soda used in plots IV. and V. (Table I.) has not had a very decided effect on the composition. It is to be remembered, however, that the dressings used were very moderate. We can, however, distinctly trace to its influence the increased percentage of sugar, the larger amount of nitrogen which is non-albuminoid, and the lower percentage of ash in plots IV. and V. compared with II. and I.

The small and half-starved bulbs in XII. give an interesting analysis. They contain a fair amount of dry matter, and in the dry matter a large amount of sugar. So that sugar formation has not been at all checked. Their most noticeable feature is the amount of nitrogenous matter they contain. Their dry matter is the richest of all both in albuminoid and non-albuminoid nitrogen. In this connection it may be noted that though no analysis of the Cleghorn soil from these plots was made, analyses were made of similar soil from adjacent plots on which other experiments were being conducted. These analyses showed that the soil is not remarkably deficient in nitrogen, though also not rich in this element, but is very deficient in the important ash constituents, phosphoric acid and potash, in a form available to plants. The available ash constituents were determined by Dr. Bernard Dyer's method (J. Chem. Soc., Vol. LXV.), and only 0.0039 per cent. and 0.0054 per cent. respectively of available phosphoric acid were found in two samples.

Before proceeding to deal with the experiment of 1895, the methods of sampling and analysis made use of will be described. It gave me much trouble to devise a method for obtaining a perfectly fair sample of a plot of  $\frac{1}{2}$ th of an acre, without having to carry off an inconveniently large sample. I found that several different methods have been used by previous investigators, all of which are open to serious objection. At last the following method was adopted, which seemed to me as fair a one as could be devised. Each plot consisted of three drills each about 110 yds. long. Four points were taken at nearly equal distances along the outside drill of plot I. From these points parallel lines were drawn right across the whole series of plots. From each of these lines a yard was measured off at right angles along one drill in each plot. Two of these yards were measured on the central drill, and one on each of the side drills of each plot. Every turnip, large or small, on these four yards was raised and included in the sample, from that plot. It may be remarked that at Easterboard the crop was very even, and quite free from disease and lent itself readily to accurate sampling. There were two unmanured plots, I. and XIII. Of these, XIII. was a complete failure, hardly a single plant surviving till the time of raising. On I., curiously enough, almost as large a number of plants were alive at the end of the season as on any other plot. But so small and miserable were these plants, that they had hardly any resemblance to turnips, and from a little distance the plot looked nearly as bare as XIII. Each sample contained from 15 to 20 roots. On arrival at the laboratory each sample was washed, dried, and weighed. From this and the number of roots in the sample, the average weight of the roots from each plot was calculated. A segment through the centre, from top to bottom, was then taken from each root, in order to provide a sample for analysis. In all the plots except I. the segment was  $\frac{1}{2}$ th of the root. In the case of plot I. the whole root was taken.

The ordinary method is to cut these segments into thin slices, in order that they may dry readily. They are then hung up and dried at a gentle heat till they are hard enough to grind. The ground material is then completely dried, and the dry powder used for determinations of nitrogen, ash, fibre, &c. During this drying, the material becomes very dark in colour, especially if the temperature be raised too quickly, and a certain amount of decomposition of dry material undoubtedly takes place. This vitiates all the results obtained from this dry matter. For not only has the composition undergone some change, but all the calculations are based on the assumption that this is the

true dry material of the turnip. Sugar determinations are made in a separate sample, which is pulped or rasped down and then has its juice extracted.

This method is not only inaccurate but extremely tedious. Dr. Aitken, who has great experience of root analysis, says: "It might seem from this description, that the sampling and drying of the samples of a turnip crop was a comparatively easy matter, while in reality it is a complex and laborious operation, requiring several months for its accomplishment" (Trans. Highland Soc., Scotland, 1884, p. 360). This method was no doubt necessary when one had to determine nitrogen in dry material by the soda-lime method.

Some preliminary experiments convinced me that when using the Kjeldahl method for nitrogen determinations, all the necessary determinations could be made from the fresh turnip pulp. My samples were therefore pulped by putting them through a small sausage machine, which was found very convenient for the purpose. The pulp was at once thoroughly mixed, and the samples immediately weighed out into previously weighed dishes. If this is done quickly, with two operators working, the whole process can be gone through in a few minutes, and there is thus no danger of error from loss of moisture by evaporation, or from fermentation. I found a good physical balance which turned with three or four mgrms. best for the weighings. As one is weighing a pulp containing about 90 per cent. of moisture, the samples are correspondingly large, and weighings to two places of decimals with the pulp are as accurate as, or more accurate than, weighings to three places with the dry powder.

Five quantities of pulp were weighed out from each sample:—

(1.) For sugar determination, about 100 grms. This was weighed into a small, wide-mouthed bag of close strong linen hung over the mouth of a beaker.

(2.) For moisture and ash, about 30 grms., weighed into a flat dish.

(3.) For fibre, about 30 grms. weighed into a conical flask.

(4.) For total nitrogen, about 10 grms., weighed directly into a Kjeldahl cooking flask.

(5.) For albuminoid nitrogen, about 10 grms., weighed into a beaker.

(1.) *Sugar*.—The mouth of the bag is tied up tightly. The juice is then expressed by pressure. I found a strong potato-masher, such as is ordinarily used for domestic purposes, admirable for this purpose. By soaking the bag in successive small quantities of hot water, and squeezing again, it was found that the sugar could all be extracted by the use of less than a litre of water. The solution so obtained is clarified, inverted, made up to a litre, and the sugar estimated by any suitable process.

(2.) *Moisture*.—The pulp dried much more easily than I expected. If the heat is not raised above 100° little darkening need occur. The pulp dries to a somewhat porous mass, and any decomposition which takes place is very slight compared with what takes place in drying large samples by the old method, when the drying takes days, or even weeks. The dry mass burns easily in a muffle at a low red heat, to a nice light ash.

(3.) *Fibre* was determined directly in the pulp by the usual acid and alkali method.

(4.) *Total Nitrogen*.—The nitrogen determinations in the wet pulp gave no trouble. With 20 c.c. of the strongest sulphuric acid and a small drop of mercury the pulp always boiled quite clear in less than an hour. It was liable to froth a good deal at first, but a small shaving of paraffin at once checked that.

(5.) The albuminoid nitrogen was at once determined by Stutzer's method with copper hydrate.

Duplicate nitrogen determinations usually agreed within 0.005 per cent. on the pulp. The maximum difference was 0.024 per cent., but that was a quite exceptional case.

Directly after the crop was raised, the soil on the unmanured plot, I, was sampled. It is a medium light loam, containing a little gravel and coarse sand. About 86 per cent. passed a sieve having 30 meshes per linear inch. This fine matter was used for the analysis given below.

The "available" phosphoric acid and potash were estimated by Dr. Bernard Dyer's method.

#### *Analysis of Easterboard Soil.*

	Per Cent.
*Loss on ignition .....	11.390
Lime .....	0.403
Equal to calcium carbonate .....	0.720
Phosphoric acid .....	0.128
Potash .....	0.213
Silica and insoluble silicates .....	78.990
*Containing nitrogen .....	0.318
"Available" phosphoric acid .....	0.0096
" " potash .....	0.0058

This analysis shows, that though moderately supplied with phosphoric acid and potash in a form which can be extracted by strong hydrochloric acid, the amount of these constituents which is in so readily soluble a form as to be of any use to plants is very small. It also shows the soil to be fairly well supplied with organic matter, and its contained nitrogen.

The Easterboard experiment consisted of 13 plots, each of  $\frac{1}{16}$ th of an acre. Samples were analysed from eight of these plots to illustrate the following points:—(1.) The composition of starved plants from an unmanured plot. (2.) The effect of a moderate dressing of nitrate of soda on the composition of roots receiving only a phosphatic manure. If the soil itself had been somewhat poorer in nitrogen it might, perhaps, have illustrated this point better. (3.) The effects of a rich all-round dressing of artificial manures alone, of a rich dressing of farmyard manure alone, and of a rich dressing of a mixture of farmyard manure and artificial manures on the composition. Table IV. gives the manures applied, the crop per acre for all the plots, and the number of roots per acre on some of the plots.

In order to carry out my scheme, roots were analysed from plots I., II., III., V., VI., IX., X., and XII. It had been intended to count the number of bulbs on all these plots, but we were prevented from completing this plan.

In Table V. the details of the 1895 analyses are given.

It will be noticed that the average weights, given in Table V., of the roots analysed agrees fairly well with the average weights of the total roots on the plots given in Table IV. We might expect the weights in Table IV. to be slightly higher than those in Table V. The weights in Table IV. are calculated from weighings in which the crops weighed were in an agriculturally clean condition. The weights in Table V. are derived from weighings made in the laboratory, after the samples had been thoroughly washed. The results, however, are sufficient to show that my samples represented the average sizes of the roots on the different plots fairly closely.

In this experiment, as in 1894, the roots all show a high amount of dry matter. Swedish turnips, however, have on the average a higher percentage of dry matter than other varieties. König ("Chemie der Menschlichen Nahrungs- und Genussmittel," Band I.) gives, as the mean of a very large number of determinations made by a great many chemists of repute in several different countries, 87.80 per cent. of moisture and 12.20 per cent. of dry matter in Swedes.

The analysis of the starved roots from plot I. is, as might be anticipated, extraordinary. They contain a percentage of dry matter which is most exceptional. The late Prof. Voelcker records one case of Swedes giving even a slightly higher percentage, 17.78, of dry matter than this. It is evident that these roots did not remain starved for want of nitrogen. They contain a quite extraordinary proportion of nitrogenous matter, an unusually high percentage of which is non-albuminoid. This supports the view that in the case of an ordinary soil containing a moderate supply of nitrogenous matters, the turnip crop is perfectly capable of supplying itself with nitrogen without the aid of nitrogenous manure. This is supported by the remaining columns of the table. Thus it will be found that II. and III., which got no nitrogenous manure, are not deficient in that element as compared with the samples which got dressings of nitrogenous manure, some light and some

TABLE IV.

heavy. Indeed we find that whether we take the composition of the dry matter or of the raw material, II. and III. are markedly high in albuminoid nitrogen, while those plots which received heavy nitrogenous manuring are the lowest in albuminoid nitrogen.

Plot I. also gives a very much higher percentage of ash than any of the other plots. It had been determined to estimate phosphates and potash in each sample of ash, but, owing to an unfortunate accident some of my ash samples, including I., were destroyed before I had time to deal with them. The estimation of phosphate in the ash would have been perhaps the most interesting in the whole investigation. I turned therefore with much interest to the paper published in the January number of this Journal, in which phosphate determinations are given. Unfortunately, however, the conditions of the experiments there described, in which the soils experimented upon were in such high condition that unmanured plots gave very fair crops, were so different from mine that they cannot throw any light on the important question of the composition of the ash of plants starved for want of a sufficient supply of certain essential ash constituents. Plots II., III., V., and VI. show that while the addition of

a small dressing of nitrate of soda to a phosphatic manure does not materially increase the bulk of the crop on such a soil as this, it does distinctly improve its composition in certain points. Comparing V. with III., and VI. with II., the percentages both of dry matter and of sugar are increased. On the other hand, as in 1894, the percentage of nitrogen which is non-albuminoid is also increased.

Turning to IX., X., and XII. we find that all the roots are bigger, and give a somewhat lower percentage of dry matter. In no case, however, is the average root, what can be considered very large. Plot X., which received the heavy dressing of dung, gives roots of, in nearly every respect, the poorest composition. This plot gave the heaviest crop per acre, but XII. really gives a larger crop per acre, for it gives more dry matter, and dry matter of quite as good, if not a better, composition. The amount of nitrogen given per acre in the manure to plots X. and XII. is calculated on the assumption that a ton of dung contains 12 lb. of nitrogen. On this assumption, which is a fairly safe one, these plots, and especially XII., get heavy dressings of that most expensive manure constituent nitrogen, and give little return for it.

While it would be unwise to draw any hasty conclusions especially in matters of detail, a consideration of these experiments, in the light of the many others on the same subject which have preceded them, will indicate certain lines along which improvement must be sought if this most costly and troublesome crop is to remain an important feature of our agriculture. As in so many other parts of our agricultural industries we must look more to quality and less to mere quantity. Quality varies greatly with a variety of conditions, and by cultivation and rigid selection could be much improved. The turnip crop can and should have its quality improved by similar means to those by the use of which continental workers have so greatly raised the quality and value of the beet. Next we must try to find the means of greater economy in the use of manures, and especially of the most expensive manure constituent, nitrogen. It is now generally accepted that it is not economical to lavish all our manures on the turnip crop. A small quantity of nitrate of soda is useful in pushing the plant through a risky period in its life history, and improves the quality. Large quantities of nitrogen, such as are applied in heavy dressings of farmyard manure, are expensive and wasteful. A small quantity of dung along with a moderate quantity of a phosphate manure, and, perhaps, a small quantity of nitrate of soda is more economical, and, generally speaking, gives as great a quantity of food of better quality.

#### DISCUSSION.

The CHAIRMAN presumed that the intention of the experiments was to provide agriculturists with information regarding the efficacy of manures, such as might be translated into general practice. In that case he regarded it as of prime importance that the effects of the manuring should be determined only upon such plants as a farmer would desire to grow, and under ordinary conditions of farming. The composition of turnips grown upon an exceedingly poor soil, without any manure, and weighing, say, 15 ounces each on an average, did not, in his opinion, convey information of any value; for the plants, under such severe conditions, never attained to the condition of a normal turnip. That was, of course, an extreme case; but also, in some of the manured plots, the kind of turnips grown was so much inferior to what a farmer would wish to grow that their composition conveyed little information of practical value to the farmer. If it were desired to obtain information of scientific rather than of practical interest, the end could be attained in the open field only after prolonged investigation, whereby the many disturbing influences to which crops exposed to the weather were liable had been, as far as possible, eliminated; and the samples taken of such crops must be very large in order to be reliable.

The area under experiment in this investigation was  $\frac{1}{10}$  acre for each plot, which might seem a small one, but it was double what was commonly chosen for turnip experiments, and was ample if land could be got of uniform quality. That was a difficult thing to get, and Mr. Hendrick was fortunate in getting it in this case. The Chairman could not say that he approved of the kind of plots selected, *viz.*, a three-drill plot of great length, of which only a small cross-section was taken to provide turnips representative of the bulk. When turnips were well grown they sent out their roots laterally and invaded the neighbouring drills, so that in such field experiments as he had conducted, he had always reaped the outermost drills of the plots, knowing that they had, in most cases, borrowed from the neighbouring drills. Such borrowing was especially apt to influence prejudicially the results of the experiment if the plots had not been separated by intervening unmanured drills.

Mr. Hendrick had endeavoured to overcome what he termed the personal equation in sampling, by selecting a straight section running across his three-drill plots, and using as his sample the total number of turnips included in the section. The Chairman was of opinion that that method was liable to greater inaccuracy than could be introduced by the ordinary method of selecting a sufficient number of turnips from each plot, such as was deemed fairly representative of the average growth. Large turnips that had accidentally received an unintended amount of manure, and small mis-thriven plants that might have received some

injury, were in that way rejected and not allowed to disturb the sample, which should be made up of such turnips only as a farmer would regard as normal.

So far as ascertaining the quantity of the crop per acre was concerned, the only safe way was to weigh all the crop, or at least the half of the crop contained in each plot. On the other hand, as regards the quality of the crop, he believed it was safer to trust to a sufficient number of carefully selected average specimens.

As regards the method of analysis, anything which would simplify and shorten the work would be welcome. The labour and time absorbed in drying the samples constituted a chief objection to the usual method, and if Mr. Hendrick could show by comparative experiments that the pulping method was equally reliable it would be a valuable result; but in order to show that it was a more accurate method, it would be necessary to prove that in drying sliced samples in the ordinary way there was a loss by decomposition.

In his own experience the Chairman had found that he could not accurately determine the amount of moisture in pulped samples on account of the difficulty of getting the proper proportion of sap and solids, but his samples were taken from the pulp made with the farm pulping machine, and not with the little sausage machine which Mr. Hendrick had found so suitable. He quite agreed with Mr. Hendrick in preferring the Stutzer method of separating albuminoids to the carbolic acid method, and the Kjeldahl method of estimating total nitrogen to the soda lime one, as they were easier and more convenient, though not more accurate.

There was a point which he might take note of, in which he differed from Mr. Hendrick, *viz.*, in regard to Eastch experiments, where from the presence of a large percentage of nitrogen in the very small turnips grown, he inferred that there must have been plenty of nitrogen in the soil. He did not think they were entitled from the growth of such plants to draw that inference. It would even be somewhat risky to draw such an inference from plants that had grown to normal proportions. He might not, however, have quite apprehended what Mr. Hendrick had said on that subject. He would be glad to hear Mr. Hendrick on the few points he had referred to, and had pleasure in expressing his gratification at the kind of research which the author had described to them. Such researches were very much wanted, and it would be advantageous to have them carried on at the various agricultural schools in the country.

Mr. HENDRICK, in reply, said that no doubt the Chairman would find some of his criticisms fully answered when he had time to look into the paper more carefully. No claim was made that this described work was exhaustive; in fact, it was distinctly pointed out in the paper that this was but a slight contribution to a large subject. One was accustomed to hear the so-called practical man questioning the object and use of scientific work, but it was a little surprising to hear the Chairman taking up such a position.

With regard to his method of sampling, the speaker said that one of the best points about it was that it brought out clearly what false ideas as to average size those who sampled by mere individual selection were apt to entertain. The Chairman, who had great experience on this subject, considered that the bulbs chosen were very small; that they were not such as a farmer would wish to grow. If he examined the tables he would find that the crops per acre were not, as he suggested, ridiculously small, but were good agricultural crops; nor were the numbers of bulbs per acre abnormal. The average size per acre found from these figures agreed fairly with the average size of the samples. Further, it was found that, on attempting to sample by the Chairman's own method, the samples taken were much over the average size, whether the samples were chosen by the speaker himself or by a practical farmer. The eye was attracted by the larger roots, which were picked out, and the large number of smaller ones around them were hardly noticed. It might be remarked that practical men considered the crops on plots IX. to XII. average well-grown crops for the district.

Mr. Hendrick said that he fully appreciated the difficulty as to the shape of his plots, but he had to take what he could get—not what he would like. Unfortunately he was

not in the happy position of having an experiment station and adequate means at his disposal, but had to trust to what he could persuade an intelligent farmer to give him. It was intended to take the sample for each plot entirely from the centre-drill of that plot, but when it was seen that the end-drills of the manured plots, both of which lay next to heavily manured plots, still gave no crop, though in one case all the plants were alive, it was decided to sample in the method already indicated. The manures were, of course, applied with every possible precaution to prevent overlapping. With reference to comparative experiments, he (Mr. Hendrick) did not think it necessary to burden his paper with the details of these. He had made sufficient to convince himself of the superiority and greater ease of working of his method. He might say, however, that he did not find a great deal of difference between the amount of dry matter found by the two methods. The moisture lost on the knife, hands, or in cutting up the turnips might be expected to counterbalance the loss due to decomposition. Two errors here neutralised one another. But in the case of the old method the subsequent determinations of nitrogen, ash, and fibre depended on this questionable determination of dry matter, while in his method they were absolute. He (Mr. Hendrick) could not conceive on what grounds Dr. Aitken described the Stutzer method as an easier, though not more accurate, method than Church's phenol method. He had given up the phenol method, though he found it rather easier to work, because he had become convinced that it was less accurate.

## ALUMINIUM BINARY COMPOUNDS AND THEIR REDUCTION AS CONSIDERED FROM CHEMICAL AND ELECTRICAL STANDPOINTS, INCLUDING A SYNOPSIS OF THE METALLURGY OF SODIUM.

BY HENRY S. BLACKMORE.

UNDER the head of aluminium we will consider at the present time only those aluminium binary compounds which are or have been of commercial importance in relation to reduction to metallic state, namely, the oxides, fluorides, chlorides, and sulphides; considering first those found in nature (oxides and fluorides) and, secondly, those only produced artificially by chemical reaction (chlorides and sulphides), it being our object to give a synopsis of the most important processes hitherto devised for producing and reducing these compounds, citing, so far as known, the difficulties met with and means devised for obviating them.

We will consider first the oxides, they being the practical basis for artificial or chemical production of all the other compounds. As the characteristics of the minerals containing aluminium oxide, such as corundum, clays, bauxite, &c., are all well known to chemists, we will only refer to the processes devised for commercial production or separation of the aluminium oxide from the minerals containing aluminium.

The production or separation of aluminium oxide may be classed under two heads—that of combining the aluminium oxide with alkali, to produce aluminates and final decomposition of the same while in solution precipitating aluminium hydroxide, and that of combining the aluminium oxide with acid to produce salts to be finally dissociated, such as sulphates. The various processes for producing aluminium sulphate from clay, or aluminium silicate by action of sulphuric acid, and by burning with iron pyrites, &c., and separation by lixiviation, filtration, or decantation, and final precipitation of iron by ferrocyanides, aluminium hydroxides, &c., are well known, so we will merely cite under this head the process for producing oxide from said sulphate. When aluminium sulphate is heated to bright redness it is dissociated spontaneously into aluminium oxide and sulphuric anhydride, the latter of which volatilises; it is found, however, that the dissociation is not perfect, inasmuch as much of the sulphuric anhydride is simultaneously dissociated into free oxygen and sulphur dioxide; and here is where the fatal point is reached relative to the economical production in this way; for, whereas if the sulphuric anhydride eliminated were not itself dissociated it might be absorbed by water to reproduce sulphuric acid for further use. The said dissociation into free oxygen and sulphur dioxide precludes this to a large degree, and in a practical way not more than 25 to 30 per cent. of the theoretical amount of sulphuric acid can be thus obtained, the balance of the sulphur being lost in gaseous by-products, which can only be recovered by the expensive process of oxidation.

Some years ago I turned my attention to this process with reference to devising a means of preventing the dissociation of sulphuric anhydride into free oxygen and sulphur dioxide, and finally succeeded in eliminating the sulphuric radical from the sulphate and recovering the same with very little loss. This I accomplished by heating the sulphate in retorts to a point below dissociation—that is about 175° F.; then I introduced superheated steam in a highly heated state. The sulphuric radical was immediately absorbed by the steam, producing sulphuric acid which distilled leaving behind aluminium oxide, while the occluded heat conveyed into the retort by the steam was utilised to further the reaction directly within the porous mass in a perfect manner. Whereas without the steam at higher temperature, the sulphate would be dissociated at points first in juxtaposition to the retort, producing a layer of aluminium oxide, which, being a non-conductor of heat, would necessitate a higher temperature for further action, and thus produce gaseous by-products of comparatively little value.

It might be interesting to state how I obtained this sulphate. Starting with bauxite, which is a double oxide of iron and aluminium contaminated more or less with silica, I placed it in a reverberatory furnace and heated it to low redness, in order to drive out all moisture and make it porous. I then closed the furnace and passed superheated steam through the coal with which the furnace was heated, thus producing water-gas, carbonic oxide, and hydrogen, which was then passed through the porous mass by means of properly regulated flues and dampers. The bauxite was thereby transformed so that the iron present was practically reduced to a condition insoluble in sulphuric acid. When the mass had been treated with gas for about an hour it was removed and cooled in closed containers, to prevent further oxidation. It is then mixed with sulphuric acid, lixiviated, filtered to remove iron oxide and silica, boiled down, and cast into blocks for recovering the sulphuric acid by action of superheated steam, as before described.

The Webster process employed by the Aluminium Company, Limited, of Oldbury, England, consists in heating potash alum with pitch, and treating the product with hydrochloric acid so long as sulph-hydric acid gas is evolved. The mass is then broken up, placed in retorts, and subjected in a heated state to the action of steam and air, which burns out the excess of carbon; and there remains a mixture of alumina and potassium sulphate. The latter is separated by lixiviation and filtration, and the evaporated solution is used over again, the alumina oxide retained by the filter being removed and dried.

The alkali aluminates are produced generally from bauxite by heating with alkali salt, such as sodium carbonate or sulphide, &c., or by heating cryolite (aluminium-sodium fluoride) with calcium carbonate. In treatment of bauxite the sodium or alkali aluminate produced is separated by lixiviation and filtration, leaving behind iron oxide. In this way, however, it is likely to be contaminated with alkali silicate, and thus the alumina finally precipitated from solution by action of carbonic anhydride contains silica.

Tilghman (British Patent 1847) introduces steam, carrying vapour of sodium chloride, into a mass of heated bauxite, thereby eliminating hydrochloric acid fumes and producing sodium aluminate. He also introduces steam, carrying sodium chloride, into heated aluminium sulphate, producing aluminate. Dr. K. J. Bayer in 1859 devised a process for precipitating aluminium oxide in the form of hydroxide from a solution of sodium aluminate by adding aluminium hydroxide to the solution and cooling, which precipitates and carries down a large part of the aluminium oxide previously combined in the aluminate in pulverent form. Sodium aluminate has also been and is now produced from cryolite (aluminium-sodium fluoride) by heating with calcium carbonate, lixiviating, and filtering, producing at the same time calcium fluoride. Another process has also been devised which consists in mixing aluminium sulphate with alkali sulphide and heating, which produces an alkali aluminate, eliminating sulphur dioxide, which is oxidised to produce sulphuric acid for further production of sulphate.

Having now referred to the most important methods devised for producing aluminium oxide, let us look for a moment at the processes devised for its reduction to the metallic state. Mr. H. Warren claims to have reduced aluminium oxide by action of hydrogen gas at high temperatures, concentrating all the heat in one spot of the tube in which the reaction took place.

I have made many experiments on reducing aluminium oxide by means of gaseous agents, thinking that perhaps a temperature might be found at which hydrogen would reduce aluminium oxide, on the same principle of variation of affinity of oxygen for iron at different temperatures, decomposing steam at a white heat, producing iron oxide and free hydrogen, and again giving up oxygen at a low red heat in the presence of hydrogen, producing so-called "iron by hydrogen." I did not, however, find any reaction whatsoever with dry aluminium oxide. I then tried dissolving the oxide in a molten bath of cryolite and passing hydrogen gas through it, thinking that by separating the molecules in solution they would be in better condition for reduction. Under ordinary atmospheric pressure I obtained no results, but upon subjecting to super-atmospheric pressure I obtained a reaction, and steam escaped from the safety valve. Upon finally opening the container, however, I found no aluminium, but instead a lower fluoride or sub-fluoride of aluminium, which only required about one-half the amount of sodium to reduce that the normal fluoride does. Upon trying the oxide under similar conditions with other fluxes I obtained no results, which led me to believe that the affinity of fluorine in the fluoride assisted to a large degree in the first case. Upon treatment with acetylene instead of hydrogen with other fluxes, I obtained aluminium in a fine state of division, and also a sub-oxide of aluminium of blue colour, which decomposed water with elimination of hydrogen gas and production of white aluminium hydroxide, the blue colour entirely disappearing. This is evidently the base of ultramarine, for if this blue oxide is melted with sodium silicate and sulphur, a permanent compound is produced, not decomposable by water. Dr. Joseph W. Richards has informed me that he has tried to reduce aluminium oxide dissolved in molten cryolite bath by means of natural gas, consisting principally of marsh gas, and also with other hydrocarbons under ordinary atmospheric pressure without result. There have been processes devised by which aluminium oxide is mixed with an oxide of another metal, such as iron, and reduced by carbon at high temperature, the object being to reduce the aluminium oxide by nascent iron or other metal-producing alloys of aluminium, the carbon removing and reducing the metallic oxide produced by said reduction; but they have proved to

be of no practical commercial value, as they could not be depended on. This is about all the data of importance we have relative to the chemical reduction of the oxide, and we will now look at it from an electrical point of view.

We will refer first to the Cowles electric process, which consists principally in using a furnace, wherein high temperatures are obtained by electrical resistance. At the temperature attained by this furnace, aluminium oxide can be readily reduced by carbon, but has to be retained by some other metal, such as copper, as the aluminium volatilises at the intense temperature produced if no other metal more stable under those conditions be not present; only alloys are, therefore, practically produced in this way.

Next is the Heroult process, which consists in fusing aluminium oxide, on top of copper or other metal, by electrical heat and decomposing by electrolysis, the aluminium being absorbed by the copper which is the cathode, while the oxygen combines with the carbon anode suspended in the molten oxide. For pure aluminium the cathode consists of molten aluminium.

Then we have the Hall process, in which the oxide is dissolved in a molten bath of cryolite or other fluorides and thus electrolysed, the aluminium accumulating at the bottom while the anode is consumed by the oxygen of the oxide. This is the process employed by the Pittsburg Reduction Co. at Niagara Falls, and Mr. Hall and his associates deserve great praise for the perfection to which this process has attained. It is stated in Prof. Richards' work on aluminium that Mr. Hunt has stated that with improved facilities at Niagara they will be able to reduce the cost of production by this process to 21 cts. per pound—the lowest limit.

Finally, we have the process of Gooch and Waldo, which consists in introducing into a molten bath compounds of aluminium, which are transformed by heat or steam into oxides in the bath during electrolytic action.

#### *Synopsis of Processes for Producing Sodium.*

In 1807 Sir Humphry Davy discovered this metal by electrolysis of caustic soda ( $\text{NaOH}$ ); shortly after this Guy Lussac and Thénard decomposed sodium carbonate with iron turnings at white heat. In 1808 Curadani is said to have produced sodium by substituting animal charcoal for iron turnings; next Brunner replaced animal charcoal by black flux, produced by calcining argols, placing the mixture in an iron mercury flask connected with a condenser. On heating the mixture to whiteness vapour of sodium with gaseous by-products were eliminated and sodium condensed; only 3 per cent. of the mixture was obtained as sodium. It was found that sodium carbonate fused during process of reduction, and when carbon was employed as reducing agent it floated upon the surface, so that reduction only took place at point of junction. To obviate this Deville mixed it with chalk to make it less fusible. Castner overcame this difficulty by weighting carbon, so as to keep the carbon below the surface of the molten bath; this was done by coating particles of iron with carbon by heating with tar or pitch.

The great trouble experienced in processes where carbon is employed as a reducing agent with sodium hydroxide is that the carbon oxides, eliminated during reduction, combine with a large part of the caustic soda, producing sodium carbonate, which has to be reconverted into caustic, or the apparatus will be quickly destroyed by the high temperature required to reduce the carbonate.

In 1886 I invented a process for reducing sodium from caustic soda by action of nascent iron, producing the caustic soda from carbonate directly in the mixture. Later I reduced molten caustic soda by means of iron by hydrogen, or a finely-divided iron heated to redness, and gradually introduced it into the molten soda, at which time a reaction took place, sodium vapour and hydrogen being eliminated and iron oxide produced, which settled to the bottom, and was withdrawn from time to time. The soda dissolved out and evaporated, and iron oxide dried, the soda being used over and the iron reduced by hydrogen again, a portion of the hydrogen being recovered after condensing the sodium for this purpose, the process being practically continuous without formation of carbonate or other salt of soda, which was detrimental to the process, and admitting of almost

entire reduction of caustic soda. I also introduced iron in a finely-divided molten state with good results.

Dr. Curt Netto heats carbon and introduces caustic soda in molten state, so that it drops on the heated carbon, sodium and gases passing into condensers, and carbonate produced being automatically withdrawn from lower part of retort and reconverted.

The Cunningham process consisted in introducing into molten caustic soda at or near the bottom of the reducing retort finely-divided carbon in a heated state, which passed up through the mass, decomposing it.

The principal electrolytic processes devised are those of Ludwig Grabau and H. Y. Castner. Grabau electrolyses molten sodium chloride, chlorine being eliminated at the anode, and sodium at the cathode, which is allowed to distill. Castner electrolyses molten caustic soda at a low temperature, skimming the sodium off the surface of the bath. It is stated that sodium can be produced by this process for 15 cents per pound. Prof. Rogers, of Milwaukee, suggests producing alloys of sodium and lead by using molten lead for cathode and finally distilling off the sodium.

Great difficulty is experienced in employment of alkali chlorides on account of their extreme volatility at the temperature employed, as they distill off with the sodium and contaminate it. The disintegration of electrodes and corrosive action on apparatus is also a bad feature, as well as the cost of electricity required to perform reduction. In the employment of caustic alkali, as in Castner's process, considerable alkali carbonate must necessarily be produced by action of the carbon anode.

#### *Aluminium Fluoride.*

Aluminium fluoride is found in nature combined with sodium in the form of cryolite. This compound has been produced artificially by mixing solutions of aluminium sulphate and sodium fluoride, when artificial cryolite precipitates in gelatinous form, which is separated by filtration or decantation and dried. When this cryolite is reduced by metallic sodium, producing aluminium, the sodium fluoride is dissolved and used over to produce more cryolite. Aluminium sulphate has also been introduced directly into molten alkali fluoride, the alkali sulphate produced being dissolved out. This process for producing aluminium fluoride was invented by Ludwig Grabau, of Hanover, whose process for reduction will be cited hereafter.

#### *Aluminium Chloride.*

Aluminium chloride is generally produced by mixing aluminium oxide with fine carbon, working up into a dough with oil, pressing into porous bricks, which are then dried and placed in retorts. When heated to redness, dry chlorine gas is introduced and passed through the mass. This, in the presence of carbon which absorbs the oxygen from the aluminium oxide, combines with the aluminium, producing aluminium chloride which sublimes. Sodium chloride is often mixed with the carbon and alumina, in order to produce a double chloride, which is more permanent in air and much more easily handled. Aluminium chloride can be produced by passing carbon bisulphide and hydrochloric acid gas alternately over heated aluminium oxide. Camille A. Faure, of storage battery fame, invented a process in 1888, which consists in heating aluminium oxide to redness and passing vapour of petroleum carrying chlorine over and through it.

#### *Reduction of Chlorides and Fluorides.*

We will consider the reduction of these two compounds under one head, as the processes of reduction are analogous to a large extent. There have been processes devised whereby aluminium chloride was reduced by heating it, and passing metallic sodium vapour over it, and *vice versa*, heating sodium and passing vapour of aluminium chloride over it (Deville), also by bringing the two vapours together in a heated chamber precipitating aluminium in small globules (Frismuth), also by melting double fluoride of aluminium and sodium (cryolite), and forcing an ingot of solid metallic sodium down into it (Netto), and heating practically infusible aluminium fluoride *per se* and pouring

upon it molten sodium (Grabau). But in all these processes great trouble is experienced by reason of the violent reaction which takes place while reducing the aluminium and distributes it throughout the flux in such a manner that it is almost impossible to collect it into a mass, on account of its lightness. In view of this fact, in 1889 I devised a process to overcome this violent reaction or agitation of the molten bath. I employed a carbon-lined retort in a vertical position, at the bottom of which was molten aluminium, and floating upon it the flux, carrying aluminium fluoride or chloride to be reduced. Below the surface of the molten aluminium at the bottom of the retort, I introduced molten sodium, by gravity from a reservoir placed at a high point, by means of a pipe connection. Upon the gradual introduction of sodium in contact with the aluminium it alloyed with it, passing up to the surface of the free aluminium in juxtaposition to the flux carrying the compound to be reduced, reducing the aluminium therefrom in contact with the surface of the molten mass of aluminium, with which it immediately combined without agitation, the reduced metal as it was gradually growing up from the bottom.

The processes for electrolytic reduction have, with a few exceptions, been based upon the dissociation of molten aluminium chlorides or fluorides in the presence of an anode consisting of bauxite or aluminium oxide mixed with carbon, the object being that as the chlorine or fluorine is liberated at the anode during action, aluminium chloride or fluoride will be regenerated by action of said elements upon the alumina and carbon anode, the product being absorbed by the bath to be afterwards decomposed by electrolysis depositing aluminium at the cathode, the difference between the processes being merely a little change in apparatus employed to bring about the result. Grabau suggests the presence of some alkali salt in the bath, to absorb the chlorine or fluorine liberated during electrolysis, and Faure suggests electrolysis of aluminium chloride and utilising the chlorine liberated to produce bleaching powder.

#### *Aluminium Sulphide.*

Aluminium sulphide I consider as the most important compound of aluminium relative to economical reduction, as the affinity of sulphur for aluminium is comparatively slight, while the electro-negative constituent sulphur is comparatively inexpensive.

Petitjean (British Patent of 1857) describes a process for producing aluminium sulphide, which consists in heating aluminium oxide to redness and passing vapour of carbon bisulphide over it, whereby the carbon seized the oxygen of the alumina, and the sulphur combined with aluminium, producing aluminium sulphide. By this process only about one-third of the oxide was converted into sulphide, the reason being that aluminium sulphide, which is partially fusible, coated the particles of infusible oxide and prevented further action. Aluminium sulphide has been successfully produced as aforesaid by Freymy, Reichel, Comenge, Prof. Joseph W. Richards, of Lehigh University, and many times by myself.

Aluminium sulphide produced in this manner was, however, of no practical commercial value, for the reason that the waste of aluminium oxide was enormous, being about 66 per cent., while the mass was practically infusible at ordinary temperatures, and not in condition for practical reduction. When the sulphide thus produced was subjected to action of reducing agents, the aluminium was reduced in small globules throughout the infusible mass in such a manner that it was impossible to combine it into a button.

Aluminium oxide has been heated with sulphur, a mixture of sulphur and carbon, and sulphydric acid gas without producing aluminium sulphide. The reason for the reaction of carbon bisulphide, and not the elements carbon and sulphur *per se*, is that in the formation of carbon bisulphide a great amount of heat is absorbed, which is given out upon reaction with aluminium oxide, thus bringing the reaction within bounds of reasonable temperatures.

Comenge, of Paris, suggests preparing aluminium sulphide by placing aluminium oxide at one end of a clay

retort and charcoal at the other, then heating and passing in sulphur vapour through the charcoal, the product being conveyed over the aluminium oxide at the opposite end.

The process of Petitjean has also been assisted by mixing the aluminium oxide with carbon, as for producing chloride, and then passing carbon bisulphide vapour over it. Free sulphur vapour will not convert this mixture into aluminium sulphide, as chlorine does into chloride.

Realising the importance of the practical production of aluminium sulphide, I took up the matter some time ago, and have devised the following processes. In order to avoid the difficulties experienced in Petitjean's process in reference to coating of particles of alumina with fusible sulphide, I employed a molten bath of sulphides and fluorides of sodium and potassium, the mixture of sodium and potassium salts melting at a lower temperature than either of the others independently. I then introduced into the molten mass aluminium oxide, which dissolved therein; then I passed vapour of carbon bisulphide through the mass, converting the whole of the aluminium oxide into sulphide. As there were no particles to coat with sulphide to retard the reaction, the sulphide thus produced was in solution in the molten bath, and in better condition for reduction than aluminium sulphide *per se*. I also suspended aluminium oxide in a molten bath, in which it was not soluble, such as chlorides of potassium and sodium, and subjected it to the action of carbon bisulphide vapour, whereby the insoluble particles of alumina were superficially coated with aluminium sulphide, which, being soluble in the molten bath, was dissolved off, exposing new surfaces to action. I also combined aluminium oxide with alkalis, producing aluminates, which I fused and subjected to the action of carbon bisulphide vapour, converting the whole into a double sulphide of aluminium and alkali.

In carrying out these perfected processes it became evident that their commercial importance depended largely on the cheap production of carbon bisulphide, so I turned my attention to the production of that compound. I found that the principal expense in producing carbon bisulphide was occasioned by destruction of retorts, which being composed of iron were rapidly destroyed by the sulphur vapour. I then experimented with a view to employment of fireclay retorts, but found their porosity a great disadvantage, as the carbon bisulphide produced would pass through the pores, converting the aluminium oxide, silica, and other ingredients into corrosive sulphides of disintegrating nature. In order to overcome this I prepared my retorts in the following manner, taking for the basis of my operation the absorbing properties of porous matter for lead oxide, suggested by the cupelling process. I then coated the inside of the clay retorts with lead oxide, and heated to whiteness. The lead oxide was absorbed, filling the pores of the retort. I then coated again with a mixture of lead oxide, powdered feldspar, and quartz, burning as before, and finally coating with lead oxide mixed with sodium silicate, and burning in again in presence of vapour of carbon bisulphide, which converted the superficial coating of lead oxide into sulphide, thus practically preventing further corrosive action; and, after several continued weeks of test, am satisfied that the retorts will, with occasional coating of lead oxide, last for years without replacement, thereby materially cheapening the process of production.

#### *Reduction of Aluminium Sulphide.*

Comenge reduced aluminium sulphide by means of iron and copper filings. Reichel claims, also, to have reduced aluminium in this way. F. Lauterborn states the reduction with iron is brought about at red heat. Prof. Joseph W. Richards, in his standard work on aluminium, states that Dr. J. D. Lisle, of Springfield, Ohio, has reduced aluminium sulphide with zinc. Prof. Richards also states that he has himself reduced aluminium sulphide with tin and iron filings. This reduction was performed with sulphide produced by the Petitjean process, and contained only about 33 per cent. of aluminium sulphide, the balance being unconverted alumina, which rendered the sulphide hard to reach with reducing agents.

By employing the solution of aluminium sulphide in molten fluxes, as produced by my process, I have been able

to reduce practically all the sulphide by action of iron. This iron I employ in a highly heated molten condition, thereby introducing considerable heat directly in the mass, and is introduced into the molten bath containing the aluminium sulphide in small shot formation, produced by passing the molten iron through a fireclay sieve. The retort being about 10 ft. deep, allows all the iron to become sulphurised before reaching the bottom, thus liberating aluminium. The iron sulphide produced accumulates in a molten condition at the bottom of the retort, from whence it is first withdrawn, then the aluminium, and finally the flux, which is employed to dissolve more aluminium oxide, to be converted as before into sulphide by action of carbon bisulphide vapour.

The reduction of aluminium sulphide by electrolysis is performed with less expense than any other aluminium compound, it only consuming one-half the electric energy required for electrolysis of the oxide. The processes devised and in operation at the present time are those of Bucherer, who produces his sulphide by mixing aluminium oxide with an alkali polysulphide and carbon, heating it to a high temperature and then subjecting to electrolysis. This process for producing aluminium sulphide was evidently invented by Petitjean, and a subject of his British Patent of 1857. Next we have the Jaenigen process (German Patent of 1895), which consists in introducing a powdered mixture of aluminium oxide and sodium carbonate into a heated chamber containing an atmosphere of carbon bisulphide vapour. As this mixture is gradually sifted into this atmosphere of carbon bisulphide at intervals, it is claimed to be transformed into a double sulphide of aluminium and sodium before reaching the bottom, at which point is situated a crucible or melting pot, in which the material accumulates and is fused by heat of an electric arc and finally electrolysed, aluminium separating at the cathode and sulphur at the carbon anode. The sulphur combines with the carbon of the anode, producing carbon bisulphide, which is distilled and used over.

The Aluminium Industrie Actien-Gesellschaft, of Neuenhausen, also patent in Germany, under the same date, a process, in which they reduce aluminium sulphide at a temperature below that required to produce carbon bisulphide at the anode, and free sulphur distills which is used over again.

#### DISCUSSION.

Prof. CHANDLER asked whether the process which had been described had gone beyond the experimental stage, and was in present operation.

Mr. BLACKMORE said it would be in about one week. The furnaces were all completed. It had been done on a small scale, and proved that it could be carried out on a large scale. The making of the sulphide of aluminium was carried on to quite a large extent—probably about a ton and a half to two tons of material in the retort.

Prof. CHANDLER presumed that the supposition was that this would be a more economical process than those processes which were now employed.

Mr. BLACKMORE said it would be, because from the sulphide of iron produced they could recover the sulphur; but it would be, even if they threw away sulphide of iron. It would not cost over 6 cents a pound to produce aluminium sulphide.

Prof. CHANDLER said he had witnessed the Castner process of making sodium at Birmingham, and without going into details as to cost, it was certain that the process was a successful chemical operation. The works were in full operation. There were long rows of iron pots containing the melted sodium hydroxide, the melting being done by the resistance to the current. About three times an hour workmen came with a kettle and ladle, opened the lid of the sodium pot, and ladled out metallic sodium. The yield of those works at the time he visited them was a ton of sodium a day, which was sold for about 200*l*. This process had been introduced in two or three places in Germany, and works were now being erected at Niagara Falls to put it into practice there.

What it cost to make the sodium, Mr. Castner was not willing to tell, nor was much sodium being sold, as Mr. Castner had devices to use it, and was really his own customer for it. A considerable portion was converted into peroxide of sodium, and sold in that form. At the present time a considerable portion was employed for the manufacture of cyanide of sodium and potassium, for gold extraction. The advantage of making cyanide of sodium and potassium in this way arose from the fact that when the yellow prussiate of potassium was heated with sodium, neither oxygen nor alkaline carbonates were introduced, and the product was an almost chemically pure mixture of cyanide of sodium and cyanide of potassium, and which actually tested, on the cyanide of potassium basis, over 100 per cent.

He had also witnessed the aluminium process as conducted at Niagara Falls, and formerly conducted at Kensington, near Pittsburg, and that, too, seemed to be as simple and beautiful an electro-chemical process as could possibly be carried out. There were iron vessels there some 6 ft. by 8 ft. broad and 2 ft. deep, lined with carbon. These vessels constituted the cathode. There were some 30 anodes of very compact carbon hanging from copper rods, in three rows of about 10, about three inches in diameter. The cryolite bath had previously been used in another pot, and the impurities electrolysed out, so that the cryolite that was actually employed as the bath for forming the aluminium contained no silicon and no metal which would contaminate the aluminium. The pure alumina was fed into this pure cryolite bath, and the electrolysis proceeded regularly. Whenever there was a short supply of alumina, the resistance of the bath increased, and an indicator showed at once that the alumina had been consumed, and workmen simply shovelled in some more, the process consisting chiefly in shovelling in alumina and ladling out aluminium, day in and day out.

As to the expense, that was something he had never had an opportunity to investigate, and whether these new processes would result in a large economy in the cost of production remained to be seen. He presumed Mr. Blackmore had figures, gained by experience, which satisfied him as to the result.

Dr. G. A. PROCHAZKA noted that Mr. Blackmore spoke about aluminium suboxide as being the mother-substance of ultramarine. Without wishing to raise the question of the constitution of ultramarine at the moment, he took issue on that point. Aluminium suboxide was not the mother-substance of ultramarine.

Dr. H. ENDEMANN had written some years ago regarding the constitution of ultramarine. He had shown that it was a substance containing more atoms of non-metallic elements than metallic elements. If they considered in the formula of ultramarine the aluminium combined with this excess of non-metallic substances, they found  $Al_2O_3$  as a residue in the combination. There were really more non-metallic elements with aluminium in combination than there ought to be if it were a substance of the composition of alumina; hence there would not be a suboxide of aluminium. It must be a substance corresponding to even a higher oxide than alumina.

Mr. H. S. BLACKMORE mentioned that oxide of aluminium was very porous, so that this material would be, and any other material, such as sulphur, would be very apt to be absorbed in the material; so they could not tell whether it was actually combined or not, except by very careful investigation.

Dr. ENDEMANN said he had carefully investigated ultramarine, which consisted of even-coloured globules of ultramarine, under the microscope. It looked like a glass. It did not give a very good colour, but at the same time it was blue throughout, and gave a blue powder on being pulverised, but it was not quite as good as the ordinary ultramarine. It had been exposed to too high heat, in his opinion. It was from the examination of this dense sample that he conceived the idea that ultramarine must be looked upon as a derivative of  $Al_2O_3$ .

## ALCOHOL DERIVED FROM GRAIN, IN THE MANUFACTURE OF COAL-TAR DYES.

BY GEORGE A. PROCHAZKA.

MANY of you are without doubt familiar with the requirements of the coal-tar dye industry with regard to grain alcohol.

Grain alcohol, as used in the industry with which I am connected, fulfils three distinct functions:—

I. Alcohol is used as a solvent pure and simple, for the extraction and purification of raw materials employed by us, and some of our finished colours.

Our firm, the Heller and Merz Co., produce an eosine of extreme purity by crystallisation from alcohol. The alcohol can be recovered pretty completely, and generally the same degree of purity as originally employed. The recovered product may be used in subsequent operations.

II. Alcohol is used as a vehicle or solvent, in which two or more chemicals are allowed to act upon each other for the production of an entirely new body. The alcohol does not enter into chemical combination, but very often a portion of it is destroyed by the secondary action of these chemicals. The balance may be recovered to be used in subsequent operations. We use it largely in the production of coloured bromine and iodine compounds (bromofluoresceins, rose-bengale). The recovered alcohol is not as pure as the original, while the unavoidable loss in this class is greater than in the first.

III. Alcohol enters into chemical combination with the compounds produced. It cannot be recovered at all, as in I. and II. The ethyl group of the alcohol forms an inseparable constituent, and could not be isolated in the form of alcohol, without destruction of the entire compound.

The consumer demands of the dyestuff manufacturer as full and varied a line of shades of colours as possible. The introduction of the ethyl group, either by itself or in place of the methyl group, produces new and striking results. The manufacturer employs grain alcohol to get his valuable ethyl group, not on account of any personal preference for grain alcohol, but because he must use it. He has no choice.

Colours with the ethyl group are produced industrially in two ways:—

A. Ethyl derivatives of coal tar are prepared that are not dyes. These are converted into dyes by more or less complex methods.

B. A dyestuff of a certain shade is converted into a dyestuff of another shade by ethylation.

The following ethyl derivatives of coal-tar, not dyes, are at the present time largely employed in the manufacture of coal-tar dyes:—Diethylaniline, Ethyl-methylaniline, Ethyl-o-toluidine, Ethyl-benzylaniline, Diethylmetamidophenol, Ethoxybenzidine, and Quinaldine. The last is included because aldehyde is used in its production.

### Dyes derived from these Raw Materials.

#### 1. Diamidodiphenylmethane derivatives:—

*Emerald Green*.—Salts: Tetra-ethylamidodiphenylcarbinol.

*Patent Blue V*.—Salts of *m*-oxytetra-ethylamidodiphenylcarbinoldisulpho acid.

*Guinea Green*.—Salts of diethyldibenzoyldiamidodiphenylcarbinoldisulpho acid.

*Acid Green Yellow*.—Salts of the trisulpho acid.

*Patent Blue A*.—Salts of *m*-oxydiethyldibenzyl-diamidodiphenylcarbinoldisulpho acid.

*Acid Blue 6 G*.—Salts of *m*-oxydiethyldiamidodiphenylditolylcarbinoldisulpho acid.

#### 2. Triamidodiphenylmethane derivatives:—

*Ethyl Violet*: Hexa-ethylpararosaniline. Fast Acid Violet 10 B. Alpine Blue. Acid Violet 6 B. Acid Violet 6 B. Alkali Violet. Acid Violet 6 B N. Acid Violet 7 B (S. Schultz-Julius tables, III. ed., 314—320).

#### 3. Diphenyl-naphthyl dyes:—

Victoria Blue R. Night Blue (Schultz-Julius, III. ed., 335—336).

4. Pyrouine B (Schultz-Julius, 341).
5. Rhodamine 6 G G B (*ibid.* 344–346).
6. Thionine Blue G. Oestr. New Methylene Blue X (*ibid.* 442–445).
7. Quinoline Yellow
8. The derivatives of ethoxybenzidine, known as:—  
Diamine Blue B. Diamine Black E. Diamine Black P O.  
Diamine Blue 3 R. Diamine Red N O (*ibid.* 225–229).

#### *Dyes derived from others by Ethylation.*

(Chrysophenine (*ibid.* 251), Diamine Scarlet 3 B (*ibid.* 1–4), Diamine Yellow X (*ibid.* 230), Congo Orange R (*ibid.* 215), Rhodamine 6 G (*ibid.* 344), Anisoline (*ibid.* 347), Spirit Essence (*ibid.* 356).

The so-called Wilson-Tariff Act of 1894, while increasing the internal revenue tax on alcohol from grain from 90 cents, to 1·10 dols. per proof gallon, allowed a rebate on grain alcohol used for industrial purposes under regulations to be formulated by the Treasury Department. These regulations were never formulated, the tax was not refunded, and the whole matter is now in litigation. In June 1896, Congress repealed the rebate section of the tariff law, and referred the entire question to a Joint Committee of the two Houses, made up of members of the Ways and Means Committee of the House, and the Finance Committee of the Senate, under the chairmanship of the Hon. Orville P. Platt, of Connecticut, who has taken a great interest in the matter. This Committee has been investigating the matter thoroughly. A special delegate was sent abroad to examine the question in different countries of Europe. Hearings of great interest were given in New York and Washington, and it is to be hoped that the long-desired relief will at last be given to those interested.

#### *The Effect of the Tax upon the Coal-tar Dye Industry.*

Ethyl colours cannot be manufactured with taxed alcohol in competition with foreign manufacturers who get their alcohol free of tax. Our main competitors—the manufacturers of Germany—have tax-free alcohol, and are treated very liberally by their Government in that respect.

One example—the important raw material diethylaniline, and the valuable green colouring matter, “Emerald Green,” derived from it—will be sufficient:—

Value of 100 per cent. Alcohol :

	Dols. ets.
1 gall. or 63 lb. Tax paid .....	2 48
1 lb. ....	0 37
Tax on 1 gall. ....	2 20
Tax on 1 lb. ....	0 33

*Diethylaniline*.—1 lb. requires in its production not less than  $\frac{1}{2}$  lb. of 100 per cent. grain alcohol, rather more.

Alcohol value in 1 lb. diethylaniline :

	Cents.
Tax paid .....	18·5
Free of tax .....	2·0
Difference .....	16·5

The German product, diethylaniline, made with tax-free alcohol, is worth then less than 30 cents per lb.

Emerald Green derived from diethylaniline sells for about 50 dols. per lb. for the imported article, duty paid. It contains ethyl groups, corresponding to somewhat less than 40 per cent. of grain-alcohol, or 14·8 dols. per lb. of colour in tax-paid alcohol, or more than 25 per cent. of the selling price of the colour, duty added.

Alcohol, free of tax, per lb. of colour, 1·6 cents.

The tax in this class of colours is prohibitive. It is impossible for us to manufacture them in competition with the foreign article. It also acts as a very serious bar to the consideration of ethyl alcohol in the inventive development of this important and highly scientific industry in this country.

Where alcohol can be recovered in part, the tax hampers very seriously. The cost of the alcohol used in our manufacture amounts to about 10 per cent. of the value of the colour (alcohol tax paid); with alcohol free, this would amount to a little more than 1 per cent., a very serious difference in the close competitive markets of recent years.

#### DISCUSSION.

Prof. CHANDLER asked whether the author felt hopeful of obtaining some relief?

Dr. PROCHAZKA said that the Select Committee appeared to be very favourably disposed towards those industries which required grain alcohol. Of course, they had strong opposition to meet from the manufacturers of wood alcohol, varnishes, and turpentine. In that way the opposition was somewhat concentrated, but he thought relief would have to come. As the meeting would see, it was impossible to tackle those products. He had brought the matter before them to awaken some additional interest in the matter.

Prof. CHANDLER asked if it was proposed to denature alcohol?

Dr. PROCHAZKA said that the Committee spoke principally of methylation, which would hardly answer their purpose, because they wanted pure alcohol, if they could get it. For instance, if they took methylated alcohol when they wanted to ethylate, they might have very interesting results. When trying to make diethylaniline with methylated spirits, the results might be of an unexpected nature.

Mr. HENRY CLEMENTSON said that the Western farmer found himself burning his corn, when the distiller, if he had an outlet for his alcohol, which he would have if they had alcohol free of tax, would take the farmer's corn at a good price. The farmer considered it a very serious question. In the United States they had 128,000 bushels distilling capacity per day, and under the present conditions the distillers could use about 40,000 bushels capacity only. By the statistics that the Congressional Committee got while they were abroad, they found under the free alcohol laws of Germany that the industry increased there in seven years something like 1,000 per cent. If they could get half that, the distilling capacity of the country would be utilised, and, instead of the farmer of the West burning his corn, the chemists of the country could develop their chemical factories, and the makers of dyestuffs could make dyes at home. Speaking as a manufacturer of alcohol, he thought that the regulations, instead of encouraging the industry in every way they possibly could, did everything to hinder the industry and its development from a scientific standpoint. They were confined in their hours of fermentation, and the manner in which they might manipulate it and also put to the expense of very heavy bonds in order to do the business. In fact the regulations were such, and the bonds required were of such an enormous amount, that it was only by combination that the industry could be carried on. The Government were promoting a trust in alcohol. He thought from what he learned in Washington, that the present Congress would certainly give them a modified form; that is, certain industries would be allowed to have alcohol free of tax, under certain restrictions. The consensus of opinion there, among those who had it in charge, was that the Government and the people at large were not used to the idea as yet; that it would have to be brought about gradually. For instance, probably the varnish industry would get free alcohol; perhaps they would select the coal-tar dyes as one industry, and possibly some other industries; and as time went on, and they found that those industries are very largely increased and benefit derived therefrom, they would extend it to others.

Mr. M. TOWN thought the Chemical Societies of the United States, namely, this Society and the American Society, had not taken any steps towards investigating the free alcohol question. The matter was ripe and something ought to be done in connection with it. The manufacturers of varnishes and colours throughout the United States had endeavoured to obtain free grain alcohol for use in the arts, and he thought that a Society of such standing as theirs should send a deputation to Washington or communicate with those at the head of the Ways and Means Committee. Such a deputation would have great weight, and manufacturers and consumers of alcohol would stand a better chance of getting alcohol free in the arts and sciences and manufactures than they would have otherwise.

Prof. CHANDLER reminded the meeting that there was no alcohol tax before the war. He had a very vivid recollection of how he was affected by the tax. He was in the

habit of using alcohol in his laboratory in Union College for burning in lamps, as they had no gas. He formerly paid 16 dols. a barrel for 95 per cent. alcohol. Then the Internal Revenue Law was passed in order to raise money to carry on the war, and the next barrel he bought cost over 200 dols. The cost went up from 16 dols. to over 200 dols. The tax was then at the rate of 1 dol. a gallon for pure alcohol. That was a war measure, but it had been in force so long that the generation of people who were living when it was adopted had passed away. There were only a few left, and people of to-day had always been accustomed to this Internal Revenue tax and accepted it as the proper thing. That was the reason the inertia was so hard to overcome; and possibly the temperance societies were in favour of it and threw the weight of their influence against the removal of the tax.

With regard to the methylating of spirits, some years ago the Treasury Department, with a view to initiating legislation upon this subject, applied to the National Academy of Sciences for information as to methylating alcohol; and as to the result, Prof. Marsh appointed a committee of the National Academy of Sciences, with Prof. Remsen and himself as members, to ascertain whether it would be easy to remove the methyl alcohol, together with such bodies as usually accompany it, in case methylated spirits were allowed to come into free use. The Committee found that there was no difficulty whatever in removing every trace of the methyl alcohol and all the substances that accompanied it, and that without difficulty an entirely satisfactory alcohol could be made by the modern methods of distillation, with the aid of alkalis. The Treasury Department seemed to think this raised a serious obstacle in the way of permitting the sale of methylated spirits, and the matter was dropped at that time. They were adding in Europe, in addition to methyl alcohol, pyridine, and he understood that there was now an establishment in San Francisco engaged in manufacturing pyridine from California petroleum, to be used in denaturing alcohol in Europe.

Mr. CLEMENTSON said that that point was brought up in the Senatorial Committee. He himself stated his opinion before that committee that people who wanted to defraud the Government would not be found among the educated classes, especially among chemists. The man who started to defraud the Government certainly would not buy

methylated spirits for the sake of obtaining alcohol. When he could buy a bushel of corn for 20 cents, and get 1 $\frac{1}{2}$  galls. of proof spirits from it, he would hardly pay, say, 30 cents for a gallon of alcohol. It would be too costly an experiment. He would require very elaborate apparatus to do that, and as a general rule illicit distillers employed very cheap apparatus, so that should they get caught they did not lose much. He did not think the Government took the right ground in regard to that point. Furthermore, there had been some experiments tried in Charles Cooper's establishment in Newark, and there, with very elaborate apparatus, they did not succeed in de-methylating spirits. The experiment showed that after very careful distillation on a large scale with 100 galls., over 5 per cent. of the methylated spirits remained in the distillate, which would make it unfit for chemical or drinking purposes.

Prof. CHANDLER explained that their Committee took the ground that it was just as easy for the Government to prevent purification of methylated alcohol as it was now to prevent surreptitious distillation. Therefore that was no argument against methylated spirits.

#### SEWAGE PRECIPITATION AT WORCESTER, MASS.

BY H. P. EDGIV.

In considering the possibilities of any method of sewage treatment it is quite necessary to consider the average results of work performed on a practical scale, under ordinary conditions and extending over a considerable length of time. It will be found that deductions have frequently to be made from the results of laboratory experiments, and that these deductions often seriously reduce the estimate of the qualitative and quantitative efficiency of the process.

In this connection it may be of interest to examine the record of efficiency of the treatment of the sewage at the purification works at Worcester, Mass., where about 16,000,000 galls. are treated daily by precipitation. It must be remembered, however, that the sewage there dealt with is very dilute, averaging throughout the past year only about 0.500 part albuminoid ammonia per 100,000, and that storm water is treated, which at times seriously interferes with the treatment, and to such an extent that its efficiency is considerably reduced.

TABLE SHOWING THE RESULTS OF TREATMENT OF SEWAGE AT WORCESTER, MASS.

Date.	Average, December to December.			Average, December to July.			Average, July to December.		
	Albuminoid Ammonia. (Parts per 100,000.)	Per Cent. Total Albuminoid Ammonia removed.	Per Cent. Suspended Albuminoid Ammonia removed.	Albuminoid Ammonia. (Parts per 100,000.)	Per Cent. Total Albuminoid Ammonia removed.	Per Cent. Suspended Albuminoid Ammonia removed.	Albuminoid Ammonia. (Parts per 100,000.)	Per Cent. Total Albuminoid Ammonia removed.	Per Cent. Suspended Albuminoid Ammonia removed.
1894	0.506	50.78	89.54	0.422	46.63	83.26	0.622	53.78	94.36
1895	0.518	51.63	91.11	0.504	49.69	91.73	0.558	52.93	90.75
1896	0.497	53.92	92.02	0.400	52.00	91.45	0.649	56.10	93.35
Average	0.507	52.11	90.89	0.442	49.44	88.81	0.600	54.27	92.82

This table is made up from the results of daily analyses of sewage and effluent. 24 portions of effluent taken hourly and 48 portions of sewage taken half-hourly comprise the samples for daily analysis. This table is arranged so that a comparison can be made between the results of treatment during the wet and dry portions of the year and the average for the entire year. Many conditions beyond the control of the city affect the result, so that it is somewhat difficult to draw conclusions from the figures for each year, but a satisfactory comparison may be made between the averages. It will be noticed that the sewage is much stronger in the dry season than in the wet season, and that this difference has a marked effect upon the efficiency of the treatment. In the wet season the per cent. organic matter removed varied from 46.63 in 1894 to 52.00 in 1896, averaging 49.44 per cent. In the dry season the variation was less, being about 3 per cent., or from 52.93

per cent. in 1895 to 56.10 per cent. in 1896, and averaging for the three years 54.27 per cent.

The suspended organic matter appears to be subject to the same variation. In the wet season of 1894 but 83.26 per cent. was removed, while in the corresponding season of 1896 it reached 91.45 per cent. In the dry season the variation was from 90.75 per cent. to 94.36 per cent., 1894 being the highest.

It can be readily seen that conclusions from the success of a laboratory treatment of a sample of this sewage taken during either the dry or the wet season could not be applied exactly to the results of treatment upon a large scale and extending over a considerable length of time. There are other conditions bearing upon this point, but which cannot be illustrated by any tables of figures: for example, variations in the chemicals contained in the sewage.

In recent years there has been a growing tendency toward the abandonment of chemical precipitation as a method of sewage treatment, and a general feeling that a universal remedy for sewage purification troubles had been found in the methods of land treatment. This feeling has been greatly strengthened by the admirable work done by the Massachusetts State Board of Health, under the able direction of Dr. Thomas M. Drown and Dr. William T. Sedgwick. In this subject, the action of bacteria having been found to be a potent factor in the processes of purification, as in a great many other branches of science, the general fascination for the infinitesimal organisms has led to exorbitant claims and irrational opinions. But, however exaggerated these estimates of the value of land treatment may have been, it is certainly true that much advance has been made in the knowledge of sewage treatment, and it seems probable that this vexing question will cause less trouble in the future than it has in the past, and that much more intelligent action will be possible than has been attained hitherto.

There are, however, many obstacles in the way of land treatment, and these may in many cases be overcome by the aid of precipitation. It would seem that there are conditions under which each method can be worked successfully, and conditions under which they should be used together.

A few conditions under which chemical precipitation can be successfully applied either by itself or in connection with various methods of land treatment follow:—

1. Where there is insufficient dilution afforded by the water into which the discharge is made for crude sewage, but where it is ample for a chemically precipitated effluent.
2. Where the discharge is to be into a tidal body of water and it is impracticable to discharge crude sewage.
3. Where it is not possible to provide a sufficient quantity of land to treat the crude sewage.

#### DISCUSSION.

Mr. EDDY, in reply to a question from the Chairman, said that the chemical treatment employed at Worcester consisted in the addition of lime to the sewage. It was not, however, what was known as the "Lime Treatment." They had large wire drawing establishments in the City, and the pickling liquids from these works were turned into the sewers, so that the addition of lime to the sewage threw down a precipitate of iron.

Mr. R. C. WOODCOCK asked whether oxidation in sewage was not only helped by micro-organisms, but whether it was not altogether due to this cause. Prof. Warrington had published some very important researches on the oxidation of ammonia into nitrites and nitrates, owing to the presence of micro-organisms, and he proved it very cleverly in this way: He took tubes, about 3 ft. long, filled with earth and allowed a weak solution of ammonia salts to be filtered through when the earth was in proper condition, and if the flow of ammonia salt was not too rapid, he found that the effluent contained no ammonia whatever, the whole being oxidised into nitrites or nitrates, or both, according to the organisms he had present. Now, taking those tubes that were active in their work and passing a little chloroform vapour through them, which either destroyed or kept the organisms in a torpid condition, washing out the chloroform vapour by means of air, and then passing through the same solution at the same rate, no oxidation whatever took place. Now, taking another tube so treated and inoculating that tube with a little of the earth from one that was active, at once the earth set up activity again, which undoubtedly proved that micro-organisms did the whole work there.

The researches of Tidy and Frankland also very strongly showed that most of the oxidation in flowing streams was due to micro-organisms, and not simply to the absorption of the oxygen direct by the organic matter. Was this, in Mr. Eddy's opinion, due to direct absorption of oxygen or to these micro-organisms?

Mr. EDDY stated that the oxidation of sewage was almost exclusively brought about by micro-organisms. If sterilised sewage were passed through sterile sand, no oxidation to speak of took place. An interesting experiment was to

watch the oxidation of sewage in a bottle plugged with cotton to keep out organisms from the air. Upon allowing it to stand for a month a gradual change from the albuminoid into ammonia as free ammonia, and thence to nitrites, and even to nitrates, occurred in the solution. It took a considerable time. The odour, which at first was comparatively slight, increased to a maximum, and then gradually decreased. The growth of the organism increased and decreased *pari passu*. With sterilised sewage one got no change whatever and no odour.

Mr. REUBENS asked whether the author had noted some records of experiments in which iron and zinc were hung in cages in the ducts for the conveyance of the sewage.

Mr. EDDY, in reply, said that he had not seen an account of those experiments. They were quite similar, however, to experiments in the electrical treatment, only that zinc was not used. That was really chemical treatment, because hydrate of iron was thrown down as a precipitant. He did not recollect any experiments with zinc and iron.

Prof. CHANDLER, alluding to the use of zinc, said that there was a reaction of zinc with water and air, which did not appear in the text-books, recorded by a German investigator by the name of Taube. Wet granulated zinc became coated with white hydroxide of zinc; and Taube found that the following reaction took place:—

When zinc, water, and air came together, the zinc took hydroxyl, and hydrogen peroxide was formed at the same time, so that while zinc appeared as a reducing agent under ordinary circumstances, in this case it might actually be the means of bringing about an oxidation. Iron had recently been used extensively in Antwerp and some other places to purify drinking water.

## I.—PLANT, APPARATUS, AND MACHINERY.

Steam Boilers, Preventing Scale in. Eng. and Mining J. 1897, 63, 45.

THE introduction of kerosene, drop by drop, into the boiler is advocated on account of its cheapness and the fact that it leaves no residue therein, and has no injurious effect on the iron. An injector is described, so constructed that the amount of kerosene fed into the boiler can be very closely regulated.—A. S.

#### PATENTS.

*Treating and Extracting Solids with Washing Liquids or Solvents, Impts. in or relating to Apparatus for.*  
T. Fairley, Leeds. Eng. Pat. 1666, Jan. 23, 1896.

The solids are fed through a cylinder by a screw conveyor, and are mixed by the blades of the conveyor with a stream of the washing liquid or solvent flowing through the cylinder in the opposite direction. The form of conveyor employed is that of an ordinary screw conveyor divided longitudinally into two halves, the halves being adjustable on each other, so that the threads of the screw on one half may precede or follow those on the other half by any regulated distance. The apparatus may be jacketed, so that it can be heated or cooled, as desired.—R. A.

*Evaporating Apparatus [Multiple Effect], Impts. in.*  
S. M. Lillie, Philadelphia, U.S.A. Eng. Pat. 5431, March 10, 1896.

A NUMBER of evaporators, each comprising a series of heated tubes or other heated surfaces, over which the liquid is circulated by a pump, are connected together to form a "multiple effect," and are provided with suitably arranged pipes and valves to enable the liquid to be sent through the evaporators in succession, in either direction. An escape pipe is provided for conducting the water of condensation from a hotter or higher pressure evaporator to the steam chamber of a cooler or lower pressure evaporator, this pipe having a steam trap to prevent the escape of steam with the water of condensation. The invention also comprises various improvements in the construction of the evaporators and the arrangement of the circulating pumps, the pumps being provided with nozzles adapted for circulating the liquid and discharging it from the evaporators. The entrance of the liquid into the evaporators is controlled by an automatically operated feed valve.—R. A.

*Vessels for holding Corrosive Substances or the like, Impts. in.* P. Funfak, Leipzig, German Empire. Eng. Pat. 25,031, Nov. 7, 1896.

VESSELS for holding acids, alkalis, solutions of salts, and similar substances, are made of wood or other suitable material, lined with celluloid.—R. A.

*Evaporating Water Containing Salts and Calcareous Matter, Impts. in Apparatus for, and in Heating Furnaces for Removing the Incrustations from the Coils of such Evaporating Apparatus.* S. Straker, 139, Cannon Street, London. Eng. Pat. 28,411, Dec. 11, 1896.

THE present invention relates to evaporating apparatus of the kind described in Rayner's Specification, Eng. Pat. 5972 of 1888, and Caird and Rayner's Specification, Eng. Pat. 10,700 of 1893, for evaporating water containing large quantities of salt and calcareous matter. The box-shaped fronts which form the evaporator doors, and carry the evaporator coils, are mounted on wheels, to run on rails, so that they can be readily removed from the evaporating apparatus and run into a heating furnace, for the removal of the incrustations from the coils. The furnace employed, consists of a rectangular sheet-metal casing with a smoke-funnel at the top, and with a sliding door, and provided internally at the bottom with a disc-shaped asbestos wick, on to which petroleum is made to flow from a perforated tubular star connected by a pipe with an external supply of petroleum.—R. A.

## II.—FUEL, GAS, AND LIGHT.

*Naphthalene, Stoppages in Gas Mains due to.* A. Hoffmann. J. f. Gasbeleuchtung, 40, 1897, 97—98.

FROM observations made by the author at the gasworks of Kaiserslautern, it is shown that stoppages in mains and

pipes due to naphthalene, are not entirely prevented, in spite of the adoption of the most perfect system of cooling the gas before its introduction into the mains. Large air-coolers were erected, and it was whilst repairing a defective joint at one of the coolers, that the cause of the mystery was discovered. Most gasworks having steam-boilers, make it a rule to connect all apparatus with the general steam system, in order to blow them out, should it at any time be found necessary to do this. Owing to a faulty valve communicating with the last cooler of the series, steam was introduced into the vessel; and although the temperature of the gas could be reduced to 14°, it was impossible to condense the steam entirely. The naphthalene which had been deposited in the cooler was volatilised by the steam, and carried with it into the mains. After adopting measures for preventing a recurrence of this evil, the difficulty was entirely overcome. With a view of ascertaining whether the gas, after its passage through the coolers, still contained naphthalene, the author allowed a continuous current of steam from a small pipe to flow into the town's main for two days. The experiment was attended with serious consequences, and had to be abandoned after the first day, numerous complaints about stoppages in the gas-pipes being received. Whether the trouble was due to the presence of naphthalene in the cooled gas, or was caused by the volatilisation of old naphthalene which had been deposited in the pipes before the adoption of the air-coolers, remains an open question, although the author considers the latter view the more probable of the two.—D. B.

*Gas Engines, Combustion of Illuminating Gas in.* Haber and Weber. Ber. 30, 1897, [2], 145—151.

TWO Deutz engines were used: A, 4-horse, with flame-ignition, and gearing arranged so that the gas-supply was either fully open or shut at each stroke; B, 2 horse, with glow-tube ignition, and geared so as to open the gas-supply partially as well as fully, and thus regulate by altering the proportions of the gases for explosion. The burnt gases were aspirated from the exit tube, and analysed. The combustible portions were burnt over platinum or palladium, first at a low temperature to burn the hydrogen, afterwards at a higher temperature to burn the methane. Qualitative analysis having shown that carbon monoxide was also present, that and the hydrogen had to be burnt together, and wire was used rather than asbestos covered with the spongy metal, as local rise of temperature and consequent combustion of methane were thus more easily avoided. The fillings and explosions were registered electrically, to avoid drawing combustible gases into the sample for analysis if an explosion should "miss."

At full load no appreciable amounts of combustible gases were found in the exhaust, as the following figures show:—

—	CO <sub>2</sub> in	Additional Amounts		"Degree of Incompleteness," (100 × (2) (1) + (2))
	Exhaust.	after Combustion of	Residue.	
	(1.)	(2.) CO <sub>2</sub>	(3.) H <sub>2</sub> O.	
A	2.1326	0.0046	0.0089	0.22
"	1.4079	0.0048	0.0066	0.34
B	2.9585	0.0124	0.0106	0.42
"	2.3226	0.0129	0.0152	0.55

At half load very perceptible amounts of unburnt gases were present, the figures for B giving 6.15 and 8.38 for "Degree of incompleteness," and corresponding with an average content of:—CH<sub>4</sub>, 0.13 per cent.; CO, 0.14 per cent.; H<sub>2</sub>, 0.12 per cent. The corresponding percentages in the case of A were 0.092, 0.085, 0.058 respectively.

*Gas for Domestic Lighting, Value of. [Incandescent Mantles.]* V. B. Lewes. J. Soc. Arts, 1897, 45, 101—111.

THE oxides from which incandescent mantles are made, do not produce a very great illuminating effect when used alone, the illuminating value per cb. ft. of gas, of mantles made thus, being as follows:—Commercial thoria, 6.0; pure

thoria, 1.0; commercial zirconia, 3.1; pure zirconia, 1.5; ceria, 0.9; yttria, 5.2; lanthana, 6.0; commercial erbia, 1.70; pure erbia, 0.6; alumina, 0.6; chromium oxide, 0.4; barium oxide, 3.3; strontia, 5.5; magnesia, 5.0. Ceria gives a reddish-yellow light; erbia, zirconia, and barium oxide, a yellow light; alumina, a whitish-yellow; and strontia and magnesia, a white light. Although neither thoria nor ceria, when pure, have any particular power of emitting light, yet, if 1.2 per cent. of ceria be mixed with the thoria, the mixed oxides emit a light 14 to 16 times greater than either of the substances used, whilst on increasing the amount of ceria, the luminosity gradually diminishes until, with equal weights of the two, the light emitted is in proportion to the illuminating power of the constituents.

C. Killing states that the luminosity of incandescent mantles is due to the catalytic action of the oxide in a state of extremely fine division, which is added as an excitant to the skeleton formed of the chief material of the mantle, and he found that traces of metallic platinum or iridium, or even gold, osmium, ruthenium, and palladium, act in a similar way to ceria when added to the thoria mantles. With regard to this statement, the author observes that if the catalytic action be the true explanation of the phenomenon, further additions of the excitant ought to increase the incandescence, and certainly would not decrease it, as is the case.

The author's opinion with regard to the injurious effect upon the eyesight of artificial illuminants, is that the best light is one essentially different from ordinary daylight, and as free as possible from the actinic rays present in sunlight. Crookes states, as a conclusion from a series of experiments, that the injurious effect of artificial lights on the eye being principally attributable to the invisible ultra-violet radiation, the cold greenish-blue Welbach light may be considered to be 2.5 times as harmful as the warm pinkish-yellow light of the "sunlight" mantle.—A. S.

*Electric Lighting, Underground.* J. Daw, jun.  
Inst. Mining and Met., 1897, 1—5.

A portable electric lamp 2½ ins. square and 8 ins. high has a "dry" battery in the lower part, and a 1 to 3 candle-power incandescent lamp with porcelain reflectors and switch above. The lamp bulb is protected by a stout glass cylinder, held in place by four brass uprights. The battery consists of one positive plate placed between two negative plates, each composed of plumbic oxide, pumice powder, and india-rubber solution; and the electrodes are separated by an adhesive cellulose moistened with sulphuric acid. Two of such cells are contained in the base of the lamp, and being coupled in series give a total E.M.F. of four volts. The electrical storage is equal to 7 ampere-hours. In charging, the current must not exceed 0.8 ampere. After one month's constant use, sufficient (a trifling amount of) sulphuric acid (sp. gr. 1.100) is added to re-saturate the cellulose composition. The weight of the cell varies from 1 lb. to 3½ lb., according to the time that it will be required to supply light. A one-candle power lamp will last for 16 hours without re-charging. The lamp at present costs 25s., and is expected to have a life of at least 5 years. The energy used in charging is 42 watt-hours, and since the amount of each charge is 7 ampere-hours, the actual cost of a charge to last 12 hours, is 0.052d., taking the cost of generating electricity at 1½d. per unit of 1 kilowatt-hour. Allowing for repairs and the renewal of bulbs, the total cost of charging and maintenance may be taken at ½d. per lamp per charge.—W. G. M.

#### PATENTS.

*Gas Burners, An Impt. in Atmospheric.* J. Modler,  
Westminster. Eng. Pat. 24,839, Dec. 27, 1895.

An atmospheric gas-burner tube having lateral holes for entrance of air to mix with the gas, so arranged that the streams of air are directed obliquely upwards and inwards. The mixture of gas and air thus produced, burns with a highly heating flame.—A. S.

*Artificial Fuel, Impts. in, and in the Manufacture of.*  
H. C. B. Forester, Penybryn, Sketty, near Swansea.  
Eng. Pat. 682, Jan. 10, 1896.

The artificial fuel is prepared by crushing or reducing coal or the like solid carbonaceous body, mixing it with petroleum, tar, creosote or creosote oils, pitch, naphthalene or naphthalene salts, resin, or other solid or liquid hydrocarbon, and heating the mixture in an externally heated closed vessel under pressure. The mixture is continuously forced through the retort, and is afterwards pressed or moulded if desired.—R. S.

*Furnace for producing Coke, A New; with or without suitable Apparatus for collecting the By-Products.* G. W. Breffit, Leadenhall Street, London, F. G. Trebarne, Wrangbrook, Glamorganshire. Eng. Pat. 841, Jan. 13, 1896.

The furnace is in the form of a muffle, subdivided into narrow chambers, into which, containers or boxes of metal or thin fireclay slabs, and containing the coal to be coked, can be passed. The furnace is initially heated by a fire grate, and the products of combustion travel internally and all around the muffle by suitable flues. When sufficiently carbonised, the boxes are removed, a cover fitted over them, and they are allowed to cool. The gaseous products from the containers may be (1st) collected, the liquid constituents separated, and the gases returned to the combustion chamber, and there burned; (2nd) led at once to the combustion chamber and burned, a suitable arrangement of flues therefor being illustrated; (3rd) allowed to collect in the muffle, and burned, when desired, by admitting oxygen; or (4th) led from one container to the next, whereby a large amount of carbon in the gases is deposited upon the coke, thus tending to enrich and harden the latter.—R. S.

*Non-Exploding Mechanical Admixture of Oxygen and Hydrogen, A Process and Furnace Installation for Continuous Process of Production of a.* C. Polony, Mittelgasse, Vienna. Eng. Pat. 1300, Jan. 18, 1896.

This non-exploding mixture of oxygen and hydrogen is obtained by the dissociation of steam. It may be separated afterwards into its constituents, or otherwise treated. The three essentials for producing the mixture are: sufficient heat, an impermeable casing, and friction within the producing furnace. The latter has a central chamber, five pairs of concentric semicircular channels arranged in three communicating tiers, the two semicircular pairs being separated by a wall from one another so as to form two independent furnaces as regards working. All the channels and the chamber are built of chromic iron ore. Numbering the channels from the centre chamber outwards, air or oxygen passes downwards through the fourth tier of channels, and enters a mixing or combustion chamber beneath, which also receives the products of combustion from a grate below. The mixture then passes upwards through the first and third tiers, and then across and downwards through the fifth tier, and so to the chimney. The steam for treatment is admitted to the top of the second tier, and, passing downwards, is heated sufficiently to be dissociated, and may be collected in this state. Or the mixture of oxygen and hydrogen may be led to the lower end of the central chamber to react upon any body placed therein, as sodium chloride to obtain caustic soda and hydrochloric acid. If sulphur dioxide be caused to mix with the dissociated gases, sulphuric acid is obtained. Should the temperature fall, the mechanical mixture quietly recombines to form water. If the constituents are required separately, a thin fire-brick partition, platinum in thin sheets, an electric spark, or other means may be adopted. When the first (diffusion) method is adopted, the oxygen may be used instead of air for the combustion process, whereby pure carbonic acid is obtained, or, by a modification, carbonic oxide.—R. S.

*Incandescent Oil Lamps, and Igniting Devices therefor, Impts. in or relating to.* A. J. Boulton, London. From

The Société Dubois Frères, Paris. Eng. Pat. 2022, Jan. 28, 1896.

A BURNER in which the wick tubes are arranged so as to form, at the upper end, an annular vaporising-chamber, which is surrounded by the lower edge of the mantle, the said chamber containing a central chamber having a central conduit terminating in a funnel surrounding the wick tubes, in which funnel the mixture of carburetted air is made. A bell is arranged over this funnel, communicating with the lower part of the outside of the annular chamber and with the wick tubes, and having on its lower edge a recess for the passage of an igniter, and two other recesses for supplying air to the said igniter.

The upper edge of the annular chamber is surrounded by a ring, to prevent admission of non-carburetted air into the interior of the mantle, whilst the upper end of a tube of very small diameter enters the chamber, the lower end being turned upwards and brought under a central opening in the wall separating the burner from the body of the lamp, which opening may be closed or opened by means of a flap-valve operated from outside by means of a key. The vapour of oil heated in the annular chamber passes through this tube and through the opening mentioned, into the mixing funnel, and thence through the central conduit into the central chamber, where the mixture of carburetted air is heated ready for supply to the mantle.

The igniter has two wick-holding tubes, which are introduced so as to surround the wick tubes and central conduit, in order to start vaporisation and to light the lamp.—A. S.

[*Incandescent "Mantle Fluid."*] *The Manufacture of Fluid for Impregnating Bodies or Suitable Fabrics, Threads, Fibres, or the like, for Illuminating or Lighting Purposes; An Improved Process for.* B. Puchmüller, Schöneberg. Eng. Pat. 26,167, Nov. 19, 1896.

A MIXTURE of magnesia and baryta is dissolved in "a suitable liquid or acid" ("bismuth acid, antimonie acid, meta-antimonie acid, citric acid, acetic acid, oxalyltricarboxylic acid," &c.), then evaporated, the vitreous or salt-like residue pulverised, again dissolved in another liquid or acid ("nitric, tartaric, dioxysuccinic, pyrotartaric, malic, succinic, or formic acids"), mixed with distilled water, and the resulting solution used for impregnating fabrics, &c. Oxide of uranium and strontia may partially or wholly replace the magnesia and baryta.—H. B.

*Incandescence Gas Lighting, Impts. in Means for.* R. Van De-Ghinste, Brussels. Eng. Pat. 26,304, Nov. 20, 1896.

MANTLES are to be made of wires composed of an alloy of platinum with rhodium, iridium, or palladium, or with mixtures of these. When used with a Bunsen burner the mantle may consist of pure platinum wire, or of an alloy of platinum with 2 or 5 per cent. of iridium, the wire measuring about 0.005 mm. in thickness and the meshes about 0.4 mm. in width. When an intense flame is to be employed, such as that got from a Bunsen burner constructed so as to allow of a free circulation of atmospheric air where the gas escapes from the nozzle into the burner tube, or from a burner in which an air-current is used for injecting the gas, the wires should be 0.1 mm. thick and the meshes 0.5 mm. wide, good results being obtained by employing wire of pure platinum, or of an alloy of platinum with 5–20 per cent. of iridium, or of an alloy of platinum with 10 per cent. of iridium and 10 per cent. of rhodium, or of an alloy of platinum with 10 per cent. of rhodium.—H. B.

*Lamps for Burning Hydrocarbon Oil or Spirit, Impts. in or connected with.* A. Kiesow, London and Berlin. Eng. Pat. 2281, Jan. 31, 1896.

IN LAMPS in which an S-shaped or other wick tube descends to near the bottom of the reservoir, and is sealed by the oil, it becomes necessary to admit a small supply of air to the reservoir, in order to equalise the pressure and allow the free flow of oil to the wick. The object of the invention is to connect the wick tube with the reservoir so that the flame cannot flash back through the connection into the reservoir. At the upper part of the wick tube, and at one side thereof,

a horizontal channel is stamped from the inside, so as to protrude on the outside, and upon the interior of the tube this channel is covered by a light plate, which thus converts it into a tube. The channel is arched from the horizontal line, so that its ends are lower than the centre. At the highest point of the arch there is a small hole opening into the reservoir, and at each end are small holes opening into the wick tube. Thus, the interior of the wick case is placed in communication with the reservoir, and the air can pass through; but the passage is so narrow and circuitous that the flame cannot flash back, and if any oil should, accidentally or by condensation, lodge in the channel, it will flow out at the holes at each end, into the wick tube. Instead of a stamped channel being made, an arched tube may be soldered on to the outside of the wick tube, and perforated as above, or a minute tube or channel of S-form may be furnished, one end communicating with the wick case, the other with the reservoir.—H. B.

*Washing, Scrubbing, and Purifying Gas: Impts. in Apparatus for.* S. Hersey, K. Hulet, and Chandler, Ltd., Palace Chambers, Bridge Street, Westminster. Eng. Pat. 5686, March 13, 1896.

THE APPARATUS consists of a vertical column divided into a number of superposed compartments, up which the gas passes whilst the washing liquid flows downwards. The latter enters by a pipe at the extreme top, falls on to a tumbling vessel, which distributes it over a horizontal perforated plate, from which it passes between two superposed sets of corrugated vertical iron plates, the plates of each set being placed close together, but at right angles to the other set. From these compartments it flows through two more compartments connected by an overflow pipe having a regulating valve, and finally escapes from the lower of these two compartments by an overflow pipe having a valve. The gas to be treated enters at the bottom of the column, and flows upwards through the last two compartments mentioned, by means of special roses dipping into liquid. The gas next passes upwards between the corrugated plates, and then escapes. The major claim is for apparatus for the above purpose, consisting of a gas- and water-tight vessel divided into a number of superposed compartments, some of which contain roses of special construction, and some sets of vertical corrugated plates, this vessel being provided with an inlet and outlet for the water or cleansing liquid. The employment of a tumbler to project water, &c. into the apparatus, and of a perforated plate for spreading the water, &c., is also claimed, as also the combination of parts to form the whole apparatus.—R. S.

*Gas-regenerative Furnaces [Water-sealed Valve], Impts. relating to.* E. Johnson and J. Thompson, Lemington-on-Tyne. Eng. Pat. 5738, March 14, 1896.

"THE novelty of this invention consists in the method of applying a water-sealed valve for changing the direction of the current of the gas or air when entering into separate flues." The flues communicate with an upright chamber, which may be circular in plan, and is halved vertically by means of a central partition, the two halves being open at the top. Round the upper edge of each chamber and across the partition runs a narrow trough containing water, to serve as the water seal. Rising from the middle point of the partition is arranged a central upright spindle carrying at right angles the valve or lid, which is large enough to completely cover one compartment of the chamber. Surrounding the under-side of the lid is a downward projection, which dips into the water trough and so forms an air-tight seal to prevent leakage. When it is desired to alter the direction of the gas or air, the spindle, carrying the lid, is raised till the downward projection clears the trough, and the lid is then turned round until it comes over the opposite compartment of the chamber; it is then lowered until the projection dips into the water trough. Now the previously open compartment is covered and the previously covered compartment is opened. The valve may be used for reversing the direction of the flow of steam or other gaseous products of metallurgical processes.—H. B.

*Acetylene Gas, Impts. in Apparatus for Use in the Production of.* C. G. Luis, Denmark Hill, Surrey. Eng. Pat. 1332, Jan. 18, 1896.

THE improved apparatus consists of a vessel divided horizontally into two partitions, the upper of which contains the water and the lower the calcium carbide. A tube conveys the gas as it is liberated, to the space above the water in the upper chamber. This chamber is provided with a safety-valve. The amount of gas generated, is automatically regulated by the pressure of the gas on a ball-float or a diaphragm actuating a conical valve, which controls the flow of water to the carbide. Suitable air-tight caps are provided for replenishing the chambers and removing the waste. The apparatus may be constructed either as a table-lamp or for the supply of several burners. A series of wire gauzes are arranged in the gas exit pipe, to prevent lighting back under reduced pressure.—J. A. B.

*Acetylene Gas, Impts. in Apparatus for use in the Manufacture of.* E. B. Pym, Kensington, and J. Gore, Clerkenwell. Eng. Pat. 3219, Feb. 12, 1896.

THE pressure of gas in the mains is said to vary considerably with apparatus as heretofore constructed. The patentees obviate the defect by introducing a second storage chamber provided with a float or diaphragm subject to the pressure of the gas therein. The float controls the movements of the valve which admits the gas from the first chamber; and thus the pressure in the second chamber, from which the mains are fed, is kept fairly uniform. If the pressure of gas in the first chamber rises unduly, the valve lifts independently of the control of the float, and the pressure in the second chamber rising, a water seal is forced and surplus gas escapes to the air. The patentees also claim a duplex generating apparatus provided with cocks and by-passes on the water supply for the purpose of automatically diverting the flow of water from one generating chamber to the other as soon as the carbide in the first is exhausted. The first chamber may then be recharged with carbide, and the water will be automatically diverted back thereto as soon as the carbide in the second chamber is exhausted.—J. A. B.

*Acetylene and other Hydrocarbon Gases, An Improved Apparatus for Generating.* J. F. Blakeley, Ravenshorpe, Yorks. Eng. Pat. 5150, March 7, 1896.

CARBIDE is placed upon horizontal or inclined trays in a chamber, at the bottom of which water enters from a supply pipe furnished with a tap, actuated, through levers, by a bell governor, which rises and falls with increase or decrease of the pressure of the gas in the chamber. When the gas is evolved more rapidly than it is consumed or stored, the pressure rises and the supply of water is automatically diminished and the evolution of the gas thereby decreased. In another form of the apparatus, the generating chamber has a water-jacket, through which the gas-outlet pipe passes on its way to the holder. The latter controls the water supply in the same manner as does the governor in the first form. In a smaller apparatus, the carbide is put on a grate and water is admitted at the bottom of the chamber from an annular cistern at the top by means of a siphon. When gas is evolved too freely, the increased pressure in the chamber forces the water back into the cistern. In the middle of the top of this apparatus is a special closed conical chamber for feeding the generating chamber with carbide without interruption of the process. Preference is given to a combination of two generators with one storage gas-holder.—J. A. B.

*Acetylene Gas or other very rich Hydrocarbon Gas, A Method of Burning.* J. R. Wigham, Dublin. Eng. Pat. 4285, Feb. 26, 1896.

THE gas is forced to the point of combustion through tubes with fine needle-hole outlets (equal to No. 7 or smaller of English make) through which the gas issues in straight jets, in contradistinction to fish-tail or batswing jets. Where powerful lights are required, the jets are arranged in groups closely side by side or concentrically, so that the whole somewhat resembles an Argand deprived of a chimney glass. Over each jet or group of jets is suspended a tube of mica or other material, to cause an upward current that

renders the flame smokeless and steady. The burner tubes are surrounded with a conical-shaped perforated metal cover, to check the current of air and heat it somewhat, before it comes in contact with the flame. The claim is for the method of burning acetylene gas.—H. B.

*Lighting by Acetylene or other Gases rich in Carbon, A New or Improved Burner for.* S. D. Gillet, G. Forest, and J. E. O. Bocaudé, Paris. Eng. Pat. 27,086. Under International Convention, May 30, 1896.

THE gas is mixed with air, previous to combustion, on the Bunsen principle. The gas first passes through metallic gauze into an upright nozzle which is fixed within a chamber. In the wall of the chamber are air-inlet apertures at a convenient height in relation to the mouth of the nozzle. In one form of the apparatus a slide is arranged to regulate the inward current of air. The mixing chamber terminates in a small orifice at its upper part, above which is a tapped part into which any suitable ordinary burner, such as the batwing, may be screwed, at the mouth of which the mixture of gas and air is burned.—H. B.

*Acetylene Gas, Impts. in the Production and Purification of, and in Apparatus therefor.* A. Sehemilt, Vitry sur Seine, and O. Kaufman, Paris. Eng. Pat. 16,432, July 24, 1896.

ACETYLENE is produced by adding carbide in small quantities to a relatively large bulk of water, and is purified by passage in turn through dilute acid, solutions of lead acetate, acidified copper sulphate, and caustic soda, which remove respectively ammonia, sulphuretted hydrogen, phosphoretted hydrogen, and traces of acid. It is then passed through a chamber containing hygroscopic material, and is subsequently compressed and liquefied. The purification and drying of the gas are said to render unnecessary the use of refrigerants during compression.

The improved generator has a reciprocating slide working gas-tight between its top and the mouth of a hopper. There is a hole in the slide which comes alternately beneath the hopper and above a hole in the generator-top, and thus conveys carbide from the hopper to the generator. The carbide drops on a grid just below the level of the water in the generator. In the generator is a rotating stirrer, and pipes are provided for maintaining the water-level and removing both gas and lime sludge. The stirrer prevents the waste from depositing.—J. A. B.

*Acetylene Gas Generators, Impts. in.* H. H. Lake, London. From V. Hanotier and G. Hostelet, both of Chimay, Belgium. Eng. Pat. 27,697, Dec. 4, 1896.

THE apparatus consists of several superimposed vessels with appropriate connections. The lowest vessel receives calcium carbide, on which water from a higher compartment is sprayed. In the event of surplus production of gas, the flow of water is automatically diverted into an empty compartment. The surplus gas at the same time forces a water seal and passes into a spherical chamber and thence into a chamber containing sulphuric acid, by which it is absorbed. When the gas production is normal, the gas bubbles through water in another compartment, the upper part of which is furnished with a grid loaded with quicklime and two fine wire gauzes. The purified gas circulates around the carbide receptacle, and thus recovers a portion of the heat disengaged by the chemical action, and arrives at the places of consumption in a heated state.—J. A. B.

*Acetylene Gas, Improved Generator, Purifier, and Holder.* A. G. Smith, Aberdeen. Eng. Pat. 22,646, Oct. 13, 1896.

CALCIUM carbide is put into a perforated tube with projecting wires, which serve to support it on a pair of quadrants attached to the inner surface of a bell. A lower pair of quadrants act as guides for the tube. The bell is slipped into an outer vessel containing water. The gas-exit pipe passes downwards through the water, and water condensed from the gas is drawn off from a tap at the base of the upright tube fixed by the side of the generator, into which upright vertical tube this gas-exit pipe passes. This vertical tube is packed with pumice or other material, and

serves as a purifier. The claims are: (1) "For the means of holding the calcium carbide in the gas holder"; and (2) "For the combined condenser and purifier provided by means of the upright pipe and the tube at the side."—J. A. B.

*Acetylene Gas, Impts. in Apparatus for the Production and Combustion of.* R. Furr, Paris. Eng. Pat. 24,274, Oct. 30, 1896.

THE apparatus consists of two concentric vessels, the inner one of which is closed to the air, and has suspended within it a cage loaded with carbide of calcium. The vessels are in communication near the base, and are charged with water to a certain height. A layer of petroleum floats on the water in the inner vessel. When the evolution of acetylene occurs at a greater rate than its consumption, the pressure within the inner vessel forces down the liquid and leaves the carbide in contact with the petroleum, whereupon the evolution of gas at once ceases. The residue from the carbide falls through the meshes of the cage. A gas generator and a lamp embodying the improvements claimed, are described in detail.—J. A. B.

*Electric Furnaces [Carbides], Impts. in and relating to.* S. Regnoli, F. Lori, R. Pignotti, M. Paudaleoni, and M. Besso, Rome, Italy. Eng. Pat. 13,297, June 16, 1896.

APPARATUS is illustrated for the collection and utilisation of combustible gases from electric furnace reactions for heating up the material previous to electric treatment, or maintaining the space around the furnace at a high temperature, or for other purposes; treating the material in an atmosphere formed by the same gases as are generated in the furnace, which is surrounded by an air chamber heated by burning the recovered gases, with the object of diminishing the dispersal of heat. The furnace has a bottom in the form of a sliding case easily changeable to avoid breaking up a portion of the furnace when changing the electrodes, and is lined with refractory material of feeble conductivity to avoid the formation of lateral arcs.—J. C. R.

*Electric Furnace [Carbides], A New or Improved.* F. H. Haviland, A. Holloway, J. B. Collier, and W. H. Murch, Beaumont, Tex. Eng. Pat. 15,448, July 13, 1896.

THE electric furnace or pot for containing the material to be treated, is set in a furnace for the purpose of heating it and its contents, and, when a high temperature is reached, setting up the electric arc. The pot (plumbago) is shown as one electrode.—J. C. R.

*Charcoal Fuel Blocks, Impts. in the Manufacture of.* S. Katz, Hamburg. Eng. Pat. 21,098, Sept. 23, 1896.

SOLID briquettes or blocks of charcoal are made from waste wood, sawdust, or other disintegrated wood, and are then heated under pressure, whilst excluded from air, till reduced to charcoal.—R. S.

*Purifying Gases or Vapours [Coal Gas, Furnace Gases &c.], and gaining By-Products therefrom, and subjecting Gases or Vapours to the Action of Solid or Liquid Substances, and the Converse, by Means of Centrifugal Action; Impts. in, and Apparatus therefor.* E. Theisen, Baden-Baden, Germany. Eng. Pat. 23,595, Oct. 23, 1896.

THE patentee employs the method of obtaining intimate frictional contact between gases and liquids described in the specification of his prior patent, Eng. Pat. 16,726, 1892 (this Journal, 1893, 742), to obtain the separation from gases or vapours of certain of their impurities or separable constituents, or to cause the gases or liquids to react upon a thin layer of liquid or solid matter, or the converse. The apparatus employed consists essentially of a chamber, or a revolving cylinder, or a series of such, against the inner surface or surfaces of which the gases or vapours are caused to impinge by the action of revolving vanes, various modifications of this form of apparatus being described. The inner surfaces of the chambers or cylinders may be supplied with a layer of liquid or solid material of such a nature that the required absorption of, or chemical reaction with, the gases will be obtained, or the absorbing layer may be

deposited by centrifugal action from the gases themselves. As an example, the separation of tar, ammonia, sulphuretted hydrogen, and carbonic acid gas from coal gas is fully described in the specification.—R. A.

*Electric Device [Arc Lamp] for Showing the Relation of Oxygen and Nitrogen in Mines and other Places, Improved.* L. Cohn, Breslau, Germany. Eng. Pat. 28,609, Dec. 11, 1896.

"For controlling the state of the air in mines, chemical and other works" an open arc lamp is employed which is placed in circuit with a meter on the dial of which contact pins are fixed in connection with an alarm bell, which registers a "dangerous surplus of nitrogen" through variations in the burning of the lamp.—J. C. R.

#### IV.—COLOURING MATTERS AND DYES.

*Curcumin from Turmeric, A Review of the Composition of.* Camician and Silber. Ber. 1897, 30, 192.

THE authors have repeated the experiments of Jackson and Menke (Beilstein's Handbuch H., Aufl. III., 414), who attribute to the body the empirical formula  $C_{21}H_{23}O_6$  and the constitution  $C_6H_3(OH)_2(OCH_3)_2.C_{15}H_{17}.COOH$ . The pure curcumin employed by the authors was recrystallised from methyl alcohol and benzene until a constant melting point of 183° was obtained; the crystals occurred in two forms—in brilliant red needles and as lighter coloured prisms; both forms melted sharply at 183°. The melting point of Jackson and Menke's curcumin was 178°. Ultimate analysis led the authors to adopt the empirical formula  $C_{21}H_{23}O_6$  and the constitutional formula  $C_6H_3(OCH_3)_2(OCH_3)_2$ .

On acetylating this pure curcumin, diacetylcuremin, which crystallised from alcohol in long yellow needles melting at 170°–171°, was obtained. The constitution of this product was found to be  $C_{21}H_{19}O_8(OCH_3)_2(OCH_3)_2$ . On methylating curcumin, a small crop of crystalline golden needles melting at 135°, and having the constitution of dimethylcurcumin,  $C_{21}H_{25}O_6(OCH_3)_4$ , was obtained. In addition to these products, curcumin is found to form definite compounds with phenylhydrazine and with hydroxylamine. The hydroxylamine body, the formula of which is given provisionally as  $C_{21}H_{25}NO_6$ , occurs in clumps of fine needles, having a melting point of 173°. The composition of this and of the phenylhydrazine compound require further attention.—J. O. B.

*Dinitronaphthalenes, the Formation of.* C. Gassmann. Bull. Soc. Ind. Mulhouse, 1896, 381–382.

NITRIC acid acting upon naphthalene produces at first  $\alpha$ -mononitronaphthalene, and on further action in the presence of sulphuric acid, a mixture of dinitronaphthalene 1:5 and 1:8, results. At low temperatures and with very strong acids the 1:8 derivative is chiefly formed, while for a larger yield of 1:5 dinitronaphthalene, high temperatures and the ordinary concentrated acids should be employed. In order, for example, to obtain a considerable yield of the 1:8 dinitronaphthalene, 128 grms. of naphthalene are mixed with 110 grms. of nitric acid (61.7 per cent.  $HNO_3$ ), when mononitronaphthalene is formed and floats as an oil on the surface. The mixture is cooled, and a previously cooled mixture of 360 grms. of ordinary concentrated sulphuric acid and 100 grms. of fuming acid (60 per cent.  $SO_3$ ) is gradually introduced together with 150 grms. of nitric acid (61.7 per cent.), a low temperature being maintained. When all has been added, the mixture is heated for 12 hours on a water-bath and the liquid poured whilst still hot into 5 litres of cold water. The products are collected on a filter, well washed with water to remove adhering acid, and separated by Beilstein's method with acetone. With the quantities here given the yield of crystalline products is 79 grms. of 1:5 dinitronaphthalene and 115 grms. of the 1:8 derivative.—R. B. B.

*Yellow Dyestuff derived from Dinitrofluorescein.*

F. Reverdin. Ber. 30, 332–334.

THE subject-matter of this paper has already been abstracted (Eng. Pat. 3966 of 1896; this Journal, 1897, 137). The sub-

stance obtained by the action of ammonia on dinitrofluorescein has probably the formula—

and dyes level shades on wool from an acid bath. The fastness to light of this dyestuff, as well as of its ethyl ether, surpasses that of the fluorescein derivatives, although inferior to that of tartrazine. The action of ethylamine on dinitrofluorescein gives an orange, whilst *p*-toluidine yields a yellowish-brown dyestuff for wool. By acting with ammonia on tetranitrofluorescein no decisive result was obtained, but by allowing 1 kilo. of tetranitrofluorescein, 1 kilo. of caustic potash, and 1½ litres of water to stand for some days at the ordinary temperature, a yellow colouring matter is produced, which, however, is very fugitive to light.—T. A. L.

*Phenolphthalein, Quinoid Derivatives of.* R. Nietzki and E. Barendhardt. Ber. 30, 175—180.

The oxidation of fluorescein ether gives the quinoid-fluorescein ester, which further yields the quinonoid-diethyl ether and the monohydroxyl ether (Nietzki and Schröter, Ber. 28, 44). Phenolphthalein does not, however, behave in the same way. Its carboxyl ester has already been prepared (Herzig, Ber. 28, 3258; 29, 158), but this, on oxidation, is not converted into a quinonoid-phthalin ester. This reaction does, however, take place with the tetrabromophthalin ester, which dissolves to a colourless solution in alkalis. On treating the alkaline solution (containing 4KOH) with potassium ferrieyanide, a deep blue solution is obtained, which, on standing, deposits the potassium salt of tetrabromophenylphthalein ether—

This substance is a pronounced dyestuff, and gives pure blue shades on wool and silk. If a dilute alkaline solution of the ether be carefully acidified with acetic acid, an almost colourless solution is obtained. On dipping a skein of wool or silk into the latter, and warming, the fibre is dyed blue, from which it follows that the animal fibre acts as an alkali towards the colour acid. This blue colour is also produced when the free ester comes into contact with the skin. On further ethylation, the yellow quinonoid-diethyl ether is obtained, and this, on saponification, yields the ethyl hydroxyl ether, which up to the present only exists in the lactoid form, and has the formula—

This gives an acetyl compound when treated with acetic anhydride, whilst tetrabromophenolphthalein, when heated with ethyl bromide and alkali, only gives the lactoid-diethyl ether.—T. A. L.

*Azo Dyestuffs derived from α-Naphthol and α-Naphthylamine Sulphonic Acids, Constitution of.* L. Gattermann and H. Schulze. Ber. 30, 50—55.

The formation of azo dyestuffs from the sulphonic acids of α-naphthol and α-naphthylamine has been held to be

dependent on the two following laws:—1. The diazo group enters para to the hydroxyl or amido group if this position be free. 2. If the para position be substituted by a sulphonic acid group, but the ortho position be free, the diazo group enters there. Several cases are, however, known in which azo dyestuffs of the ortho series have been formed even though the para position is free. The authors have examined the azo dyestuffs obtained by combining diazobenzene chloride with 1·4'-naphthol sulphonic acid, 1·4'-naphthylamine sulphonic acid, and 1·3-naphthol sulphonic acid. The 1·3-naphthylamine sulphonic acid would not combine with diazobenzene chloride, but only with *p*-nitrodiazobenzene chloride. All these products were reduced with stannous chloride, the sulphonic acid group being subsequently removed by means of sodium amalgam. The resulting products were either 2·1-amidonaphthol or 1·2-naphthylene diamine. In the case of the dyestuff from diazobenzene chloride and 1·4'-naphthylamine sulphonic acid, a further proof that the azo group enters ortho to the amido group was given by the fact that the benzylidene derivative obtained by the action of benzaldehyde did not give off benzaldehyde when heated with acids, as Goldschmidt (Ber. 23, 496, and 24, 1000) has shown is the case with amido-azo dyestuffs of the para series. From the results obtained, the two following laws have been formulated:—1. If the position para to the hydroxyl or amido group be free, and the ortho and peri positions relative thereto are unsubstituted by sulphonic acid groups, dyestuffs of the para series are formed. 2. Azo dyestuffs of the ortho series are formed if the para position be occupied, or if it be free and the ortho or peri position relative to it contain a sulphonic acid group, providing, of course, that the ortho position is free. In further confirmation of the above laws, it is noteworthy that 1·2·4'-naphthol disulphonic acid does not combine with diazo compounds in spite of a free para position.—T. A. L.

*2·3'-Naphtholsulphonic Acid, Action of Nitrous Acid on.* R. Nietzki and T. Knapp. Ber. 30, 187—190.

In the preparation of 1·2·3'-nitronaphthol sulphonic acid (used for the manufacture of eikonogen), the formation of a red by-product has been frequently observed. In order to obtain this product in larger yield, the authors stir 2·3'-naphtholsulphonic acid (Schaeffer acid) or the sodium salt, to a paste with nitric acid of sp. gr. 1·3, and run in fuming nitric acid saturated with nitrous acid at a temperature of 0° C. An equal volume of water is then added, the crystals are filtered off and washed with dilute nitric acid until the wash-water is a dark red. Analysis gives figures corresponding to the formula  $\text{C}_{20}\text{H}_{13}\text{NS}_2\text{O}_8$ . The analysis and reactions of the substance point to its being allied to indophenol, and probably possessing the constitutional formula—

When treated with an excess of aniline on the water-bath, it is converted into the anilide—

It yields a crystalline leuco compound with stannous chloride and hydrochloric acid, but on oxidation this gives a bluish-violet coloration, and not the original dyestuff.

—T. A. L.

*Diquinoyltrioxime and Tetranitrophenol.* R. Nietzki and F. Blumenthal. Ber. 30, 181—186.

By the action of hydroxylamine hydrochloride (1½ mols.) on dinitrosoresorcinol (Fast green), an intermediate product is formed, which differs from the tetroxime obtained by Goldschmidt in being insoluble in alcohol, and from dinitrosoresorcinol, in giving blood-red instead of green salts

with iron. The substance is diphenyltrioxime, having the constitution 2,1,3,4 or 1,2,3,4,  $C_6H_5O_3(NOH)_2$ . The action of acetic anhydride in the cold yields a diacetyl derivative,  $C_6H_5N_3O_4(C_2H_3O)_2$ , m.p.  $142^\circ C$ , which, on boiling with acetic anhydride forms an anhydride,  $C_6H_5N_3O_5$ , melting at  $181^\circ C$ . This latter substance gives with ferrous (but not with ferric) salts, a dark green iron salt which crystallises from acetic ether. On reducing the trioxime with stannous chloride and hydrochloric acid and adding alcohol and sulphuric acid, the sulphate of a new triamido-phenol is precipitated. It gives a blue coloration with ferric chloride and other oxidising agents, and also yields a picate, a triacetyl derivative melting at  $230^\circ C$ , and a tetra-acetyl compound, m.p.  $211^\circ C$ . The oxidation of the trioxime did not yield any definite products, and the action of nitric acid, even dilute, gives a tetranitrophenol. This product, which probably has the constitution—

is very easily soluble in water, acetic acid, and acetic ether, but less easily in benzene and petroleum spirit. It melts at  $130^\circ C$ , and occasionally explodes violently. This property is also possessed by the potassium and silver salts. The substance is a well-defined dyestuff, and gives yellow shades (almost similar to dinitronaphthol) on wool and silk, somewhat redder than picroic acid, and of almost twice the strength.—T. A. L.

*Carulignone Dyestuffs.* C. Liebermann and J. Flatau.  
Ber. 30, 231—242.

With a view of further investigating the constitution of carulignone and determining the position of the quinone-groups, the authors have studied the action of certain amines on the substance. They find that primary aromatic amines react with carulignone according to the following equation—

forming deep blue dyestuffs giving induline-like shades. Secondary amines like methylaniline, acetanilide, and diphenylamine do not, however, react, and the fact that benzyllaniline after prolonged heating does give a colour, is ascribable to the circumstance that this product splits up during the process into benzaldehyde and aniline. Similarly, tertiary bases like dimethylaniline and quinoline are without action, and, in fact, this reaction may be made use of for detecting the presence of 1—2 per cent. of aniline in quinoline. The compounds obtained have probably one of the following formulae—

that is to say, they are peculiar quinone anilides, giving however, dark blue shades. As compared, for instance, with naphthoquinone anilide, which is yellowish-red, these products bear the same relation to it that the phenyl do to diphenyl derivatives, the latter of which, in their azo compounds, give as a rule darker shades than the former. This may possibly be an explanation of the blue colour of the new compounds. Even sulphurous acid easily reduces the dyestuffs to leuco derivatives, and this fact renders difficult their employment in dyeing. They can be employed directly from a solution or else from the reducing vat, but are deficient in fastness. The first term of the series would be known as dianilidodimethoxydiphenylquinone, for which the trivial name lignone blue is suggested. The preparation of one of its homologues, *p*-dimethyl lignone blue, is as

follows:—10 grms. of carulignone and 120 grms. of glacial acetic acid are heated together and treated with 8 grms. of *p*-toluidine. The reaction only lasts a short time, and on cooling, the dye-stuff separates out (with a yield of 60—70 per cent.), and may be recrystallised from glacial acetic acid. Homologous and analogous derivatives are obtained from aniline, *p*-bromaniline, *m*-chloraniline,  $\alpha$ -cuminidine, *o*- and *p*-anisidine, anthranilic acid, *m*- and *p*-amidobenzoic acids, and sulphanic acid.—T. A. L.

## PATENTS.

*Sulphonic Acids of Alkyl Derivatives of Meta-amidophenolphthaleine (Rhodamines).* Manufacture of. O. Imray, London. From "The Farbwerke vormals Meister, Lucius, and Brüning." Hoechst a M., Germany. Eng. Pat. 2099, Feb. 10, 1896.

Certain alkylated *m*-amidophenolphthaleins give salts which are only stable in presence of an excess of acid, and are decomposed in the dyeing process, becoming insoluble. The patentees avoid this difficulty by converting the rhodamines into sulphonic acids by treatment with fuming sulphuric acid at a low temperature. Thus, 5 kilos. of symmetrical di-ethyl-*m*-amidophenolphthalein or its hydrochloride are gradually stirred into 100 kilos. of fuming sulphuric acid (10 per cent.  $SO_3$ ) at a temperature below  $20^\circ C$ . The melt is agitated until a sample dissolves to a clear solution in water containing no excess of alkali. After pouring into water, the precipitation of the sulphonic acid is completed by the addition of salt. The free sulphonic acid is then dissolved in sodium carbonate solution and evaporated to dryness. Wool completely exhausts the acid dye-bath and is dyed the same shade as the unsulphonated di-ethyl rhodamine, with a brilliant fluorescence. The free sulphonic acid is sparingly soluble in water, more easily in alcohol with a bright yellowish-red colour and a greenish-yellow fluorescence, whilst it is insoluble in benzene, chloroform, ether, and acetic ether. The alkali salts are easily soluble in water to yellowish-red solutions having a yellowish-green fluorescence.—T. A. L.

*Safranine Azo Dyestuffs Soluble in Water.* Manufacture of. O. Imray, London. From "The Farbwerke vormals Meister, Lucius, and Brüning." Hoechst a M., Germany. Eng. Pat. 5090, March 6, 1896.

The compounds obtained by combining diazotised Safranines with  $\alpha$ - and  $\beta$ -naphthols and their sulphonic acids are insoluble in water. By allowing the combination, however, to take place in presence of ammonia, soluble compounds are obtained, and an especially valuable one is produced from  $\beta$ -naphthol. The same result is effected by acting with an ammonium salt on the insoluble compounds. The following quantities are employed:—7 kilos. of Safranine T (from tolylene diamine, *o*-toluidine, and aniline) are dissolved in 500 litres of water and 5.5 litres of hydrochloric acid (28.7 per cent.), and diazotised with a solution of 1.6 kilos. of sodium nitrite. The diazo solution is then run into a well-agitated solution of 200 litres of water containing 2.9 kilos. of  $\beta$ -naphthol and 8.5 kilos. of 20 per cent. ammonia. After stirring for two hours, 50 litres of brine are added, and the precipitated dye-stuff is filter-pressed and dried at a low temperature, or used as a paste. It dissolves easily in cold or warm water with a bluish-violet colour, and dyes mordanted or unmordanted cotton indigo-blue shades.—T. A. L.

*New Raw Materials (Benzidine Derivatives), and of Direct-dyeing Colouring Matters derived therefrom; Manufacture of.* C. D. Abel, London. From "The Actien Gesellschaft für Anilin Fabrikation." Eng. Pat. 7313, April 4, 1896.

The new raw materials are derivatives of diphenylamine and benzidine, and are represented by the following general formula:—

where D is the radicle of a benzidine compound. The latter are prepared by reducing the nitro compounds

obtained by condensing benzidine with *o*-chloro-*m*-nitrobenzene sulphonic acid. These diamido compounds can be converted into tetrazo derivatives, which, after combination with various components, give dyestuffs dyeing unmordanted cotton from an alkaline or salt bath. The following is the preparation of the condensation product:—27.8 kilos. of the sodium salt of *o*-chloro-*m*-nitrobenzene sulphonic acid and 18.4 kilos. of benzidine are dissolved in alcohol containing 50 per cent. of water, the whole being then heated to 150° C. in a closed vessel. The sodium salt of *p*-nitrophenyl benzidine-*o*-sulphonic acid is then precipitated with salt. To effect the reduction, a solution of 40.8 kilos. of the sodium salt is boiled with 50 kilos. of sodium sulphite until a blackish-green solution is obtained, when, on cooling, most of the *p*-amidophenyl benzidine sulphonic acid separates out, the rest being precipitated by salt. The tetrazo compound, obtained in the usual manner, can be combined either with the same or with different components, or if such be taken that after combination, they can be further diazotised, trisazo dyestuffs are produced. Thus a dark black for cotton is obtained by combining the tetrazo compound from 37.8 kilos. of the sodium salt of *p*-amidophenyl benzidine sulphonic acid with 14.3 kilos. of  $\alpha$ -naphthylamine, again diazotising with 7 kilos. of sodium nitrite and the necessary quantity of hydrochloric acid, and running the compound into a solution of 47.8 kilos. of  $\gamma$ -amidonaphthol sulphonic acid kept alkaline with sodium carbonate. The dye-stuff, after separation in the usual way, dyes cotton a dark blackish-blue, and this product, on further diazotisation and combination with *m*-tolylene diamine, either in solution or on the fibre, gives dark black shades.—T. A. L.

*Substantive Trisazo Colouring Matters [Blues, Blacks], Production of.* W. E. Heys, Manchester. From The Chemical Works, formerly Sandoz, Basel, Switzerland. Eng. Pat. 28,810, Dec. 16, 1896.

By combining tetrazo derivatives with certain amines in equimolecular proportions, rediazotising the intermediate products, and combining these compounds with two molecular proportions of an azo compound, valuable trisazo dyestuffs have been obtained. The amines generally employed have been  $\alpha$ -naphthylamine, Clève's  $\alpha$ -naphthylamine sulphonic acids, and certain amidonaphthol sulphonic acids. It has not, however, been possible hitherto to employ amines of the benzene series, since experiment has shown that the compounds formed were not amido-azo derivatives, but diazo-amido compounds, and incapable of further diazotisation. According to the present specification, *p*-xylylene ( $(\text{CH}_2)_2\text{NH}_2=1:4:2$ ) is an exception to this rule, and gives a readily diazotisable intermediate product. By combining this diazotised derivative, for example, with two molecular proportions of amidonaphthol sulphonic acid II, dyestuffs are obtained which dye unmordanted cotton indigo to greenish-blue. These products are diazotisable on the fibre, and, after development with  $\beta$ -naphthol, give deep black shades fast to washing. The following are the quantities employed:—A solution of 6.1 kilos. of *p*-xylylene and 6 kilos. of hydrochloric acid (21 B.) in 80 litres of water, is added to the clear tetrazo solution from 9.2 kilos. of benzidine at about 5° C. and stirred for about two hours. The intermediate product separates as a brown precipitate, and in order to complete the reaction, 26 kilos. of sodium acetate dissolved in water are added. After standing 10 hours at 5° C., 25 kilos. of hydrochloric acid are run in, and the mixture is diazotised by gradually adding a solution containing 3.5 kilos. of sodium nitrite. The brownish-black precipitate dissolves to a reddish-yellow solution, which is then run into 600 litres of water containing 34.5 kilos. of amidonaphthol disulphonic acid II, 4.5 kilos. of caustic soda, and 40 kilos. of sodium carbonate. After standing 12 hours, the mixture is heated to boiling and the dyestuff is salted out, filtered, pressed, and dried. It dyes unmordanted cotton indigo-blue shades from a bath containing salt, and when diazotised on the fibre and combined with  $\beta$ -naphthol it gives a deep black, with *m*-phenylene or *m*-tolylene diamine a greenish-black, and with resorcinol a dark green.—T. A. L.

*Violet and Blue Colouring Matters of the Triphenylmethane Group, Production of.* W. E. Heys, Manchester. From The Chemical Works, formerly Sandoz, Basel, Switzerland. Eng. Pat. 30,015, Dec. 30, 1896.

THESE dyestuffs are obtained by condensing tertiary derivatives of  $\beta$ -naphthylamine—such as methyl- or ethyl-phenyl- $\beta$ -naphthylamine, methyl- or ethyl-tolyl- $\beta$ -naphthylamine, methyl- or ethyl-xylyl- $\beta$ -naphthylamine; or secondary derivatives, such as  $\alpha$ -naphthyl- $\beta$ -naphthylamine or  $\alpha$ - $\beta$ -dinaphthylamine—with tetramethyl- or tetra-ethyl-diamidobenzophenone by means of phosphorus oxychloride. The products formed, since they contain a  $\beta$ -naphthyl group, can be readily sulphonated, and yield compounds which give pure shades fast to alkalis. The tertiary derivatives are obtained by alkylating phenyl- $\beta$ -naphthylamine by the ordinary methods, and methyl-phenyl- $\beta$ -naphthylamine forms large colourless prisms melting at 52° C., whilst ethyl-phenyl- $\beta$ -naphthylamine melts at 55° C. and crystallises in white plates. The following example illustrates the method employed for the production of the dyestuffs:—A mixture of 19 kilos. of methyl-phenyl- $\beta$ -naphthylamine, 20 kilos. of tetramethyldiamidobenzophenone, and 7 kilos. of toluene is agitated in a closed vessel on a water-bath and cooled to 30° C., when 13.5 kilos. of phosphorus oxychloride are added. In about 15 minutes a reaction sets in, and the temperature rises to about 120° C. After about an hour, the melt is cooled, powdered, and dissolved in 1,000 litres of hot water, and salted out. It can be used directly for sulphonation, or may be purified by washing with toluene or redissolving in slightly acid water and reprecipitating. It forms a greenish crystalline mass, which dyes wool a pure violet. In order to sulphonate it, 20 kilos. of the product are dissolved in 60 kilos. of 100 per cent. sulphuric acid, to which 40 kilos. of fuming sulphuric acid (54 per cent.  $\text{SO}_3$ ) are gradually added at 20°–30° C. When a sample dissolves in a large quantity of hot dilute caustic soda, the melt is poured out to ice and the dyestuff is filtered off. In order to purify it, it is dissolved in 1,000 litres of hot water containing the necessary quantity of caustic soda, filtered, and precipitated with salt and acetic acid. The product dyes wool a pure violet similar in shade to "Acid Violet 7 B," but has the advantage in being fast to alkalis. By condensing tetramethyldiamidobenzophenone with  $\alpha$ - $\beta$ -dinaphthylamine and sulphonating the product, a dyestuff is obtained which gives blue shades on wool from an acid bath.—T. A. L.

## V.—TEXTILES: COTTON, WOOL, SILK, Etc.

*Silk: The Effects of Weighting on the Fibre.* R. Gnehm and E. Bänziger. *Färber Zeit.* 8, [1], 1–2, and [2], 18–22.

By the tin phosphate-silicate process, the weight of silk may be increased 50–60, and even 100–120, per cent. without deteriorating the fibre, whilst feel and lustre are actually improved. It has been found, however, that silk thus treated has, in many instances, become tender after having been stored for some time, without any cause for this change being assignable. This circumstance has led the authors to study the effects on the fibre of the above method of weighting silk at different stages of the process.

In practice, this process is carried out as follows. The silk is steeped for one hour in a solution of stannic chloride of 25°–30° B., squeezed to remove surplus liquor, rinsed, and steeped for  $\frac{1}{2}$ –1 hour in a warm solution of a soluble phosphate of 3°–5° B., and is again rinsed. The silk thus prepared is treated for  $\frac{1}{2}$ –1 hour in a warm bath of a soluble silicate, and washed. The silicic acid is the chief constituent of the weighting, and the object of the process is to precipitate in the fibre a mixture of silicate and phosphate of tin along with free silicic acid, whilst by the former alkaline method, stannic oxide only was deposited. By five successive passages through the stannic chloride, phosphate, and silicate baths respectively, the silk may be increased in weight 100–120 per cent., as against 15–20 per cent. by the older process. The above order of treatment is sometimes varied. In some works the silk is not passed through the silicate bath after each phosphate bath, as this would give the silk a harsh feel, and tender the fibre.

The authors conducted their investigations as follows. After each treatment, the quantities of tin, phosphoric acid, and silica absorbed by the silk, were ascertained by an analysis of the ash, and the fibre was tested for strength and elasticity. The silks used in the experiments were organzine, Italian, 18 22 D, and tram, and Japanese, 40 D.

The results are given in the subjoined tables.

with each other, the "variation of fibre" is given in a separate column. These numbers are the difference between the mean of 10 trials and the mean of the numbers below the first mean, expressed in per cent. of the former. Thus, let the mean of 10 trials be 134, and that of the lower numbers 127; then  $134:(134-127) = 100:X$ ; or  $X = 5.2$ .

P, Na, and Si in the tables stand for "pinksalt" (stannic chloride), sodium phosphate, and silicate baths respectively; and the numerals before each, indicate the number of passages of the silk through each bath.

Conclusions:—1. The results obtained show a considerable excess of  $\text{SnO}_2$  in the fibre—that is, more than would be required to form neutral salts. Thus, in organzine silk which has been passed once through a pinksalt and once through a sodium phosphate bath, a compound corresponding to the formula  $4\text{SnO}_2 \cdot \text{P}_2\text{O}_5$  seems to have been formed.

2. As the weighting progresses, so the elasticity decreases; temporarily, however, especially after a passage through the silicate bath, there is a slight recovery.

The tensile strength is not materially affected.

3. The heating of even heavily weighted silk for 40 hours at a temperature of  $40^\circ\text{C}$ . has no appreciable influence on the strength of the fibre. But if this temperature be increased (say to  $55-65^\circ$  for 40 hours), then the elasticity, and partly also the tensile strength, seem to suffer diminution.

4. Direct sunlight has a fatal influence. The strength of fibres exposed to light fell to one half and more below that of samples which had not been exposed; and in one case, where the silk had been passed six times through the pinksalt, the fibre was so brittle that its strength could not be ascertained at all. Under the microscope this silk exhibited sharp cross cuts, and on the fibre small nodules were deposited.

As it is impossible to expose hanks evenly to light, the effects of the latter on the different fibres must vary accordingly, and this is shown to have been the case by the numbers of "variation."

The observation is also of interest that the strength and elasticity of the fibre, which have suffered from a passage through the pinksalt solution, are again slightly recovered after a passage of the silk through a phosphate or a silicate bath.

The authors have examined several samples of dyed silk, weighted, and the results were confirmatory of the above conclusions, *viz.*, that heating to  $40^\circ\text{C}$ . has no injurious effect, but that light weakens the fibre considerably.

The following table shows the influence of light after an exposure of 18 days, chiefly during rainy weather, for 14 days without any direct sunlight, and a few hours of sunshine only on the remaining four days. The numbers in the first column indicate the degrees of weighting, whilst the letters *a* and *b* signify different modifications of the process.

# PATENTS.

*Fibrous Material [Eucalyptus Fibre], The Manufacture of an Improved.* J. A. Maquaire, Paris. Eng. Pat. 3533, Feb. 17, 1896.

THE material is obtained by suitable treatment of the fibres of the eucalyptus. These fibres are subjected to successive treatment with warm water, alkali, and acid, after which they are washed with resin soap and then with water. The fibres are then dried, scutched, and stripped, and carded to form "eucalyptus wool or wadding." The resins removed during the above treatment are restored to the wadding by slow fumigation in a cylinder.

The material is stated to be applicable to the manufacture of felt, and also capable of being spun either alone or together with other textile fibres of animal or vegetable origin.—R. B. B.

*Dressing or Finishing Compound for Woven Fabrics, An Improved.* E. R. L. Blumer, jun., Zwickau, Germany. Eng. Pat. 28,670, Dec. 15, 1896.

THE compound consists of magnesium chloride, borax, starch, and rye flour. The borax is added in order to neutralise any hydrochloric acid liberated by decomposition of the magnesium chloride, and the rye flour prevents the absorption of moisture.—R. B. B.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

*Gum for Thickening, A New.* Ch. Gassmann. Färber Zeit. 8, 2—4.

THE author has made trials with various new gums, and found a good substitute for tragacanth, &c. in the new thickening material termed "Sleph" (Labiche, Mulhouse). The advantages of this gum are said to be that it is easily removed from the fibre by washing, leaving the latter soft, and in not tinting wool and silk yellow during steaming to the same extent as other gums commonly used in printing. A quantity of from 50—60 grms. of sleph boiled with 500—600 grms. of water, and diluted to 1 litre, yields a mucilage suitable for printing.—I. S.

*Manganese Brown, Sulphocyanide Discharges on.* F. Reisz (with report by C. Schæn). Bull. Soc. Ind. Mulhouse, 1896, 378—380.

THE use of sulphocyanides as discharges for Manganese Brown has been described by Brand (Bull. Soc. Ind. Mulhouse, 1896, 79; this Journal, 1896, 449). The present author recommends for a red discharge, a printing colour consisting of 50 parts of thickening, 50 parts of ammonium sulphocyanide (400 grms. per litre), 10 parts of acetic acid 6° B., and 24 parts of alizarin (20 per cent paste); after printing with this colour, the cloth is steamed. In the case of chromium mordants, the author finds that (1) pure chromium sulphocyanide does not discharge the brown; (2) a mixture of 800 c.c. of a thickened saturated chromium sulphocyanide solution and 200 c.c. of hydrosulphocyanic acid (23.6 grms. per litre) has little effect in the cold, but on steaming discharges the brown and fixes on the fibre a green oxide of chromium; (3) a mixture of 660 c.c. of chromium sulphocyanide and 40 grms. of hydrosulphocyanic acid discharges even in the cold, and on steaming fixes a greenish-yellow oxide; (4) 800 c.c. of chromium sulphocyanide, together with 140 c.c. of sodium sulphite 40° B., and 60—70 c.c. of acetic acid of 6° B., discharge feebly in the cold and readily on steaming, with fixation of a dirty grey oxide. For a blue discharge 750 c.c. of thickened chromium sulphocyanide, 100 c.c. of Alizarin Blue S, and 150 c.c. of sodium bisulphite of 40° B., may be used. The brown in this case becomes a little paler, probably owing to excess of sulphurous acid.

C. Schæn confirms the author's statements, and remarks that for a clear bright red some hydrosulphocyanic acid should be added to the above-described alizarin and alu-

minium colour. In all cases the brown tends to be partially reduced on steaming, and this may easily lead to uneven colours.—R. B. B.

*Turkey-Red, An Impt. in the Dyeing of.* T. Baldensberger. Bull. Soc. Ind. Mulhouse, 1896, 382—384.

IN order to avoid the chief defects of Turkey-red dyeing, viz., the necessity of frequently cleaning the dye-baths to remove grease, uneven dyeing (when dyed on the winch), and the great length of time required (when dyed in the jigger), the author recommends the use of an alkaline alizarin solution, prepared by dissolving 10 kilos. of alizarin (20 per cent. paste) in 40 litres of water containing 1 kilo. of ammonia. The pieces are dyed in the jigger; they are first passed through cold water containing a calcium salt, more water is then added, the bath heated to 56° C., and the alizarin solution added in two, three, or four portions according to the length of the piece. The bath is raised to the boil in half an hour, and boiled for 15 minutes; after 10 passages the bath is almost completely exhausted; the pieces are then washed and cleared in the ordinary manner. It is stated that the red is superior in brilliancy to that obtained without the use of ammonia, that the colour is perfectly even, and that one hour suffices for the dyeing of three pieces, 1½ metres in width, by this method, while three hours would be required for the dyeing in the ordinary winch machine.—R. B. B.

*Aniline Black [Oxidation] from Aniline Fluoride.* H. Lindner. Leipziger Färber u. Zeugdr. Zeit. 1897, 46, [2].

ANILINE fluoride, the author states, has the advantage over aniline chloride of not attacking the vegetable fibre to the same extent as the latter, whilst yielding a full and good black. Its only drawbacks are that the black dyed with it has not quite the desired lustre, and that its price is somewhat higher than that of the chloride.

Aniline fluoride being much more neutral than the chloride, it requires a somewhat larger proportion of oxidising agents, such as sodium chlorate and copper nitrate, and aluminium chloride is to be substituted for the corresponding acetate. If the right proportions of the several ingredients are taken, the oxidation proceeds as evenly as with aniline chloride.

The author has obtained good results by working as follows:—5,100 grms. of aniline fluoride are stirred up with 10 litres of tepid water. In another vessel are dissolved 900 grms. of sodium chlorate in 4 litres of water, and in a third vessel 450 grms. of ammonium chloride in 4 litres of water. When cold, these three solutions are mixed together, and to them are added 3 litres of copper nitrate and 100 grms. of aluminium chloride, and the whole is made up to 30 litres.

The copper nitrate is prepared as follows:—To a solution of 900 grms. of copper sulphate in 3 litres of boiling water are gradually added, whilst stirring, 900 grms. of soda crystals. After the precipitate has settled, the supernatant liquid is decanted, and 400—500 grms. of nitric acid are added to the residue until the latter is dissolved.

The aluminium chloride is prepared by dissolving 1,000 grms. of alum and 600 grms. of barium chloride in 4 litres of boiling water, and allowing the precipitate to settle. The clear solution is used.—I. S.

# PATENTS.

*Rapid Tanning of Hides, Process and Apparatus for the; applicable also for Dyeing and otherwise Treating Leather.* H. L. J. Roy, Paris, France. Eng. Pat. 2572, Feb. 4, 1896.

See under XIV., page 250.

*Dyeing, Bleaching, or Scouring Fibrous Materials, Impts. in Apparatus for.* T. Halliwell, Eccles. Eng. Pat. 2840, Feb. 7, 1896.

THE apparatus described, consists of two closed vats connected at the bottom by a pipe, and two condensing chambers placed above these vats. The condensing chambers are connected with an injector, by means of which, air or steam

may be exhausted from either of the vats. A vacuum is produced in each vat alternately, and the liquor thus caused to pass from one vat to the other, this movement of the liquor being automatically reversed, when a certain level is reached, by means of a float and slide valve. In this way the liquor is repeatedly drawn through the cops, or other material in the vats, in alternate directions.—R. B. B.

*Cutch, Impts. in preparing, for Sale and for Use.* J. R. Carruthers, Tradeston, Glasgow. Eng. Pat. 3178, Feb. 12, 1896.

ANY ordinary form of cutch is subjected to the action of hot or dry air in a centrifugal machine or otherwise, and is then reduced to powder. The powder is next granulated by treatment with steam, water, or other suitable liquid, and by the action of mixing and drying apparatus.

In another modification of the patentee's process, the original cutch is made into a paste with water, the paste dried and granulated as before, or spread into sheets, dried, broken up, and sieved into powders of various grain.

By any of the above means, a product similar in colour and appearance to the original cutch is obtained, but one which, in that it is more easily handled, dissolved, and measured, is more useful, technically and commercially.

—E. R. B.

*Fast Colours on Animal Fibre, The Production of, by the Aid of Oxide of Titanium.* J. Barnes, Accrington. Eng. Pat. 5712, March 14, 1896.

OXIDE of titanium ( $\text{TiO}_2$ ) in a more or less hydrated condition may be fixed upon the wool fibre by boiling in a solution containing titanium tetrachloride ( $\text{TiCl}_4$ ) and cream of tartar, the mordant containing these two substances being previously prepared. It is claimed that titanium mordant yields bright and fast colours intermediate in shade between the colours produced with chromium and with aluminium mordants.

A titanium mordant may also be prepared by dissolving hydrated titanium oxide in oxalic acid; in this case the mordanting bath should not be heated above  $160^\circ \text{F}$ .

Silk may be mordanted by steeping for several hours in a cold solution of titanium tetrachloride at  $10^\circ \text{Tw}$ .

For further details, see this Journal, 1896, 420.—R. B. B.

*Crape-like Designs on Cotton, Linen, and other Fabrics or Yarns of Vegetable Origin; A Chemical Process for the Production of White or Coloured.* J. Weiss, Heidenheim-on-Brenz, Germany. Eng. Pat. 8235, April 18, 1896.

IN this modification of the mercerising process, the fabric is impregnated with caustic alkali and immediately printed with acids, salts, or metallic oxides soluble in alkali, which neutralise the caustic alkali in the printed parts and thereby prevent the contractile action from taking place in those portions of the fabric. By varying the constituents of the printing mixture, a great variety of coloured crepon effects may be obtained. For instance, chromic acetate produces green chromic oxide; salts of aluminium and tin are decomposed by the alkali, and the oxides of those metals, thus fixed upon the fibre, act as mordants for alizarin or other dyestuffs. Ferric chloride yields ferric oxide, which can be combined with potassium ferrocyanide to form Prussian blue. If the printing mixture be composed of tannin and acetic acid, the printed portions may be dyed with a basic colouring matter, or if the fabric be impregnated with  $\beta$ -naphthol, dried, mercerised, and printed at once with diazo solutions containing acetic acid, the printed portions are coloured with the resulting azo compound.

By analogous methods, white crape-like effects may be produced upon a coloured ground.—R. B. B.

## VII.—ACIDS, ALKALIS, AND SALTS.

*Sulphide of Sodium, Electrolytic Oxidation of.* Scheurer-Kestner. Bull. Soc. Chim. 17, [2], 1897, 99.

A PAPER has recently been published by Durkee on the oxidation of sulphide and sulphhydrate of sodium by electrolysis. This author finds that, whereas oxidation by air or

gaseous oxygen gives rise to hyposulphite (thiosulphate), oxidation by means of the electric current causes the formation of sulphate. He further states that during the process, sulphur is precipitated, and hyposulphite (thiosulphate) can be detected in the solution; that is, the oxidation of the sulphide to hyposulphite occurs as an intermediate step in the formation of the sulphate. Scheurer-Kestner points out that the electrolytic oxidation of sodium sulphide was patented in France in 1875, and that in 1881 he published a note on the reaction. Working with sulphide only, and not hydrosulphide, he failed to note at any time either deposition of sulphur or formation of thiosulphate; and from his observations that the electrolysis always occurred with an unavoidable evolution of oxygen, and that it required the same time to oxidise by electrolysis, solutions containing the same quantity of sulphur, whether the sulphur was present as sulphide or as thiosulphate, he comes to the conclusion that it is inadmissible to consider an intermediate oxidation to thiosulphate as occurring, and that the oxidation proceeds directly to sulphate, thus:  $\text{Na}_2\text{S} + \text{O}_2 = \text{Na}_2\text{SO}_4$ .

## PATENTS.

*Carbonic Acid, Impts. in means for Obtaining, from Gaseous Mixtures.* W. Raydt, Stuttgart, Germany. Eng. Pat. 873, Jan. 13, 1896.

THIS is an improvement on Eng. Pat. 13,456, 1895 (this Journal, 1896, 594), in which a method is described of obtaining carbonic acid from furnace and other mixed gases by bringing these into contact with moistened alkali carbonate, and heating the resulting bicarbonate. According to the present improvements, instead of moistening the carbonate to be acted upon, the gases, heated to  $70^\circ \text{C}$ , are led through layers of asbestos, small coke, or other suitable absorbent material, kept moist by a spray of distilled water, ordinary water being unsuitable. The gases thus moistened then permeate layers of the carbonate raised intermediately, within a chamber divided into compartments by a series of heating pipes communicating by external chambers. The apparatus may be arranged for passage of the entering gases either upwards or downwards, but in such manner that the gases only reach the layers of carbonate after they are moistened by traversing the wet absorbent. The apparatus used in the previous process, may, with certain modifications such as indicated, be made available.—E. S.

*Ammonium Nitrate and other Salts, Impts. in the Manufacture and Purification of.* T. Fairley, Leeds, Yorks. Eng. Pat. 1667, Jan. 23, 1896.

132 PARTS of ammonium sulphate and 170 parts of sodium nitrate, slightly moistened if necessary, are heated, with constant stirring, until a temperature of  $108^\circ$ — $110^\circ \text{C}$  is attained, and the partially fused mass is maintained at this temperature for from 3 to 5 minutes. The product thus formed consists essentially of ammonium nitrate and sodium sulphate, but the reaction is not complete, and the patentee states that a similar product is obtained by heating 160 parts ammonium nitrate and 142 parts of anhydrous sodium sulphate to  $110^\circ$ .

The mass is extracted with boiling alcohol (methylated spirit containing 85 to 93 per cent. of real alcohol), to which is added ammonia corresponding to 0.5 per cent. of the alcohol. This ammonia, by preventing the formation of an acid liquid during extraction, enables a purer product to be obtained, and prevents corrosion of the metal portions of the extraction apparatus.

The alcoholic solution contains the ammonium nitrate admixed with about 10 per cent. of sodium nitrate, whilst the insoluble residue consists of sodium sulphate, together with about 8 per cent. of ammonium sulphate.

The mixed sodium and ammonium nitrates are, after evaporation and recovery of the alcohol, washed in an upright cylindrical vessel, with cold water or a cold saturated solution of ammonium nitrate, which dissolves out the more soluble sodium nitrate (see following abstract). The process may be made continuous; the most purified ammonium nitrate discharged from the top of the percolator is, after drying, ready for use.

It contains less than 1 per cent. fixed or solid impurity. The liquid from the percolator is evaporated and the dry salts added to the next material treated; to these is also added the ammonium sulphate recovered from its admixture with sodium sulphate by treatment with boiling water.

—J. T. C.

*Ammonium Nitrate, Impts. in the Manufacture of.* T. Fairley, Leeds, Yorks. Eng. Pat. 1668, Jan. 23, 1896.

THE object of the invention is to obtain a practically pure ammonium nitrate from the mixed nitrates of ammonium and sodium obtained when a solution of sodium nitrate is treated with ammonium bicarbonate or ammonia and carbon dioxide. The separation of the mixed nitrates depends on the fact that at low temperatures sodium nitrate is more soluble than the ammonium salt. The concentrated solution of the mixed nitrates is fed in at the bottom of a cylindrical vessel, externally cooled to about  $-15^{\circ}\text{C}$ , and the ammonium nitrate delivered at the upper end, is purified by washing with cold water or with a cold saturated solution of ammonium nitrate. The liquid remaining from the cooling process is used to dissolve fresh quantities of sodium nitrate for treatment in the ammonia-soda process above mentioned, and the cooling of the solution of the mixed nitrates may be partially effected by saturating the solution obtained in one operation with the dried salts obtained on evaporating the solutions obtained in a previous operation. By this means much of the external refrigeration may be avoided.—J. T. C.

*Silicates of Sodium and Potassium, Nitric and Sulphuric Acids, and Caustic Soda and Potash; Impts. in the Manufacture of.* W. Garroway, Glasgow, N.B. Eng. Pat. 2489, Feb. 1, 1896.

FROM 1 to 2 parts of sand or ground flint is mixed with 1 part of sodium nitrate, or with an equivalent proportion of potassium nitrate, and the mixture is heated in an iron retort, which may be arranged over a pyrites burner when the process is worked in connection with a sulphuric acid plant. Superheated steam and hot air are admitted. The nitric acid evolved may be condensed, or taken to a Glover tower. The alkali silicate formed is lixiviated, and the liquid may be treated with lime to precipitate silica, leaving caustic soda or potash in solution. Any insoluble silicate resulting from the process may be applied in the manufacture of cement. The apparatus employed is shown in connection with a sulphuric acid plant.—E. S.

*Carbonic Acid Gas passing from Lime Kilns and designed for Liquefaction, A New or Improved Process for the Purification of.* A. D. Delsemme, Liège, Belgium. Eng. Pat. 3662, Feb. 18, 1896.

LIME-KILN gases are pumped into high towers, down which streams of water descend, and are then passed into close receivers containing potash lye, which, when saturated with carbonic acid, is heated to recover the gas. The moist carbonic acid is then taken through a refrigerating apparatus to a gasometer, and, before being liquefied in a compressor, is dried by contact with calcium chloride.—E. S.

*Sulphate of Ammonia, Impts. in or relating to Saturators for Use in the Manufacture of.* P. Duggan, Rosher-ville, Kent. Eng. Pat. 5011, March 5, 1896.

THE upper portion of the saturating vessel is preferably cylindrical in shape, but the lower part is made conical or curved, so that the sulphate as it forms, falls towards an outlet situated at the vessel's lowest point, and from this passes into a discharge pipe.

The saturator is fitted with a cover made in parts, hinged together, so that workmen may readily get inside, when necessary. Through this cover pass pipes for the admission of the ammonia gas and sulphuric acid, and an outlet tube is provided for gases or vapours generated in the saturator.

The ammonium sulphate formed, either falls directly into the discharge pipe, through which it is driven by means of an injector and delivered into the drainer, or is discharged by the action of gravity alone. In the latter case the quantity passing out is regulated by a valve or plug worked from the top of the vessel and fitting into the outlet at the bottom of the saturator.

If an injector be employed, the author claims the arrangement by which this injector is applied externally to the vessel forming the saturator.—J. T. C.

*Cyanides, Improved Means for Recovering from Waste Products in Gas, Chemical, and Iron Works.* G. P. Lewis, Catford, Kent, and F. S. Cripps, London. Eng. Pat. 5184, March 7, 1896.

GAS liquor, from which ammonia has been distilled off after addition of lime or an alkali, is run into a cooling tank, and mixed with a solution of sulphurous acid or ferrous sulphate. The mixture is then caused to overflow through an interposed strainer into another tank, in which it is treated with a solution of a copper salt to precipitate cuprous sulphocyanide. To obtain ammonium sulphocyanide from this precipitate, it is treated with the crude ammonium sulphide liquor produced on cooling the waste gases arising from the distillation of the gas liquor, after absorption of the ammonia from them. The copper sulphide resulting, is dissolved to obtain a copper solution for re-use. Potassium or sodium sulphocyanide is produced by using, instead of the ammonium salt, an alkali sulphide obtained by passing the waste gases referred to, through a caustic alkali solution. Sulphurous acid for use in the process, is produced by burning the waste gases in suitable apparatus.

The process may be applied to a liquor obtained from sulphur-free spent iron oxide, by boiling it with lime. The solution, which contains calcium ferrocyanide and sulphocyanide, is treated, first with sulphurous acid, and then with a mixture of ferrous and ferric salts. Prussian blue is thrown down. The decanted liquor is then treated to obtain cuprous sulphocyanide as in the process first described.—E. S.

*Nitrate of Ammonium, Impts. in the Manufacture of, and in the Apparatus therefor.* G. Craig, Glasgow, Scotland. Eng. Pat. 5815, March 16, 1896.

MIXTURES of nitrate of potash or soda with ammonium sulphate are heated together with sufficient water to ensure thorough double decomposition.

The resulting mixture is dried, and the hot, pasty mass well agitated during cooling, so that a loose powder is obtained. From the cold powder, ammonium nitrate is obtained in pure condition by extraction with anhydrous or high-strength ammonia. Owing to the high pressure exerted by the ammonia, strong vessels must be employed, and, to avoid corrosive action by the ammoniacal ammonium nitrate solution, the vessels should be of enamelled iron, or tinned or aluminium-lined iron.

An apparatus is described consisting of extraction vessels and filter and a filtrate-receiving vessel for the ammoniacal nitrate solution. By means of a pump in connection with this latter vessel, the ammonia is recovered by suction, and after compression through a condenser, whereby it is liquefied, it passes again to the extraction apparatus to do fresh work.

To obtain a pure product, the temperature must be low and the ammonia in such excess that it takes up the ammonium nitrate to form a solution containing from 50–60 per cent. by weight of this latter substance.

The cold produced in the filtrate vessel may be utilised in the condensation of the ammonia.

The nitrate of ammonium is removed as a white powder through a manhole in the bottom of the filtrate vessel.

—J. T. C.

*Aluminate of Barium and Aluminate of Strontium, Impts. in the Manufacture of: and the Production of Alumina, Sulphate of Barium, and of Strontium, and other Products from the same.* D. A. Péniaffoff, Huy, Belgium. Eng. Pat. 6096, March 18, 1896.

To obtain barium aluminate, a mixture of barium sulphate, alumina or bauxite, and a metallic sulphide or polysulphide (as barium sulphide or pyrites), is heated, and the sulphurous acid evolved is collected and utilised in lead chambers or otherwise. Formulae are given to show the proportions of the materials to be used in each case. When carbon is employed in the production of the aluminate, the proportions should be so adjusted as to prevent the formation of carbonic oxide, as according to the equation—

in which  $4\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$  is taken as representing bauxite.

The crude barium aluminate obtained, is treated with a solution of an alkali sulphate or acid sulphate, to obtain a solution of caustic alkali and a residue of barium sulphate, for re-use. Or the aluminate may be lixiviated, and the solution precipitated by the alkali sulphate, but in this case, some alumina remains combined with the alkali. Or the barium aluminate solution may be converted into hydroxide by stirring in presence of "crystallised hydrate of alumina," or by vigorous agitation without admixture. All the reactions remain unaltered when barium compounds are replaced by those of strontium.—E. S.

*Carbonic Acid Gas, Improved Process and Apparatus for the Manufacture of.* B. T. L. Thomson, London. Eng. Pat. 6835, March 28, 1896.

STEAM is passed through a heated cylinder, charged with carbon, and the mixture of carbonic oxide gas and hydrogen produced is, after passage through a cleansing vessel, sent into one of a pair of heated cylinders containing copper oxide, or other oxide, capable of acting similarly, where the carbonic oxide is converted into carbonic acid and the hydrogen into steam. The mixture of carbonic acid gas and vapour is then passed into a cooler or washer, whence the gas passes to a reservoir. A pair of oxidising cylinders is provided, so that the reduced oxide in one may be reoxidised by pumping air through it, while the other is being used in the reverse process. The upright cylinders set in fireplaces, with accessory apparatus of pumps, four-way cocks, entrance and exit tubes, &c., are shown.

—E. S.

*Disinfecting, Deodorising, and Bleaching Agents [Hypochlorites produced by Electricity]. Impts. in the Manufacture of, and in Apparatus therefor.* M. Crawford, London. Eng. Pat. 14,852, July 4, 1896.

Is electrolysing sea-water or other saline solution for the production of hypochlorites, it is proposed to obtain greater efficiency by separating the electrodes by porous divisions, agitating the electrolyte, and keeping down the temperature by cooling agents.—J. C. R.

*Crude Acetic Acid, Process for Purifying.* A Schmidt, Cassel, Germany. Eng. Pat. 25,100, Nov. 9, 1896.

THIS process is for the removal of the empyreumatic constituents (tar, sulphurous acid, &c.) from crude acetic acid, and consists in treating the crude, warmed acid with oxygen under pressure.

The apparatus employed, consists of a high, strong-walled charcoal filter with acid-proof lining, fitted with the necessary pressure-regulating apparatus, and capable of being suitably heated. Near the top and bottom of the cylinder are perforated plates; the space between these is filled with charcoal or coke in pieces about the size of nuts.

The compressed oxygen is forced in at the bottom of the apparatus; the acetic acid is pumped in and distributed at the top. The tarry matter of the acid is oxidised to form insoluble resinous substances, which are retained by the charcoal in the filter, and the purified acid passes out at the bottom of the apparatus through a U tube sufficiently deep to correspond to the pressure employed. Any

sulphurous acid present is oxidised to sulphuric acid, which passes out with the acetic acid. The latter acid is finally freed from this impurity by distillation over a suitable quantity of pure sodium acetate.—J. T. C.

*Caustic Soda Solution, Impts. in the Preparation of, from Soda Residues.* F. J. Seyfried, Mulheim-on-Rhine, Germany. Eng. Pat. 26,889, Nov. 26, 1896.

"Pure transparent solution of caustic soda" is obtained by treating the dirty-red solution of soda residues with hydrated lead oxide. But it is preferred to carry out the process by adding a lead solution, as of the nitrate, followed by addition of milk of lime. In practice, two opened drums of the soda residues are immersed in water boiled by steam, and a the decanted solution, brought to a strength of about 40 per cent., is forced by a steam jet into an elevated tank, and a solution of 1 kilo. of lead nitrate is added, and then a bucketful of milk of lime. After subsidence, the clear liquor is drawn off into one of two lower vessels.—E. S.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

*The Acid Clays [Fireclays], Classification of.* Kosmann. *Thonind. Zeit.* 20, [68], 933.

THE silicates of alumina (clays and fireclays) containing in the dry state not more than 36 per cent. of alumina—e.g.,  $\text{Al}_2\text{Si}_2\text{O}_7$ —belong to the acid class of clays, and, by reason of their fusibility, are of less value for firebrick than the silicates—e.g.,  $\text{Al}_2\text{O}_3$ ,  $2\text{SiO}_2$ , and  $\text{Al}_2\text{O}_3$ ,  $\text{SiO}_2$ —richer in alumina. The last-named silicate is highly basic in character, and is on that account well adapted, either in its natural form as Andalusite, or in the condition of hydrate (Allophane), for improving the composition of fireclay, in place of bauxite. All the silicates with more than 36 per cent. of alumina are classed as basic, but in practice a higher percentage than 47 is scarcely attainable.—C. S.

*Fireproof Bricks, Manufacture of.* Diamant, 18, [35], 755–757.

So far as resistance to fusion—one of the most important properties of a fireproof brick—is concerned, it is noteworthy that combinations and mechanical admixtures of alumina and silica, such as occur in natural clay, follow the general rule that compounds fuse at a lower temperature than the arithmetical mean of the fusing points of their components. Further, that although clays rich in silica take longer to sinter at the fusing temperature of cast steel than those poorer in this constituent, they fuse to a cake much sooner than the latter at higher temperatures. This, taken together with the behaviour of the clay in presence of fluxes, indicates that alumina is the chief factor in the production of a refractory material. That the composition of natural fireclays varies considerably is apparent from the analysis of Saarau and Niederpleiss clays, classified by Bischof as 100 and 10 respectively:—

Clay.	$\text{SiO}_2$		$\text{CaO}$	
	$\text{Al}_2\text{O}_3$	In Chemical Combination.	Free.	
	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Saarau.....	36.30	38.94	4.30	0.19
Niederpleiss....	28.05	30.71	27.61	0.72

Clay.	$\text{Na}_2\text{O}$	$\text{MgO}$	$\text{Fe}_2\text{O}_3$	Loss on Calcination.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Saarau.....	0.42	0.19	0.46	17.78
Niederpleiss....	1.39	0.75	1.89	8.66

Firebrick powder consists of burnt fireclay or fragments of fireproof bricks, &c., ground to powder. Fireclays of

low plasticity (such as that obtained at Rakonitz, in Bohemia) are burnt and mixed with raw plastic clays for working up into a good fireproof material. By this process excessive shrinkage is counteracted, the particles of burnt clay forming nuclei of contraction for the surrounding raw clay, and also giving up to the latter in drying the moisture they have previously absorbed, thereby preventing the formation of cracks and fissures in the mass.

The fineness of division of the burnt fireclay is regulated according to the effect desired, coarse angular granules imparting the properties of porosity and power of resistance to changes of temperature, whilst finer particles give cohesion and power of withstanding shock, as well as diminishing the conduction of heat.—C. S.

*Slag Cement, Testing of, for Alteration of Volume, by the Austrian Method.* Mitt. des k.k. Tech. Gewerbe-Museums in Wien, 1896, 317—320.

THE tests usually applied to Portland cement in respect of fineness and binding power are equally available for slag cement, but not so the test for constancy of volume, because the latter material shows a far greater tendency to form shrinkage cracks than does any other hydraulic binding medium. In applying the test to Portland cement, the cake of cement is allowed to remain in moist air for 24 hours after its preparation, and is then heated. In this way much of the uncombined water contained in the mass, and necessary to the final hardening, is expelled; and this favours shrinkage. At the same time the cake tends to develop cracks at the edges, owing to expansion under the action of heat; these cracks are wrongly termed shrinkage-cracks, which latter would always be either in the form of concentric circles or of superficial hair-cracks, and never at the edges. The distortion and crumbling that usually accompany the formation of edge-cracks in the case of Portland cement are absent when the slag material is tested; and this fact renders it impossible to rely upon the evidence of the heat test alone in determining the constancy of volume of the latter. Hence the Austrian method of conducting this test in air is not admissible for slag cements. The steam-heating test is to be recommended for the material in question, owing to the presence of vapour throughout the operation. In testing a Portland cement that is to be used for mortar, the ordinary test, without admixture with sand, gives a satisfactory indication of fitness. But in slag cement, lime is mixed with the finely-divided slag, and if the lime be not sufficiently slaked first, or if it be over-burnt, so that it does not slake until the cement has begun to set, the expansion will cause cracks, owing to the smallness of the space between the fine particles of the material. But if sand were present (as in mortar), the interstitial spaces would be larger, and the expansion might take place without danger. A second test should therefore be applied, using a normal mortar mixture of 1:3 in order to obtain a fair reading.—W. G. M.

#### PATENTS.

*Marble-like Stucco or Plaster-Work suitable for Walls, Ceilings, and the like; Impts. in the Production of, and in Cement Mixtures therefor.* M. Hoeft, Berlin. Eng. Pat. 24,967, Dec. 30, 1895.

STUCCO or plaster-work with a glossy surface is produced by smoothly spreading upon a plaster ground or backing, a cement consisting of an intimate mixture of pure albumin (albumin of eggs or of serum) in aqueous or alkaline solution, burnt lime, and a "lean" or "poor" substance, such as finely divided natural or unburnt gypsum, overburnt gypsum, marble, limestone, or sand, or a mixture of two or more of these substances, and coating the surface of the cement so applied, with a thin aqueous or alkaline solution of the cement.

The cement powder obtained by mixing the albumin in the dry state instead of in solution, in the above mixture, is also claimed.—A. S.

*Cement or Artificial Stone, Impts. in the Manufacture of.* F. Turner, Carnarvon. Eng. Pat. 2223, Jan. 30, 1896.

POWDERED limestone and waste slate dust or stone chip-pings are mixed with water to form a "slurry," which is

spread upon coke in a kiln for absorption of the moisture and rapid drying within the kiln before burning. The mixture may, when in the "slurry" state, be poured into moulds and pressed, for the production of blocks or slabs.

—A. S.

*Marble and Similar Stone [Colouring], Impts. in the Treatment of.* D. J. J. Froment, Brussels. Eng. Pat. 24151, Feb. 3, 1896.

A process for treating marble or other similar stones, in order to give them any coloured shades, veins, and spots, consisting in leaving these stones in one or more baths composed of a solution in alcohol or ether of one or more colours of aniline or other organic colouring materials. The colouring materials are fixed by leaving the coloured stone in a bath of oil or of any other fat stuff, or by applying upon the stone, layers of the same stuff. The absorption of the organic colouring materials and of the fat stuff by the stone, may be accelerated by heating or boiling the bath which contains the stone to be treated.—A. S.

*Artificial Stone, Impts. in the Manufacture of.* J. Grunhut, Leicester. Eng. Pat. 20,432, Sept. 15, 1896.

THE manufacture of artificial stone by (1) mixing together in a dry state, sand, lime, and finely powdered sulphur, placing the mixture while still in that state, in suitable moulds, and then subjecting the mixture to the action of steam, or of sulphur vapour in combination with steam. (2) Mixing together in a dry state, sand, lime, and finely powdered sulphate of iron, copper, aluminium, or ammonium, or sulphide of sodium, placing the mixture, while still in that state, in suitable moulds, and then subjecting the mixture to the action of steam, or of steam combined with sulphate of iron, copper, aluminium, or ammonium, or sulphide of sodium.—A. S.

#### X.—METALLURGY.

*Gold Ores, Refractory Low-Grade, Treatment of, at the Ouro Preto Mine, Brazil.* S. J. McCormick, Inst. Mining and Met. 1897, 1—10.

IN this mine the gold is found associated with iron and arsenical iron pyrites, and with bismuth sulphide. As sent to the mills the ore contains 1—2 per cent. of the former, and assays about  $9\frac{1}{2}$  dwt. of gold to the ton. The crushing is effected by 92 head of stamps of various types, 4,300 tons of stuff being crushed monthly and the total cost of treatment ranging from 17s. to 22s. per ton. The free gold, mixed with pyrites, is caught on blankets placed in front of the mortar boxes; and this auriferous pyrites is further concentrated by passing it twice over blankets placed on a series of strakes. The rich product from these is washed in batéas by six women at 1s. per diem. In one of the mills (a 20-stamp mill), crushing 1,400 tons a month) the pulp from the blankets before the mills, is passed over a series of Frue vanners, which collect about 30 tons per month of concentrates, averaging 1 oz. 18½ dwt. to 2 oz. 17¾ dwt. of gold per ton. Beyond the vanners are blankets which catch a further quantity of gold that has hitherto escaped, and the final tailings assay about 1½ dwt. per ton. The vanner concentrates are chlorinated. In the two other mills (40 and 32-stamps) the first blankets are placed at the head of a series of revolvers, and after these are placed canvas strips, 3 ft. long, that collect a concentrate assaying 3 oz. 4½ dwt., which is then chlorinated. The revolver tailings assay 3½ dwt. and are passed over canvas-covered strakes, which remove another ¾ dwt. Owing, however, to the success of the system first described, the 40-stamp mill is now being supplied with vanners also.

In the chlorination works are two reverberatory calciners used alternately, with a cooling-floor, revolving barrel, leaching and precipitating tanks, and a turbine. 100 tons of concentrates are roasted monthly by six men, working in three shifts of two each. Two tons of roasted material are charged into a barrel with 17½ lb. of chloride of lime, 28½ lb. of sulphuric acid, and sufficient water to moisten the sand, and the mixture is revolved for five hours. The excess of chlorine is expelled from the gold solution by means of a small air-blower, and the gold is then precipitated

by ferrous sulphate. Cuprous sulphide was formerly employed as a precipitant, but its use has been discontinued, because it was found impossible to displace the whole of the copper by gold in the first precipitating barrel, and the separation of the gold from the regulus formed on melting, was troublesome. The treatment of concentrates assaying 2 oz. 11½ dwt. on an average, gives an extraction efficiency of 92 per cent. About 3 tons a month of a rich sand, assaying 32 oz., are roasted and chlorinated, and the extraction in this case is 95 per cent.

The cyanide process has also been tried, both by agitation and by percolation. In the former case 12 cwt. of the unroasted vanner-concentrates were agitated in a barrel for 40 hours with 1,000 lb. of a 1·25 per cent. cyanide solution. The solution was used for four batches of concentrates, and was then passed through the zinc precipitating-boxes to the storage tank, as it still retained 0·3 per cent. KCN and a little gold. About 11 lb. of cyanide were consumed per ton of concentrates. The labour item is small, requiring only the service of the foreman of the mill aided by a small boy; and the working cost is smaller than that of chlorination, but the extraction is only 80–85 per cent. Fresh moist concentrates gave most unsatisfactory results (owing to the absence of air), the best work being done with the dry porous material obtained after draining for three days. In the percolation process, the concentrates were saturated with lime in a cement-lined brick tank, washed until the reaction was just alkaline, and treated with one-third their weight of 0·3 per cent. KCN solution. After draining through, the solution was pumped over the sand again, five or six times a day, and was made up to the normal strength every morning. After a month's treatment, the extraction of gold amounted to 85–90 per cent., and the consumption of cyanide was 13½ lb. per ton of sand. But in the cyanide process, the gold recovered does not agree with the extraction shown by assay, the discrepancy amounting to 1–2 per cent., owing to the failure of the zinc to extract the last traces of gold from the dilute wash-solutions. The cyanide process was only tried because of a threatened dearth of wood for roasting purposes. Experience has now shown that if any royalty had to be paid for the use of the process, it would be more economical to retain the chlorination process even though coal had to be imported from Wales. The actual cost of extracting the gold by chlorination from 100 tons of pyritic concentrates assaying 3·225 oz. is (per ton):—for labour 12·56s., wood 11·2s., chemicals 5·36s., and repairs, 0·544s.; making 29·664s. per ton in all, and the value of the gold extracted is 127. 11s. By cyanide agitation, the total cost is estimated at 23·72s. (labour = 4·88s., and chemicals and zinc = 18·84s.), and by percolation it is estimated to be 24·338s. (labour = 1·92s., chemicals and zinc = 22·418s.), the value of the gold extracted being in each case 117. 12s. It is supposed for the purposes of the last-named calculation that the extraction by chlorination is 92 per cent., and by cyanide 85 per cent.—W. G. M.

*Gold and Platinum Nuggets and Gold Ingots. On the Crystalline Structure of.* A. Liversidge. Proc. Chem. Soc. 1897. [174], 22.

IN view of the theory that gold nuggets are built up of concentric layers deposited round a central nucleus, the author has examined a large number of specimens from various sources. The nuggets were ground down, or sliced through, to obtain sections, which were polished and etched by suitable solvents. They all possess a well-marked crystalline structure, and usually enclose foreign substances. The crystalline structure is not incompatible with an aqueous origin; and the author suggests that the gold has been slowly deposited from solution, either at ordinary or at high temperatures, the nuggets being more or less rolled masses of gold which have been set free from disintegrated veins.

*Gold, On the Presence of, in Natural Saline Deposits and Marine Plants.* A. Liversidge. Proc. Chem. Soc. 1897, [174], 22–23.

THE author gives a preliminary account of the results of the examination for gold of rock salt, sylvine, and other

similar saline deposits, bittern, seaweed, kelp, oyster shells, &c. The process of determination used was to add from 0·5 to 5 grms. of ferrous sulphate to the unfiltered solution of 100 to 1,000 grms. of the salt in water. The resulting precipitate was then scorified with lead and cupelled. The natural salts contained from 1 to 2 grains of gold per ton, whilst kelp and bittern furnished in some cases as much as from 14 to 20 grains.

*Tellurium [in Gold Ores] Occurrence of, in Montana.* R. Pearce, Eng. and Mining J., 63, (5), 117.

THE author has examined for tellurium in an oxidised form, some rich gold ores which show no outward indication of precious metals, but which by assay yielded 21·33 oz. of gold and 93·67 oz. of silver per ton. On treating the ore with hydrochloric acid the whole of the ferric oxide was dissolved, and a residue of white silicious material remained. The solution contained tellurium, indicating a quantity equal to 87·49 oz. per ton. The insoluble silicious portion contained gold and some crystals of sylvanite. These results would indicate that tellurides of gold and silver might occur below the zone of oxidation, and that in this specimen, which was mined near the surface, the tellurides were not completely oxidised.—A. W.

*Tellurium [in Gold Ores] from the Griffith Lode, Colorado.* R. Pearce. Eng. and Mining J., 63, (6), 139.

AN analysis of a mineral recently found in the above mine gave the following result:—Silver, 50·65; tellurium, 18·80; lead, 9·34; copper, 4·65; iron, 4·00; bismuth, 1·16; sulphur, 8·06; magnesium carbonate, 1·95; alloy of gold and silver, 0·48; and insoluble residue, 1·07 per cent.; total, 100·16. It was believed that the gold was combined with tellurium, but on treating the mineral with nitric acid there was no indication of brown sponge gold, which would have been the result if these two elements had been combined. The residue obtained was a bright pale yellow alloy, which proved to be 0·725 fine gold, the remainder being silver. The mineral is considered to consist of a mixture of telluride and sulphide of silver, associated with other minerals, and with the alloy of gold and silver in the quantity mentioned in the above analysis.—A. W.

*Uranium from Residues, Recovering.* A. Gawalowski. Zeits. Anal. Chem. 1896, 35, 678.

THE uranium phosphate residues are dissolved in concentrated sodium carbonate solution, the whole filtered, then ferric chloride added in sufficient quantity to precipitate the phosphoric acid, and again filtered, from the solution magnesia mixture, added in small quantities at a time, separates the rest of the phosphoric acid. After standing 24 hours and filtering, the solution may be at once acidified with acetic acid, or acidified with hydrochloric acid, precipitated by ammonia, and the precipitate, after washing, dissolved in the desired acid.—A. C. W.

*Lead Blast Furnaces, Wall Accretions on.* M. W. Iles. School of Mines Quarterly, Nov. 1896, 18–23.

THE author has investigated the “hangings” on the walls of blast furnaces and has been led to the following conclusions:—Zinc in its various forms and combinations is one of the chief causes of these accretions. Generally speaking an increase in the amount of zinc increases the trouble. Certain salts of zinc are more troublesome than others, the carbonate is the least, whilst the sulphide, especially when associated with galena in a fine state of division, is particularly so.

The finer the particles the more rapid the accumulation. Zinc is found, nearly always, as sulphide in the hangings, though in the lower portions of the furnace where the blast impinges small quantities of zinc oxide occur. The amount of zinc found by the author in these hangings during a period of 17 years averages 18·42 per cent., but the determinations, ranging over a great variety of conditions, varied from 5·3 per cent. to 63·8 per cent.

Experience has shown that it is not advisable to use scrap-iron upon heavy zinc charges, since heated metallic iron decomposes zinc sulphide, though good results have been obtained by the formation of slags containing iron in the

form of a silicate or protoxide. The amount of calcium oxide should be diminished with increasing amounts of zinc, great care being taken to avoid excess of the former, as the hangings accumulate very rapidly in presence of an excess of an alkaline earth.

The author gives the following percentage averages of the various determinations he made in his investigations:—17.26 of  $\text{SiO}_2$ , 13.26 of Fe, 1.60 of Mn, 3.30 of CaO, 10.90 of S, 18.42 of Zn, and 0.80 of Cu.

The fire assay gave as a general average of 17 years:—29.74 oz. per ton (2,000 lb.), silver; 21.06 percent. lead; and 0.197 oz. per ton (2,000 lb.) of gold.

The silica was found to exist both as free silicic acid, mechanically lodged in these hangings, and as silicates. The iron existed as silicate, oxide, and sulphide. The author adds, however, that "the sulphide enters into the hangings as a true constituent, and is a potent factor in the formation of these accretions, whilst the silicate and oxide are merely accidental or incidental."

Manganese existed as silicate, from ore which had become entangled by entering from the top ledge of the hanging. The lime existed generally as such, free and uncombined; as sulphide there was the merest trace.

The sulphur was present chiefly as a sulphide of zinc and lead, which formed the main mass of the hangings. There was always a little sulphate present. The author has from time to time observed many curious and interesting chemical compounds in these accretions; the most interesting being the chloro-bromide of lead.

He recommends the old-fashioned way of taking the gases from the centre of the furnace instead of from the back end wall. Whilst he thinks the ore-thruxes and fuel should be uniformly distributed over the entire top, yet the coarse pieces should be thrown as nearly into the centre as possible; the furnace drives faster, and there is not so much heated gas following the side walls, and hence the tendency towards hangings is much diminished.—O. H.

*Matte, Granulating.* S. E. Bretherton. Eng. and Mining J., 1897, 63, 43.

THE matte, after being tapped from the crucible or settler into an ordinary slag pot, is wheeled while hot, directly over a square wooden tank nearly full of water. Just below the top of the tank, and about 10 or 12 in. above the water, is inserted a 2-in. water-pipe with the end flattened so as to throw a thinner and wider stream. This stream of water (a pressure of 25 to 30 lb. was found to be sufficient) strikes the stream of hot matte and scatters it just before falling into the water, where it settles. The shell should not be allowed to fall into the tank, but in case one should slide out, iron bars are placed across the tank to catch it, these bars not interfering in any way with the stream of matte passing down between them.

By granulating the matte, the expense of breaking, crushing, rolling, sizing through screens, and preparing for roasting or sampling, is done away with, and a product is obtained that will roast to much better advantage than when the matte has to be crushed and rolled.—A. S.

*Spectrographic Analysis of some Commercial Samples of Metals, of Chemical Preparations, and of Minerals from Potash Beds, Stassfurt.* W. N. Hartley and Hugh Ramage. Proc. Chem. Soc. 1897, [175], 46–47.

IN continuation of the work already published (Roy. Soc. Proc., 1896, 60, 393; and Proc., 1897, 13, 11), samples were examined of steel made at Middlesbrough from the blast-furnace metal smelted from Cleveland clay ironstone, and rolled into rails; of alumina and "red mud" separated from bauxite at the British Aluminium Co.'s Works at Larnie, and of the aluminium prepared from the alumina at Foyers and of various commercial alums.

It is shown that of the constituents of the blast-furnace metal, the alkali metals, calcium, copper, silver, gallium, manganese, and lead are present also in the steel, but the chromium and nickel have been removed.

Of the constituents of bauxite, traces of sodium, potassium, calcium, copper, silver, gallium, iron, manganese, and lead are found in the metallic aluminium. These elements

are also present in larger quantities in the "red mud," and in addition, nickel and chromium are present.

*The Alums.*—Examined directly, by heating 0.5 gram. of the dried sample in the oxyhydrogen flame, sodium, potassium, rubidium, calcium, and thallium are found as common constituents, and copper, gallium, iron, and nickel as occasional constituents. On examining the precipitates produced by potassium ferrocyanide in solutions, containing 50 grms. of the alum, strongly acidified with hydrochloric acid, these precipitates were found to contain the elements sodium, potassium, rubidium, cesium, copper, silver, calcium, gallium, thallium, nickel, manganese, besides iron, which was also present in the acid radical. A sample of "aluminoferric" from Messrs. Spence and Sons, Manchester, contained all the elements found in the alums, but in much larger quantities. Of these elements, the pyrites furnished the thallium and also a trace of indium found in a by-product of the manufacture of alum, whilst the other elements were traced to the aluminous minerals, bauxite and shale. The shale was richer in alkalis and gallium than the bauxite, but a sample of French bauxite was richer in silver and lithium than either Irish bauxite or shale.

Samples of Stassfurt minerals were examined in the course of the investigation, and were found to yield spectra containing no lines of rubidium, cesium, gallium, or thallium.

The systematic examination of railway metal by such an analytical method as is here employed, might lead to results of practical importance. The method reveals the presence of small quantities of metals such as copper, silver, gallium, and lead, which have not been considered in dealing with commercial irons, and the influences of which upon the physical properties of these have not been studied.

*Steel, The Bertrand-Thiel Process.* P. C. Gilchrist. Cleveland Inst. of Engineers, Dec. 1896.

THE process consists in doing in two, or in two series of open-hearth furnaces, what has hitherto been done in one furnace, and in employing a temperature sufficiently high to cause the metal flowing from the first series of furnaces to emit a copious reddish-brown fume indicating a combustion of iron. The results are that a quality of steel equal to that from Swedish iron may be made from any non-sulphurous pig; the yield from pig iron may be more than cent. per cent. of the metal charged; and the speed of working is greater per furnace than heretofore. Possibly the speed may amount to 24 charges in as many hours from five 20-ton furnaces, or 480 tons of steel per day of 24 hours. An account of the process has been given by Hartshorne before the American Institute of Mining Engineers; and this was abstracted into the *Iron and Coal Trade Review* for October 27, 1896. The author has studied the working of the system in detail, and has followed several charges through, by sampling and analysing the products at different stages, and the results of the investigation are given in full. It is essential that the temperature should be sufficiently high in the primary furnaces to cause the evolution of brown smoke as the tapped-metal runs down the ladlers; this smoke may be due to the metal being composed of carbide of iron dissolved in fluid iron, and to the latter being so hot that it volatilises freely. At present only one primary and one secondary furnace are being used in the plant at Kladno. The author considers that not less than three, but preferably six furnaces should be used. In the latter case, four would be used to superheat molten metal from the blast furnace, 1 to desilicise and dephosphorise down to 0.1 per cent., and the sixth to reduce this to 0.01 per cent. and to make ready for casting. The metal from the superheating furnace is conveyed to the third furnace, the slag goes into a bogey. In the finishing furnace the remaining phosphorus and carbon are removed.

At present in the primary furnace the ore and lime are added with the charge (in the middle); in the finishing furnace some of the ore and limestone is added with the charge, the balance being introduced if necessary, just before it receives the metal from the primary furnace. In the heats recorded, the charge of the furnace consisted of pig and scrap to the amount of 11 or 12 tons in the

primary and 8 tons in the secondary furnace. The proportion of scrap varied from 0 to 64 per cent., and the loss of metal usually ranged from about 2 to nearly 10 per cent. The time required, varied from  $3\frac{1}{2}$  to  $4\frac{1}{2}$  hours in furnace No. 1, and from 1 to 2 hours in No. 2. In the primary hearth the carbon was commonly reduced by over 1 per cent. (from 2.5 to 3.5 per cent.), and the phosphorus by 0.7 per cent. (out of 1.7 per cent.). In one instance, the phosphorus was reduced in the first furnace from 0.581 to 0.078 per cent. while the carbon remained at 2.57 per cent. Hence it is considered that such a furnace might be used as a feeder to the basic Bessemer converter and that no after-blow would be required. The limits of phosphorus and silicon permissible, are those obtaining in blast-furnace practice, but it would appear to be advantageous to use up tap-cinder and mill-cinder (if made on an oxide or basic bottom) in the Bertrand-Thiel rather than in the blast-furnace. The loss of metal is found to be least when least scrap is used; in one instance a total charge of 20.06 tons of metal (including 30 per cent. of scrap) yielded 20.13 tons of steel. Some of the scrap must necessarily be oxidised in melting, but the oxide is partially or entirely reduced again by the metalloids in the charge. If the oxidation be effected by atmospheric oxygen, the loss must necessarily be considerable not only on account of the removal of metalloids, but because the silicon and phosphorus form acids which combine with lime and some oxide of iron. But when iron ore is used for oxidation, the removal of the metalloids entails the reduction of a greater weight of iron which is thus added to the charge. Thus the more silicon, phosphorus, and carbon there is in the pig iron, the greater will be the weight of steel obtained. It is possible that these good results may be due to the intense heat employed permitting the oxidation of the metalloids and manganese to take place with much more ease and rapidly than formerly; also to the transfer from one furnace to another getting rid of the voluminous slag and enabling the steel to be got ready for casting.—W. G. M.

*Aluminium, Action of Carbon Monoxide and Dioxide on.* Guutz and Masson. Comptes rend. 1897, 124, 187—190.

In preparing aluminium iodide by acting on aluminium with iodine in a stream of carbon dioxide, there is always incandescence, accompanied by absorption of carbon dioxide. The authors find that aluminium alone heated in a stream of the gas absorbs it very slightly, but when two boats, containing respectively aluminium chloride or iodide and aluminium, are heated in the same tube in a stream of either carbon monoxide or carbon dioxide, there is incandescence as soon as the vapour of the iodide reaches the aluminium. An increase of weight amounting to 45.47 per cent. of the weight of the metal took place, and a dirty yellow, not quite homogeneous, substance resulted. This body, decomposed by water, gave off a gas which proved to be methane (but which had an unpleasant odour like that of the gas obtained by dissolving cast iron in acids), and no appreciable residue of carbon remained. The authors give the following equation in the case of carbon monoxide.  $Al_6 + 3CO = Al_2O_3 + C_3Al_4$ .

—J. T. D.

*Aluminium Alloys.* J. Franklin Institute, 143, 145—147.

This paper is a report taken from the *Aluminium World* on the alloys of aluminium with other metals. The useful alloys are in two groups, one with not more than 15 per cent. of aluminium, and the other with not more than 15 per cent. of the other metal in the aluminium. The compound alloys are not generally dealt with. Tin improves strength and rigidity in heavy castings of aluminium; it gives also sharpness of outline with a decrease in the shrinkage of the metal. With from 7 to 10 per cent. of nickel, the best aluminium is produced for casting, where toughness combined with hardness is desired. Two new alloys for jewellery work consist of (1) 20 parts of nickel and 8 parts of aluminium; and (2) 40 parts of nickel, 10 of silver, 30 of aluminium, and 20 of tin. Manganese is one of the best hardeners, and is added as a rich ferro-manganese for castings, and as a pure oxide of manganese to

the electrolytic bath in which aluminium is produced for rolling purposes. Tungsten alloys are specially used for rolled sheets and plates, to be afterwards "spun," and generally in conjunction with other metals, such as copper, iron, and manganese. Aluminium hardened with chromium, retains its hardness after annealing or heating better than almost any other of the alloys. Titanium increases the resilience, and with chromium, copper, and aluminium produces some very hard and tough light alloys. Alloys containing zinc up to 30 per cent. are successfully used. Cadmium does not harden aluminium, but with it produces a solder. Bismuth produces fusible and brittle alloys, which oxidise rapidly when melted.—A. W.

*Nickel and Copper, Separation of, in Matte, and the Recovery of the Contained Precious Metals.* T. Ulke. Eng. and Mining J. 63, [5], 113.

See under XXIII., page 262.

## PATENTS.

*Iron and Steel, An Improved Manufacture of, and Method of Extracting Gold and Silver from Ores.* A. J. Boulton, London. From C. J. L. Otto, Dresden. Eng. Pat. 1016, Jan. 18, 1896.

THE iron or steel is produced by heating spongy iron to a suitable temperature, in a neutral atmosphere, and under high pressure, in a reduction vessel or crucible heated from the outside. The crucible is so shaped that the iron produced may accumulate where the temperature is highest, and it should be arranged so that it may be swung or inclined so as to bring the molten metal more quickly in contact with the spongy iron. When gold or silver is present, the highest temperature is to be kept up till the precious metal is deposited by liquation on the bottom of the crucible. Compressed air is led into the crucible by means of a pipe, and the escaping compressed gases may be utilised for the preliminary heating or calcination of ores, &c.—J. H. C.

*Metallic Alloys, Impts. in and connected with.* J. P. Fullerton and A. B. King-Church, London. Eng. Pat. 2858, Feb. 7, 1896.

THE alloy is composed of lead, 91 per cent.; copper, 1; bismuth, 1; and antimony, 7 per cent.; but the proportions may be varied. It is fusible at a low temperature, expands as it solidifies, and is less subject to corrosion than brass.

In preparing the alloy, the copper is reduced to small particles, which are sprinkled over the surface of a small part of the lead, which is heated to about  $1,990^{\circ}$ , and well stirred in. The antimony is heated in another vessel, and the mixture of lead and copper added; the remainder of the lead is then added, and finally the bismuth. The articles to be made from this alloy (gas and water connections) are cast either in moulds or chills.—J. H. C.

*Metals from Refractory Ores, Improved Process for Obtaining.* J. S. Wallace, Belfast, and J. Castell-Evans, Hornsey. Eng. Pat. 2931, Feb. 8, 1896.

THE process is intended for smelting complex ores containing lead and zinc, and it is proposed, *inter alia*, to extract zinc from blende by the direct action of carbon, with the formation of carbon bisulphide.—W. G. M.

*Zinc, Recovery of, from Blende Ores; Process for.* The Exploring and Gold Mining Assoc., Ltd. From S. H. Emmens, Amador City, California, U.S.A. Eng. Pat. 4432, Feb. 27, 1896.

THE process is stated to be particularly applicable to zinc-leadsulphide ores, such as those of Broken Hill. The crushed ore is so roasted that the zinc sulphide is converted as completely as possible into sulphate, and is then transferred to a series of vats placed in cascade form, each on a slightly lower level than that preceding it. By means of overflow pipes, the excess liquor from the highest vat passes to the bottom

of the next, and, ascending through the ore, overflows to the bottom of the next vat, and so through the series to a reservoir at the end. At the bottom of each vat is a lead anode, and at the top a zinc cathode. In use, alternate vats are connected with an electrolysing current from a dynamo. Thus, at first, water flowing over the ore in No. 1 vat extracts zinc sulphate, and this solution, passing to the second vat, is electrolysed, zinc being deposited and sulphuric acid liberated; the acid liquid then passes through the ore in the third vat (without electrolysis), and, becoming neutralised by means of zinc oxide, is ready to be decomposed by the current in the next tank, and so on. When all the zinc in the ore has been extracted, the sulphate remaining in the solution is crystallised out, and the leached ore is run into settling tanks to await further treatment.—W. G. M.

*Blast Furnaces, The Construction of a Chamber or Receiver to be coupled to Existing, for Smelting Iron from the Ore, and also to New Furnaces.* W. Hutchinson, Manchester. Eng. Pat. 5225, March 9, 1896.

The chamber is built in front of the furnace and furnished with a chimney for the escape of "sulphurous" gases.

—J. H. C.

*Briquettes of Iron Ore or other Iron Compounds, and Process of Manufacturing Briquettes thus made.* L. W. A. Jacobi and G. W. Petersson, of Stockholm. Eng. Pat. 23,958, Oct. 27, 1896.

The crushed iron ores are partly reduced to spongy iron and then formed into briquettes by pressure or percussion, moisture or acids being added when necessary. Any form of furnace may be used for the partial reduction.—J. H. C.

[Gold.] *Slimes, Extracting Precious Metals from, or from other Finely Divided Material containing the same. Improved Method and Apparatus for.* D. White and T. M. Simpson, both of Stawell, Victoria. Eng. Pat. 26,066, Nov. 18, 1896.

The slimes (or ore) are treated with cyanide liquors in closed vessels, preferably conical or pear-shaped. The vessels are placed in series, each being provided with pressure- and level-gauges, and with gratings forming a false bottom, having discharge cocks or valves below. "Gas" is blown, under sufficient pressure, into each vat beneath the grating, and agitates the charge, escaping by a pipe at the top, through which it is led downwards to the bottom of the next vat. The gas is finally forced into another reservoir. Air is usually employed, and rapidly becomes charged with hydrocyanic acid, which is not lost for practical purposes, owing to the repeated use of the same "gas" for agitation. Any vat may be cut out of the series temporarily by means of control cocks, so that the charging or discharging of one vessel does not check the continuity of the whole operation. The agitation permits even the finest slimes to be rapidly treated, and the continued use of the same air for mixing the charges reduces the loss of cyanide below that which is met with in ordinary percolation practice.—W. G. M.

*Gold Saving and Amalgamating Machine, Improved.* G. Dillberg and W. Walker, both of Sydney, N.S.W. Eng. Pat. 26,490, Nov. 23, 1896.

The finely divided ore or material containing free gold is run through a fixed hopper on to the centre of the floor of a very shallow iron pan, rapidly rotated by suitable mechanism. The sides of the pan are somewhat incurved at the top, and the pan is caused to revolve at such a rate that mercury previously placed in it is driven by centrifugal force against the sides. At a short distance above the bottom is a movable cover extending nearly to the outer rim. As soon as the ore is discharged upon the rotating floor, it is driven beneath this cover, centrifugally, to the circumference, and, impinging upon the mercury, passes up the surface of the latter and escapes over the side into a circular apron. In this way gold is amalgamated, whilst, as it is claimed, the mercury is not permanently "split" by the action, owing to its tendency to reunite under the

centrifugal influence of rotation. Platinum or other heavy metal, incapable of amalgamation, remains with the mercury.—W. G. M.

## XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

### (A.)—ELECTRO-CHEMISTRY.

*Voltaic Cell, Two New Types of.* H. Pauling. Zeits. f. Elektrochem. 3, [15], 332–333.

(1.) The first of these is a double-fluid cell with two prismatic electrodes of retort-carbon. One of the electrodes stands in a cylindrical jar 20 cm. high, the other in a porous cell standing inside the jar. The electrolyte inside the porous cell is strong chlorine-water; outside it, concentrated sodium thiosulphate. The initial E.M.F. is 0.64 volt. After short-circuiting for about 50 minutes, it sinks to 0.47, at which it remains for about 5 hours, giving a current of 0.7 ampere. The external electrolyte gradually becomes turbid, owing to separation of sulphur (mainly in the neighbourhood of the electrode immersed in it, which is the anode).

(2.) The second is a modification of the ferric chloride cell. It is made up in a peculiar way so that the iron forms part of the containing vessel. A sheet of iron, 20 cm. long, 7 cm. broad, and 3 mm. thick, is bent twice so as to form three sides of a narrow oblong; the fourth (narrow) side is to be the open top of the cell. On a strong wooden board are placed several layers of sheet-rubber. The bent iron is placed edgewise on these, and inside (but not touching the iron) is placed a plate of retort-carbon of the same breadth and of suitable length. On these are placed more layers of rubber and then another board. The two boards are pressed together by iron clamps or screws. When a battery of several cells is to be made, it is not necessary to have separate pairs of boards for each; one pair of long boards will do for several cells. The iron forms the anode and the carbon the cathode. The electrolyte is concentrated ferric chloride. The E.M.F. is 0.9 volt. When the cell is in action, the ferric chloride splits up into the ions chlorine and ferrous chloride; the chlorine unites with more iron to form fresh ferric chloride:  $3\text{Fe} + 3\text{Cl}_2 = 3\text{FeCl}_2 + 3\text{Cl}_2$ ;  $\text{Fe} + 3\text{Cl} = \text{FeCl}_3$ . The spent liquid can be regenerated by passing chlorine into it and so converting the ferrous chloride into ferric chloride. If we include this in the cycle, it will be seen that the ferric chloride acts as a carrier of the depolariser chlorine, and that the only substances used are iron and chlorine, both of which are cheap. As there is no diaphragm, the internal resistance is very small. A very constant current can be obtained from a battery of such cells arranged as follows, so that the electrolyte slowly flows through them in series. The cells are placed side by side (but not in metallic contact) and nearly filled with solution. Each is then connected with the next by a siphon, which is also filled with ferric chloride solution. From a siphon at the end, the spent liquid drops into an open vessel. The fresh electrolyte drops into the first cell from a 15-litre bottle provided with a stop-cock at the bottom. In the mouth of the bottle is a rubber stopper with an open glass tube reaching nearly to the bottom of the bottle. By sliding this up and down, the rate at which air bubbles enter, and therefore the rate at which the solution drops out, can be regulated. The battery does not emit any fumes or smell. The author states that the battery is much cheaper than any other, and that 900 watt-hours can be produced at a cost of only 25 pf. Nothing is said as to the effect of the ferric chloride upon the rubber, or as to troubles which may arise as the iron of the cells is used up.—D. E. J.

### PATENTS.

*Battery Cells or Vessels to contain Acids or other Chemicals, Impts. in the Manufacture of.* [Asbestos.] D. M. Hawes, London. Eng. Pat. 1228, Jan. 17, 1896.

The cells or boxes are preferably made of woven asbestos coated or impregnated with liquid celluloid, as described in Annison's patent, 19,710, 1891 (this Journal, 1892, 904).

The asbestos fabric so treated is cut into suitable pieces to form the desired vessel, and they are cemented together with liquid celluloid. Powdered asbestos or fibre may also be worked into a dough-like mass by mixing two parts by weight with one of celluloid, and the pulp so formed is moulded by dies into the desired shape.—G. H. R.

*Electrolytic Apparatus. Impts. in. [Covers for Anode Compartments.]* Col. T. J. Holland, Taunbridge Wells. Eng. Pat. 12,149, June 3, 1896.

In tanks used for decomposing solutions of chloride of sodium, &c., so as to produce caustic soda and chlorine gas, to obviate the difficulty of making a gas-tight joint in the covers to the anode compartments, the electrolytic vessel consists of a shallow, open tank, formed of slate or other suitable material, and provided internally with longitudinally extending ledges or narrow shelves, on which rest inverted boxes of earthenware or suitable material, which form removable air-tight covers to the anode compartments. These covers are pierced to receive pipes for the supply of the solution and the withdrawal of the gas, and their sides form porous partitions between the electrodes. The anodes consist of blocks of carbon attached to a rod or bar, bolted to the bottom of the inverted box, and the cathodes are grids of iron or copper-wire basket-work, preferably double, and of U-shape.—G. H. R.

*Accumulators or Secondary Batteries. Impts. in Plates for. [Improved Casting.]* C. Pollak, Frankfurt-on-the-Main, Germany. Eng. Pat. 13,520, June 18, 1896.

The improved plates are cast under pressure in a mould, which is lined with common salt or other suitable material which will stand the temperature of molten lead, and which can subsequently be easily dissolved away. The salt is packed round a pattern or core, which is removed before the casting; or instead of the core, a lead plate of the required shape may be employed, which melts during the casting, and runs into the salt. The plates so produced consist of a core and a porous portion forming a continuous mass of metal.—G. H. R.

*Disinfecting, Deodorising, and Bleaching Agents [Hypochlorites produced by Electricity], Impts. in the Manufacture of, and in Apparatus therefor.* M. Crawford, London. Eng. Pat. 14,852, July 4, 1896.

See under VII., page 240.

*Electric Batteries. Impts. in. [Gas-tight Primary Battery.]* W. Rowbotham, Birmingham. Eng. Pat. 16,268 July 22, 1896.

THE battery is contained in a hermetically sealed outer vessel, which is divided into two compartments, one of which is further subdivided to form a liquid expansion chamber. The battery chamber proper, which contains the zinc and iron elements and the exciting fluid, is at one end, and in this section the carbons are enclosed in porous tubes closed at one end and having an intervening annular space communicating with the middle chamber, which contains the depolarising fluid. The carbons, which are tubular, are closed at their other end, and, passing through this chamber, enter the partition, and communicate with the expansion chamber, into which the depolarising fluid is forced by the pressure of the gases generated during working. The depolariser enters the carbon tubes, where it is utilised until thoroughly exhausted. Valves or other means are provided so that the compartment may be filled or emptied in succession from one of them, while, when full, electrical communication between them is cut off. The exciting fluid is preferably a strong solution of sal-ammoniac or nitrate of soda, while the depolariser consists of a mixture of 1 part of sulphuric acid, sp. gr. 1.790, to from 1 to 6 parts of nitric acid, sp. gr. 1.48.—G. H. R.

*Electrodes [Secondary Leclanché Batteries], Impts. in Peroxide of Manganese and Carbon, and in the Method of Producing the same.* A. Heil, Fränkisch Crumbach, Germany. Eng. Pat. 29,307, Dec. 21, 1896.

ELECTRODES composed of graphite and peroxide of manganese are placed in a chloride solution, free from nitrogen

(magnesium or sodium chloride), and reduced electrolytically; the current is then reversed, "and thereby converts the said electrode into a compound of chlorine." This electrode is for use in secondary (Leclanché) batteries; "no ammonia, and therefore no hydrated oxide of zinc, will be produced in the cell . . . the solution of sal-ammoniac is thereby maintained in its initial proper condition or composition."—J. C. R.

## (B).—ELECTRO-METALLURGY.

*Carborundum [Silicon and Carbon], Manufacture and Development of, at Niagara Falls.* F. A. Fitzgerald. J. Franklin Institute, 143, 81—96.

(See also this Journal, 1895, 755, and 1893, 847.) The furnaces are built of brick, the internal dimensions being about 16 ft. in length, 5 ft. in width, and 5 ft. in depth. The ends are built solidly about 2 ft. thick, through the centre of which pass the terminals, consisting of 60 carbon rods, 30 in. long and 3 ft. in diameter. These two ends are the only permanent parts of the furnace, the sides being built for each operation. The furnace is about half filled with the mixture, care being taken to keep the latter free from contact with the terminals. A semicircular trench of 21 in. in diameter is formed from end to end, the bottom of the trench being a little above the level of the lowest row of carbons. In this trench the "core" is formed, by placing coke kernels of a certain size so as to form a long, cylindrical centre, which is then covered over with further quantities of the mixture to a total height of 8 ft. The current is supplied by the Niagara Falls Power Co., at 2,200 volts, which is transformed into 185 volts before use.

Carborundum is apparently infusible, for after a certain temperature has been reached it is decomposed, without fusion, into carbon and silicon. It is insoluble in water or any acid. Its hardness is between 9 and 10, but nearer the latter, and its specific gravity is 3.23. In making wheels for abrasive purposes, the carborundum is mixed with kaolin and felspar, placed in a mould, and submitted to hydraulic pressure. The wheel is then vitrified by heating in a kiln for 7 days and cooling slowly. With very thin wheels the binding material is shellac. The cost is twice to five times that of emery, but carborundum will do more work, it is said, and do it faster and better than either emery or corundum. At present it has been found unsuitable for grinding and polishing glass, owing to its extreme hardness producing scratches. Carborundum is soluble in molten steel, and Mr. F. Luermann suggests its use as a source of silicon in the manufacture of that metal.—A. W.

*Manganese, Electrolytic Determination of.* C. Engels. Zeits. f. Elektrochem. 1897, 3, [14], 286 and 305.

See under XXIII., page 242.

## PATENTS.

*Electrolytical Apparatus [Deposition of Zinc], Impts. in.* R. Heathfield and W. S. Rawson, London. Eng. Pat. 19,828, Oct. 22, 1895.

IN Eng. Pat. 5537 of 1894 (this Journal, 1895, 756), the inventors describe apparatus for depositing zinc or other metal. Instead of employing a perforated barrel of non-conducting material partly immersed in the electrolyte, they now describe and illustrate a hermetically closed barrel containing the electrolyte, preferably more than half filled, and caused to revolve by resting flanges at its ends on rotating rollers. The anode is placed so as to be centrally insulated from the barrel. The cathode is formed of conducting bars arranged at intervals around the interior of the barrel, but insulated therefrom. Electrode contacts are made by metal discs dipping in mercury, but they may be made by brushes bearing on insulated rings or segments.

—J. C. R.

*Electro-Plating, An Improved Process of Preparing Non-Metallic Substances for. [Coating Non-Metallic Articles.]* T. M. Ash and H. N. Weldon, Birmingham. Eng. Pat. 2327, Feb. 1, 1896.

IF the non-metallic articles to be coated—such as paper, china, glass, or textile fabrics, &c.—are impervious, they are

first dipped into or sprayed with a solution which will give them a coating of silver, and they are then ready to receive an electrolytic deposit of metal by any of the ordinary processes. If the objects to be plated would be injured by the silver-depositing solution, they first receive a coating of copal or other suitable varnish. The silver bath is formed of a mixture of two solutions, formed respectively of 24 grs. of sodium potassium tartrate; and of 35 grs. of nitrate of silver dissolved in water, to which solution pure ammonia is added slowly until it becomes clear, when a further proportion of about 38 grs. of nitrate of silver is added. It is generally preferable to use only just sufficient water to dissolve the salts, but as much as 18 grs. may be added.

—G. H. R.

*Electrodes for Accumulators [Zinc-Plated Copper], Impts. in and in the Construction of Soluble Metal.* W. P. Thompson, London. From J. Julien, Brussels, Belgium. Eng. Pat. 7259, April 2, 1896.

The copper plates which are to form the supports of the soluble electrodes, are electro-plated with copper and then amalgamated with mercury, on which zinc, cadmium, or the like is electro-deposited. It is claimed that the mercury prevents these soluble electrodes from being attacked by the electrolyte, and to render the amalgamation more durable, the base of the electrodes may rest in a layer of mercury. In the case of a tubular copper electrode, its base may be closed by a block of insulating material forming a narrow rim round the tube to contain the mercury.—G. H. R.

## XII.—FATS, OILS, AND SOAP.

*Animal Fats, Contributions to the Chemistry of.* C. Anthon and J. Zink. Zeits. Anal. Chem. 36, 1—17.

THE authors give the tabulated results of a number of analyses of the fats obtained from 26 animals of different species, which are not frequently met with. The figures are the averages of several analyses. In most cases the fats from several animals of the same species were mixed together, the analysis being made on the mixture. As may be seen in the table given in the original, the specific gravity of the fatty acids is sometimes higher and in other cases lower than that of the corresponding fat. The melting and solidifying points of the fatty acids are higher than those of the fats themselves, whilst the iodine figure is generally lower. With many of the fats the acidity does not appreciably increase as the fat grows old; in other instances—fox, cat, and hare fats—it increases to a considerable extent. The iodine numbers and, in most cases, the acetyl numbers of the domestic animals are lower than the corresponding figures of the wild animals of the same species. A comparison of the results obtained with the fat of a wild goose and that of a wild goose kept in captivity is interesting. It was found that hare, wild rabbit, wild boar, and black-cock fats have drying properties, and that they contain linolic and linolenic acids. The fat of a wild boar is in this respect very different from that of the ordinary pig.

—W. P. S.

*Japan Wax, Adulterated.* C. H. La Wall. Amer. J. Pharm. 69, 18, and Pharm. J. 1897, 58, 83.

OF 59 cases containing 205—225 lb. each, 25 were found to be adulterated with starchy material to the extent of 20 to 25 per cent. The specific gravity of the adulterated product was slightly higher than that of the genuine fat (or Japan wax), and it was as a rule, free from the peculiar network of minute cracks which usually characterise the surface of cakes of pure Japan wax.—A. S.

*Fatty Acids, Note on Wechsler's Method for the Separation of.* A. W. Crossley. Proc. Chem. Soc. 1897, [174], 21—22.

See under XXIII., page 263.

## PATENTS.

*Oil from Fish, Fish Refuse, or other Oil Producing Animal or Vegetable Matters; Impts. in and Relating to the Extracting and Recovering of.* J. J. Jack and M. Blake, Greenock. Eng. Pat. 2511, Feb. 4, 1896.

A METHOD of flotation and precipitation, in which use is made of the different degrees of density of liquids or semi-liquids, as applied to the extraction of oil from fish, fish refuse, or other oil-yielding animal or vegetable matters. The process is carried out in a series of vessels, or compartments of a single large vessel, to which heat is applied by means of steam or hot water, either circulating through coils, or introduced into a jacketed space surrounding the vessels, &c. In working the apparatus, the flow of the steam or hot water is so regulated by valves, &c., connected with the vessels, &c., that any desired temperature can be maintained in any or all of these. However, for the object directly in view, the greatest heat is to be applied to the vessel or compartment forming the last of the series, in which the process within the vessels terminates, the temperature in each preceding vessel, &c., gradually decreasing until the first is reached. The tops of these vessels are set level with each other, and there are sight-glasses to indicate the levels of the various constituents in each vessel, as well as run-off pipes, siphon-pipes, and cocks for each. There is finally a suction-pump, which serves the different vessels, and is so arranged that all or any part of the contents in any one tank can be transferred to all or any one of the others in the series if required.—J. J. K.

*Oil from Seeds or other Oleaginous Substances, Impts. in the Method of and Apparatus for Extracting.* W. R. Harrison and E. Stephenson, Hull. Eng. Pat. 7379, April 7, 1896.

"An apparatus or plant," is claimed "for extracting oil from seeds or other suitable oleaginous substances by means of solvents," such as benzoline, naphtha, &c., "and for recovering and re-distilling the solvent concurrently with the extraction of the oil, and also for converting the residuum into meal, the employment of gas generators, oil extracting kettles (with internal stirrer and sweepers) condensers, air extractors, and air receivers, oil separators, store tanks, bubble tanks, and water pressure tanks together with connecting pipes, receivers, cocks and valves, worm and band or other conveyers and hoppers, the whole apparatus driven by any suitable gearing."

—J. J. K.

*Fatty Matters from Certain Animal Tissues, Impts. in the Manufacture of.* J. Davidson, Sydney, New South Wales. Eng. Pat. 25,472, Nov. 12, 1896.

FATTY tissues of cattle are digested with steam under a pressure of 30—100 lb. per sq. in., until the cellular tissue is broken up, and the fat liberated. Whilst under pressure, the "soup" and fat in a liquid state are blown out, and sent through a centrifugal separator so as to ensure the separation of all the fat.

The claim is for "An improved manufacture of fatty matter from fatty tissues of cattle, consisting in treating the crude fatty products, obtained by boiling these tissues, with hot water and steam, and straining them in a basket-centrifugal, and treating the fats obtained from the product in a centrifugal separator."—J. J. K.

## XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

### (A.)—PIGMENTS, PAINTS.

#### PATENTS.

*White Lead Pigments, Impts. in the Manufacture of, and in the Separation of Metallic Lead [with Recovery of Silver], from Lead Sulphide.* A. Macdonald, Notting Hill. Eng. Pat. 25,133, Nov. 9, 1896.

THIS is a modification of Eng. Pats. 2583 and 11,972, 1893 (this Journal, 1894, 401 and 893). The fused galea has a current of air and steam, either together or separately,

blown over its surface, whereby a basic sulphate of lead,  $2 \text{PbSO}_4 \cdot \text{PbO}$ , is sublimed, a portion of the metal is reduced, and some  $\text{SO}_2$  is evolved and can be collected for further use. The basic sulphate forms an excellent pigment, and the reduced metal retains all the silver existing in the original ore.—F. H. L.

*Distempers or Colour Washes, Impts. in.* W. A. Hall, Bellows Falls, Vermont, U.S.A. Eng. Pat. 28,233, Dec. 10, 1896.

This patent describes the preparation of a distemper or colour wash, which becomes "insoluble," waterproof, and very hard on drying. It is kept in the form of a powder, and needs only suspension in water to be ready for use. The pigment consists of tale or about equal quantities of tale and whiting; the adhesive portion is composed of 60 per cent. of dry casein and 40 per cent. of slaked lime; and the ingredients are finally mixed together in the proportion of 90 per cent. of the pigment and 10 per cent. of the casein-lime cement.—F. H. L.

#### (B).—RESINS, VARNISHES.

*Gamboge, Composition of.* G. Sassinari. Pharm. Centralh. 1896, 36, 768.

The following constituents were found in gamboge: a gum analogous to acacia gum; a volatile oil boiling between  $160^\circ$  and  $210^\circ \text{C}$ ., and containing a terpene and a camphor (this oil appears to be noted for the first time); isovitinic and acetic acids; a phenolic ester; a resin; methyl alcohol and other higher homologues, and a liquid with a fruity odour having a high boiling point and presenting the characters of an aldehyde or of an acetone. Phloroglucinol, previously recorded as a constituent, is considered to be a decomposition product.—J. O. B.

#### PATENT.

*Turpentine from Wood and Wood Waste, Improved Process for Obtaining.* A. Schmidt, Cassel, Germany. Eng. Pat. 26,015, Nov. 18, 1896.

The dried sawdust of wood, rich in resin, is formed into briquettes, heated in retorts to  $120^\circ \text{C}$ ., and subjected to a current of dry steam under slight pressure so long as turpentine continues to be evolved. The steam is then shut off, and the distillation finished in the usual manner.

—F. H. L.

#### (C).—INDIA-RUBBER, &c.

*Isoprene [From Destructive Distillation of India-rubber], Constitution of.* W. Ipatiew and N. Wittorf. J. Prakt. Chem. 1897, 55, 1.

In the dry distillation of india-rubber the hydrocarbon isoprene,  $\text{C}_5\text{H}_8$ , is obtained. Isoprene polymerises to dipentene and other products similar to india-rubber; the authors find that the hydrocarbon unites with hydrobromic acid to form a dihydrobromide identical with  $\beta$ -dimethyltrimethylenedibromide  $(\text{CH}_3)_2\text{CBr} \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}_2\text{Br}$ . On the assumption that the carbon chain is an open one, isoprene must thus be unsymmetrical methyldivinyl,  $\text{CH}_2 \cdot \text{C}(\text{CH}_3) \cdot \text{CH} \cdot \text{CH}_2$ , the addition of the second hydrobromic acid molecule taking place in a manner contrary to general rule.—A. C. W.

*Isoprene, Constitution and Syntheses of.* W. Ipatiew. J. Prakt. Chem. 1897, 55, 4.

By the action of alcoholic potash on  $\beta$ -dimethyltrimethylenedibromide (prepared by addition of hydrobromic acid to isoprene or dimethylallene), a hydrocarbon is formed which has no action on ammoniacal cuprous chloride or silver nitrate, and thus cannot be a mono-substituted acetylene. It cannot be a di-substituted acetylene, because its boiling point is lower than that of any of the hydrocarbons,  $\text{C}_5\text{H}_8$ , of that series. The product should be dimethylallene  $(\text{CH}_3)_2\text{C} \cdot \text{C} \cdot \text{CH}_2$ , but boils at  $33^\circ$ – $34^\circ$ , whilst the former body boils at  $40^\circ$ – $41^\circ \text{C}$ . The substance is isoprene, which thus must have the constitution given in the preceding abstract.—A. C. W.

See under XXIII., page 264.

*Fermentation Phenomena in Tan Liquors.* F. Andreasch. Imp. Research Laboratory, Vienna. Der Gerber, 22, [513], [514], [524], and [525].

(See this Journal, 1896, 910; 1897, 52.) After the previous general consideration of the fermentation phenomena in tan liquors, the author gives results of the examination of some typical liquors to show the connection between the organisms present and the acids found, and the progress of the fermentation in sole leather colouring pits worked on the old and new systems. For the first examples, characteristic liquors were chosen, the preparation, age, and character of which were known.

Sour oak liquors from a Rhenish tannery:—

I. Sour liquor of the third layer, five months old, contained per 100 c.c. 0.63 grm. of acetic acid; traces of lactic acid;  $\text{CO}_2$  found qualitatively to be present; alcohol found in the distillate.

Bacteriological result: Saccharomycetes, Bact. aceti, Mycoderma vini, two milk-coagulating bacteria, a mould, sarcina, and micrococcus plumosus.

II. Sour liquor nine months old:—Acetic acid 0.79 grm. per 100 c.c., lactic acid 0.41 grm., traces of  $\text{CO}_2$  and alcohol.

Bacteriological result: Alcohol yeasts, B. aceti (in small numbers), lactic bacteria and yeasts in large numbers, mycoderma, forming a thick pellicle.

Sour oak-bark liquors:—

1. Eight months sour bark, third layer:—Acetic acid 0.34 grm. per 100 c.c., lactic acid 0.26 grm., tannin 0.51 grm., non-tannin 1.08 grm.

Bacteriological result: Yeasts in enormous number, few acetic bacteria, lactic acid bacteria and yeasts, the latter predominating, isolated cells of mycoderma.

Similar liquor, first layer:—Acetic acid 0.52 grm. per 100 c.c., lactic acid 0.28, traces of  $\text{CO}_2$ , alcohol found qualitatively, tannin 0.18 grm., non-tannin 1.72 grm.

Bacteriological result: Alcohol yeasts, mycoderma, acetic bacteria in large quantity and growing strongly, lactic organisms in small quantity.

The two following tables show the regular increase of acids during the use of the liquors and the simultaneous decrease of the soluble non-tannin. The decrease of tannin is proportional to the progress of the tanning process.

The influence of the mode of preparation is easily seen. [The old method of preparing liquors and tannin having been entirely discontinued in this country, the author's remarks on the subject are omitted.]

These analyses illustrate the conclusions previously given (see this Journal, 1896, 910). The next part of the research was to examine the action of the most frequently occurring typical species of bacteria on pure tan liquors, to ascertain the special conditions required to bring them to proper development, and finally to employ the results in practice.

It is of the highest importance to know whether the tannin is decomposed by bacteria and thus lost as a leather producing agent. It has been assumed, and in a few cases shown that certain tannins are not decomposed when the liquors undergo fermentation, but the question cannot be considered as settled. With the object of deciding this, the author examined the following tanning materials: oak, pine, willow and hemlock barks, quebracho and oak wood,

*Oak-Pine Bark Liquors, prepared by Cold-Leaching (Battery).*

	Acetic Acid.	Lactic Acid.	Tannin.	Non-Tannin.	Remarks.	Bacteriological Result.
	Grms. per 100 c.c. of Liquor.					
I. (Strongest)	0.39	0.45	1.83	2.88	Strong evolution of gas. Alcohol and CO <sub>2</sub> found.	Bottom form. Yeasts, B. aceti, no mycoderma, few lactic acid organisms.
II.	0.40	0.45	1.50	2.48	Slight evolution of gas ...	Yeasts, B. aceti, and lactic organisms, principally yeasts.
III.	0.42	0.51	1.27	2.31	.. ..	Increase of acetic and lactic bacteria.
IV.	0.48	0.58	1.08	2.14	.. ..	Acetic bacteria and lactic acid yeasts ceased to develop.
V.	0.56	0.58	0.92	1.98	.. ..	Increase of lactic bacteria and mycoderma.
VI.	0.56	0.63	0.78	1.82	Pellicle of mycoderma begun to form.	Lactic acid bacteria, sarcina and mycoderma in large numbers.
VII.	0.44	0.65	0.64	1.67	Thick pellicle of mycoderma.	Progressive increase of lactic organisms, moulds, diminution of acid owing to the fresh hides taking it up.
VIII. (first colouring pit).	0.47	0.48	0.58	1.53	Mycoderma pellicle, mould growth beginning.	

The relatively high acidity of the first colouring liquor (five days old) is caused by the use of sour liquors and sour material in the leaches.

sumac, gall-nuts (knoppern), and aleppo galls, valonia, myrabolans, and divi-divi. Infusions of these were used of two concentrations, one containing double the amount of tannin of the other.

The non-tannin was separated by precipitating the tannin (a) by hide powder, (b) by magnesia. The tannins of galls, myrabolans, sumac, and pine and oak barks were prepared by the methods of Böttinger, Etti, and Löwe, and their purity tested by the gravimetric method and precipitation with ignited magnesia. Löwenthal's method appeared to be unsuitable for estimating the non-tannin as a control. The infusions were inoculated with the following organisms. *Fungi*: Alcohol yeasts, Torula, Mycoderma, *Penicillium glaucum*. *Bacteria*: Various lactic acid bacteria and air germs. A few inoculations were made with B. aceti, which confirmed the conclusion that these ferments do not decompose the tannin. Putrefactive ferments as specific consumers of nitrogen were excluded from the research. Changes of composition were supposed to take place in the liquors in the absence of bacteria, therefore in each experiment, sterile infusions exactly similar to those inoculated were put aside for comparison in order to eliminate any such influence from the result. The solutions, after sterilising in the steam steriliser (both inoculated and uninoculated), were kept in the incubator at 30° C. for 50 days. All the materials prepared as above gave negative results with regard to the fermentability of the tannin, by any of the organisms.

The solutions were examined microscopically to ascertain the growth of the organisms.

The fermentation products were estimated by comparison of the amount of substance not precipitated by magnesia before and after the fermentation. The sugars were estimated by Fehling's solution after treating with magnesia and inverting. Alcohol was shown qualitatively by the usual iodoform reaction and quantitatively by the capillary method of Vallon.

CO<sub>2</sub> was weighed after absorption by soda lime. Acetic acid was distilled off, and the distillate titrated with NaOH. It was identified by concentrating the neutralised distillate and adding ferric chloride (blood red colour). Lactic acid

was estimated by treating the residue of the fermented solution after distillation, with freshly ignited magnesia to form magnesium lactate, and estimating the Mg as pyrophosphate.

The result of the researches shows that of the organisms employed, only *Penicillium glaucum* decomposed tannin, and that the whole of the fermentation products are produced from the non tannin present in the solutions. Infusions of sumac, myrabolans, and divi-divi produced large amounts of alcohol. Infusions of double strength produced twice the amount of alcohol, the increase of tannin having no effect on the fermentation.

A table, giving the principal figures obtained during the researches will be given in the April number of this Journal.—J. T. W.

## PATENTS.

*Catch, Impts. in Preparing for Sale and for Use.* J. R. Carruthers, Tradeston, Glasgow. Eng. Pat. 3178, Feb. 12, 1896.

See under VI., page 238.

*Leathers, for their Better Preservation and Surface Preparation: Impts. in the Treatment of.* F. B. O. Ilawes, Weybridge. Eng. Pat. 3901, Feb. 20, 1896.

The leather is impregnated and surfaced with a solution of celluloid instead of the usual varnishes, &c. The resulting material is claimed to be water- and acid-proof, and also very durable.—F. H. L.

*Tanning Hides, Skins, or the like: Impts. in the Process of.* [Rapid Tanning.] J. Blunck, Warsaw, Poland. Eng. Pat. 16,764, July 28, 1896.

In this rapid tanning process, the skins or hides are unhaired and limed as usual, and are then "mordanted" by the use of common or rock salt, and thus rendered suitable for the reception of the tan liquor.

The tanning liquor is made up from extracts of the usual barks, myrabolans, valonia, divi-divi, gambier, quebracho wood, &c., until it reaches a certain specific

gravity, for instance, 4° B. To it is then added common salt, until another desired specific gravity, e.g., 8° B. is reached.

It is stated that, in such liquor, the skins or hides may be tanned in from 1-8 days without any agitation at all, whether of skins or vats, being necessary: the quantity of salt solution which is to be added to the tan liquor being "regulated according to requirements," and the duration of the resulting tannage being thereby "shortened at will."

—E. R. B.

*Rapid Tanning of Hides, Process and Apparatus for the, applicable also for Dyeing and otherwise treating Leather.* H. L. J. Roy, Paris, France. Eng. Pat. 2572, Feb. 4, 1896 (date claimed under sect. 103 of Act, July 4, 1895).

THE plant described consists of a broad endless band, carried upon and moved by, a pair of revolving drums, and since the band has to sustain great weight, suitably placed rollers assist in its support. The band is made up of rods, disposed transversely to its travel and connected together at their ends by links. Upon the rods are threaded loops, which, in their turn, are attached to suitable parts of the hides.

The whole plant is arranged above a pit containing the tanning liquor, and, when the apparatus is in motion, the hides follow the travel of the band; depending from it into the tanning liquor, from its lower limb, lying upon its upper limb, and descending and ascending at the two ends respectively. When the band descends at the front end of the plant, the hides would slip down heavily towards the pit with injurious consequences, were it not that, here, spring rollers keep the hides against the descending band.

To control the temperature of the tanning liquor and to ensure its circulation in the pit, the patentee employs a "thermo-siphon." This is a U-tube, one of the limbs of which receives liquor from the bottom of the pit, while the other returns it to the top of the pit; the latter limb is heated.

The tannage may also be assisted by electric action. In this case the rollers of the lower limb of the band are in contact with copper strips attached to the framework of the plant, and the rods and loops constructed of materials which are conductors, the anode being placed in the pit.

As to his process and its rationale, the inventor remarks that, while securing rapidity of tanning, he has succeeded in preserving, as far as possible, the beneficial effects of the ordinary hand operations of tanning, viz., the lifting of the hides from the pits, the laying of them one upon the other, and the replacing of them in the pits. He objects to the use of revolving drums and barrels conjointly with strong tanning liquors, as in other rapid tanning processes, stating that though leather of great suppleness may be obtained by these processes, yet that such leather is porous and spongy, in consequence of the irregular movements and violent shocks which attend such processes, tending to break or to injure the fibres of the hides. With most heavy leathers, it is necessary to preserve the initial stiffness and strength of the fibres, and it has been found necessary therefore to still adhere to the old costly, laborious, and slow method; no assistance, in the case of these leathers, having hitherto, in the patentee's opinion, been rendered by modern rapid tanning processes.

As to the rapidity of his process, the patentee states that, in ordinary tanning, it is usually considered necessary to lift and replace a hide 100 times during 30-45 days, while, with his machine, using suitable tanning liquor made up from extracts to strengths of 0-6° B., with the assistance of heat, and in some cases with that of electricity, an ox hide of average weight can be readily tanned in 48 hours; hides in the crust, split hides, and horse hides in 24 hours; and calf skins in six hours. When working with a linear speed of 18 metres per hour, 120 hides, it is said, may be treated at once; so that one machine, working only by day, could readily tan 1,000 hides per month.

The inventor also describes another form of machine with only one drum and no endless band. Here the hides are attached to wood strips, which form the periphery of the revolving drum.

The inventor also claims the use of the machines for treating skins, hides, or leathers with other liquors, e.g., in dyeing and other processes.—E. R. B.

## XV.—MANURES, Etc.

### PATENTS.

*Apatite and other Mineral Phosphates, Impts. in the Treatment of, and Manufacture therefrom of Products suitable for Fertilising Purposes.* J. G. Wiborgh, Stockholm, Sweden. Eng. Pat. 2678, Feb. 5, 1896.

THE apatite, or other phosphate, is pulverised and mixed with a sufficient quantity of caustic alkali or alkaline carbonate, and the mixture subsequently heated to a red or yellow heat in a suitable oven in order to get a tetra-calcium-sodium (or potassium) phosphate produced according to the following formula:—

About 20 per cent. of carbonate of sodium is required for a pure apatite; should felspar (or silicic acid) be present, more alkali, up to 30 per cent., must be added.

The tetra-calcium-sodium phosphate is insoluble in water, but is easily soluble in Wagner's ammonium citrate solution.—J. T. C.

*Superphosphates, Process and Apparatus for the Drying and Disintegration of.* O. Heymann and A. Nitseh, Breslau, Germany. Eng. Pat. 24,776, Nov. 5, 1896.

THE large moist lumps produced by the action of sulphuric acid on raw phosphates are, as soon as formed and while still hot (about 96° C.), lifted by means of an elevator and transferred through a shoot into a revolving disintegrating cylinder, the shell of which is formed of wire netting of suitable mesh.

Hot air may be introduced into the cylinders, and the angle at which the cylinders are placed during the operation is adjusted according to the nature of the material treated.

The dried and disintegrated material passes through the meshes of the cylinder wall and is conveyed away through a second shoot, or, if necessary, into a second rotating cylinder, in which it is reduced to any desired degree of fineness.—J. T. C.

## XVI.—SUGAR, STARCH, GUM, Etc.

*Cane Juice, Nature of the Reducing Substances of.* H. Pellet. Bull. de l'Assoc. des Chim. de Sucre et de Dist. 1896, 14, 562-568.

IN a recent paper (this Journal, 1896, 730), Prinsen Geerligs maintains that for the study of the reducing substances present in the sugar cane, the fresh juice and not the molasses, which may contain sugar inverted during the manufacture, should be employed. He concludes that in the juice of unripe canes containing little saccharose the reducing bodies are composed of dextrose and levulose in approximately equal quantities, but that the quantity of levulose diminishes with maturity, so that in juice from ripe canes there are only traces of levulose. The present author explains that there are molasses in which the proportion of glucose arising from the transformation of sugar during working corresponds to only 16 or 18 per cent. of the total glucose, and at times much less; that such molasses give, by Pellet's method, notable quantities of levulose, which quantities correspond, moreover, to those necessary to form invert sugar with the dextrose present. The use of basic acetate of lead in all his experiments has vitiated the results of Prinsen Geerligs, in spite of subsequent treatment with sulphate of soda; for solutions containing invert sugar show higher dextro-rotations in proportion as more acetate of lead is used. But by using normal acetate of lead for the clarification of cane juice, and taking account of the action of raffinose, the reducing bodies are found to have the same effect on polarised light as invert sugar.—L. J. de W.

*Sugar Liquors, Solubility of Barium Sulphite and Sulphate in.* J. Weisberg. *Bull. de l'Assoc. des Chim. de Suer. et de Dist.* 1896, **14**, 560—561.

THE author having studied the solubility and stability of sulphite of lime from the point of view of the sugar industry, has been led to examine the solubility of barium sulphite and sulphate. He concludes that:—

(1.) Barium sulphite is almost insoluble in water and sugar liquors (10 and 30 per cent.), both hot and cold.

(2.) Barium sulphate is even less soluble than the sulphite.—L. J. de W.

*Soluble Starch and Starch Solution, Preparation of.*

O. Foerster. *Chem. Zeit.* 1897, **11**.

To prepare soluble starch, boil 200—300 c.c. of water with addition of 5 c.c. of hydrochloric acid of sp. gr. 1.124, remove the flame, and add, in a thin stream, 20—25 grms. of starch rubbed to a paste with water, stirring continually. Heat with stirring, until the liquid is clear, let cool, filter, precipitate and wash with alcohol until the chlorine reaction disappears; then replace the alcohol by ether, dry in the air, and finally over sulphuric acid.

Starch solution is similarly made, using a measured quantity of acid, the neutralised and filtered solution being made up to one litre with glycerin. The stability of the solution may be increased by evaporation of excess of water after the addition of glycerin.—A. C. W.

*"Osmose Water": A Condensed Acid Water obtained by the Evaporation of.* K. Anderlik. *Zeits. Zuckerind. Böhmen.* 1897, **21**, 287—292.

UNDER normal conditions, the condense waters of sugar factories show an alkaline reaction, which is due to the presence of ammonia partly combined with carbonic acid. In seasons when the meteorological conditions are unfavourable to the growth of the beetroot, the phenomenon called "loss of alkalinity" has been observed, the saturated juice, on concentration, yielding neutral, or even acid liquors, unless corrected by the addition of sufficient soda. Jesser sought to explain this loss by the presence of a larger amount of nitrogenous matter, which, acted on by lime, gave off ammonia during concentration, and the natural alkalinity being less than usual, was totally used up by the decomposition of the invert sugar. These researches led to the distinction between permanent and temporary alkalinity. Under these circumstances, the sugar manufacturer, in order to avoid acidity of his syrups, must seek to maintain, immediately on saturation, a permanent alkalinity. This may be effected either by the action of sufficient lime or by addition of sodium carbonate.

According to the statement of experts, a similar change occurs in concentrating osmose waters, which give water of condensation of an acid reaction. This acid condense water is recognised by a turbid, brownish appearance, from separation of basic iron salts of fatty acids. 100 c.c. of the water required for neutralisation 14.8 c.c. of decinormal KOH. 20 litres were neutralised with soda, concentrated to 500 c.c., and filtered. The residue was found to be essentially hydroxide of iron with a little formate, the other salts having been decomposed during the evaporation with soda. Of the acids in the filtrate, 91.24 per cent. was acetic acid, 3.23 formic acid, and 5.33 higher fatty acids. The acetic acid in one litre of the original condense water was 1.01 gm.—L. J. de W.

*Certain Gums, On the Origin of the Coloration of.* E. Bourquelot. *J. Pharm. Chim.* 1897, **5**, [6], 164.

THE varying brown colour seen in a greater or less degree in most gums, is considered by the author to be due to the action of an oxidising ferment which they all contain, and which, in the presence of moisture, acts on the astringent matter in disintegrating portions of the bark they traverse; forming a soluble colouring matter which tints the exuding gums. This theory explains the fact that the whiter gums are always produced from dryer regions, or are exuded during the dry season, whilst the darker gums come from moister localities or may be obtained in the wet season. Further, in any lot of natural

gum, great variation in depth of colour will be observed. The author has previously demonstrated that Senegal gum is rich in an oxidising ferment, reacting with such bodies as guaiacol and acetyl-guaiacol, cresol, and other phenols. The same or a similar ferment is found in Soudan, Cape, and Brazil gums.

It is found that solutions of these gums produce a deep coloration with astringent extracts, such as that of cinchona, and further, that small pieces of solid white gum placed in solutions of such extracts become brown and lose their transparency, resembling the brown pieces of natural dark gums. Many of these natural coloured gums give evidence of a trace of a tannin, and if extracted with alcohol, the solution will give the familiar reaction with ferric chloride. White gums give no such reaction.—J. O. B.

## PATENTS.

*Sugar and other Syrups, Impts. in and Relating to Boiling of.* E. Shaw. Bristol. Eng. Pat. 1960, Jan. 28, 1896.

THIS invention relates to apparatus for boiling sugar, glucose, and like syrups through the agency of steam. It is well known that it is more advantageous in sugar boiling to apply heat more rapidly at particular stages in the boiling process than at others, and, further, to vary the degree of heat according to the class of syrup being boiled. These ends are facilitated and more effectually performed by the provision in the steam supply-pipe to the jacket of the pan and to the coil, or either, of a reducing valve whereby the pressure, and consequently the temperature, of the steam is capable of being regulated and varied at will from the full working pressure down to any desired degree.—L. J. de W.

*Molasses and other Saccharine Liquors, Process for the Extraction of Sugar from, by Means of Barium Hydroxy-Sulphide, and the Regeneration of the Latter from the By-products formed.* W. Feld. Linz am Rhein, Germany. Eng. Pat. 6508, March 24, 1896.

WHEN caustic baryta is used for extracting sugar from molasses, there is a difficulty in regenerating it from the carbonate obtained. The present invention offers an agent capable of being easily regenerated.

Barium hydroxysulphide added to molasses at 60° to 100° C. precipitates barium saccharate,  $\text{BaO} \cdot \text{C}_{12}\text{H}_{22}\text{O}_{11}$ , leaving barium hydrosulphide in solution. After filtration, the saccharate is decomposed by sulphurous or sulphuric acid, or if carbonic acid is used, the carbonate is afterwards converted into the sulphite or sulphate. The lye separated from the saccharate is treated with carbonic acid, yielding sulphuretted hydrogen, which is burnt to sulphurous or sulphuric acid. If the available carbonic acid is so weak that the sulphuretted hydrogen would not burn, the hot lye is treated with magnesium sulphite or sulphate. The precipitate of barium salt and magnesium hydrate is treated with carbonic acid, as the magnesium carbonate filters more easily. It is then converted into sulphite or sulphate, and thus separated from the barium sulphite or sulphate for use again.

The barium sulphite or sulphate obtained in any stage of the above process is heated to redness with charcoal. The melt obtained, on treatment with water, yields again barium hydroxysulphide. —L. J. de W.

*Molasses of Raw Beet-Sugar, Process for the Production of a Food of a High Nutritive Value from.* J. Hensel, Hermsdorf-Kynast, Germany. Eng. Pat. 24,038, Oct. 28, 1896.

This new process for preparing from the molasses of raw beet-sugar, a foodstuff of high nutritive value applicable for men and animals, consists principally in treating the molasses with phosphoric acid or phosphates, and at the same time neutralising the excess of free phosphoric acid by the addition of bicarbonate of soda, in order to transform into nutritive salts the mineral stuffs, especially the carbonates, which are contained in the molasses. For this purpose, to 100 parts of the molasses, 10 parts of phosphoric acid are added, having the sp. gr. 1.200. The phosphated molasses can be mixed with paste and baked as a nourishing bread, or dissolved in hot water as a beverage to take the place of coffee. —L. J. de W.

*Sugar, Impts. in or relating to the Production of.* L. Janssens and Co., Brussels. Eng. Pat. 28,188, Dec. 9, 1896.

GROUND and sifted raw sugar is covered with 35 to 30 per cent. of concentrated and decolourised liquor produced at a temperature of from 30° to 70° C., both being heated, and then centrifugalised, when a beautiful crystalline sugar of fine grain, is obtained, containing 2 to 4 per cent. of water. To this porous and loose sugar (according to the amount of water in it), 20 to 30 per cent. of ground sugar is added, filling up the pores and giving a beautiful white appearance, though a little duller than the crystalline sugar. This product is pressed in moulds having interchangeable wooden supports on which are placed metallic plates by which the cracking of the sugar loaf is avoided. "That part of the process, which relates to the further treatment of centrifugal sugar by mixing it with ground sugar, is not new in itself, but the pressing process for moulding sugar is totally different from processes used hitherto." —L. J. de W.

## XVII.—BREWING, WINES, SPIRITS, Etc.

*Barley Plant, The Chemistry of the, with reference to its Carbohydrate Constituents.* C. F. Cross and E. J. Bevan. J. Fed. Inst. Brewing, 1897, 3, 2—18.

THE authors give a brief account of their studies on special points in the chemical life-history of the barley plant, the purpose of which was chiefly to solve the constitution of a particular group of carbohydrates present in large quantities in the cereal straws, and which, from the fact that they yield furfural under the action of acids, may be called fufuroids. These carbohydrates constitute about one quarter of the substance of the mature straw. They are not acted on by alkalis, but when digested with 1 per cent. sulphuric acid under a pressure of three atmospheres, they are selectively hydrolysed, yielding principally formal pentoses. The acid solution containing the fufuroids is neutralised and filtered, and it is found that under suitable conditions it ferments freely with yeast. After the action is complete, it will be noticed, however, that only a certain proportion of the carbohydrates have been destroyed. This partial resemblance to dextrose will, nevertheless, establish for the group a certain claim upon the attention of practical men, which will be increased when it is borne in mind that the seed envelopes of the barley have much the same composition as straw, and that they contain a proportion of easily hydrolyzable fufuroids, which find their way into the wort during the mashing process. By far the greater proportion resist this treatment, and are present in the "spent grains." Satisfactory results are said to have been obtained by treating such grains with acid, according to the instructions given in the Eng. Pat. 1895, 15,531. Some of these results are given in the paper. —J. L. B.

*Diastase, Hypothesis of a Saccharogenic, in the Beetroot.* E. Barbet. Bull. de l'Assoc. des Chim. de Sucre et de Dist. 1896, 14, 582—587.

THE difficulty of fermenting beetroot juice when the roots are not ripe, led the author to examine the hypothesis of a saccharogenic diastase in the root in direct conflict with the invertase of yeast, which is saccharophagic, and without the agency of which the fermentation of saccharose is impossible (Bull. Assoc. Chim. 14, 223).

As the leaves of the beetroot turn yellow and fall at the first touch of frost, and the root from this moment ceases to grow, its richness in sugar having reached a maximum, it is to be supposed that the saccharogenic diastase, if such there be, is very impressionable to cold, and ceases to act in frost. The author found that samples of juice after being frozen, or juice extracted from frozen beetroots, fermented as well as the same juice which had been boiled and cooled before the addition of sulphuric acid, and the commencement of the fermentation was more rapid, juice not thus treated being left far behind. —L. J. de W.

*Malt and Wort, Acids of.* H. Johnson. Petit Journ. du Brasseur, 1896, 328.

THE author has made a long series of experiments to ascertain whether lactic acid is formed during the mashing of malt or not. The acidity produced during mashing increases with the temperature of mashing from 20° C. (68° F.) to 50° C. (122° F.), but decreases above 60° C. (140° F.). Thus, in a mash carried out at 70° C. (168° F.) less acid is produced than in a mash of the same materials and proportions at 40°, 50°, or 60° C. When a small quantity of acid wort or sour milk was added to the mash, the acid formation was about doubled at 40° C., but was not increased at all above the normal at 50° or 60° C. This latter fact shows that the formation of lactic acid is active at 40° C., but ceases altogether at 50° C., and that therefore the normal formation of acid during mashing, which increases up to 50° C. cannot be due to a lactic fermentation. The addition of alcohol (10 per cent.) and of chloroform (1 per cent.) to the mash completely stops the extra formation of acid by the addition of sour milk or sour wort, but has little or no influence on the normal acid formation. The fact that the acid formation reaches its maximum at 50° C. shows that it cannot be due to simple extraction from the malt. The author believes that the acidity produced during mashing is due to a chemical or diastatic action (ceasing above about 70° C.) on some of the albuminoid or nitrogenous matters in the malt, with the formation of acid compounds more or less of the type of asparagine  $\text{COOH} \cdot \text{CH}(\text{NH}_2) \cdot \text{CH}_2 \cdot \text{CO}(\text{NH}_2)$ , or asparagic acid—

Experiments with asparagine and asparagic acid showed that these compounds behaved with alkalis and with various indicators very similarly to the behaviour observed in malt worts with those reagents. —L. T. T.

*Yeasts, Difference between Low and High Fermentation.* P. Petit. Comptes Rend. 1897, 93—94.

THE author grows the two varieties of yeast in a dextrose solution containing both ammonium phosphate and asparagine, and determines what amount of these constituents is removed by each yeast. He finds that the high fermentation yeast removed double as much asparagine as the low fermentation yeast. —A. L. S.

*Wine, Isolation by Steam Distillation and subsequent Estimation of the Glycerin in.* F. Bordas and S. de Raczowski. Comptes Rend. 1897, 124, 240—242.

50 c.c. of wine, previously neutralised with potash, are placed in a bulb-flask (300 c.c.), joined to two Woulff's bottles, which serve as receivers. The flask is submerged in a bath of saturated salt solution, the latter heated to 110° C., and a current of air aspirated through the apparatus until the wine has been evaporated to dryness. Subsequently, the air supply is somewhat reduced, and steam blown

through the flask for about three hours, after which time the whole of the glycerin will have passed into the receivers, whilst the alcohol and other more volatile constituents of the wine are expelled from the distillate, by reason of its high temperature. The combined distillates are diluted to 500 c.c. and the glycerol estimated by titration with a standard solution of potassium bichromate (24 grms. per litre) in the manner previously described (*Comptes Rend.*, Dec. 1896). As compared with Pasteur's process, the new method yields somewhat higher results.—H. T. P.

**Mashing Thicker.** W. Windisch. *Wochenschr. f. Brauerei*, 1897, 9.

THE author recommends German brewers to mash thicker for the following reasons:—

(1.) Less first wort is obtained and consequently more sparging water can be used and a better extract obtained.

(2.) The amount of mash is less and consequently there is less to heat in the mash copper, and the temperature can be raised quicker.

(3.) In concentrated mashes the diastase is better able to resist high temperatures.

(4.) Less of the undesirable constituents of the malt are dissolved in thick mashes.

(5.) Less wort is obtained and consequently less coal is consumed in the copper, and the boiling is sooner finished.

—A. L. S.

**Beer, Relation between the Degree of Fermentation and the Keeping Properties of.** W. Windisch. *Wochenschr. f. Brauerei*, 1896, 13, 1362.

IN a brewery working without an ice-machine, the fermentation was habitually carried from 12.6 per cent. to 3.4 per cent., i.e., to the high fermentation degree of 73 per cent. The beer, however, did not taste thin. After 18 days there was a slight deposit of yeast cells and the supernatant liquor kept in good condition for four months. An ice apparatus was then put in, and the temperature of the fermentation room thereby so reduced that it was only found practicable to carry the fermentation from 12.6 per cent. to 4.4 per cent. (corresponding to 65 per cent.). The beer was now found to become slightly cloudy at the end of eight days, and did not subsequently become clear. The cloud consisted of wild yeasts.—L. T. T.

**Brandies, Results of Analysis of, and Conditions of Ageing.** F. Lussan. *Bull. de l'Assoc. des Chim. de Sucre et de Dist.* 1896, 14, 587—591.

FOLLOWING the method given by Girard, Dupré, and Saglier, in the *Encyclopédie chimique*, published in 1894, and adopted by the Municipal Laboratory of Paris, for the determination of the various impurities in alcohol, the author has analysed a number of samples of brandy of known origin and age so as to obtain average values; the results promising to be of interest both from the commercial and the hygienic point of view.

In these analyses nitrogenous matters in the form of ammonia and pyridine bases, are neglected as of only secondary interest, the tables showing acids (calculated to acetic acid), aldehydes (as acetic aldehyde), also furfural, ethers (as ethyl acetate), and higher alcohols (as isobutyl alcohol), and giving the number of mgrms. of each per 100 c.c. of absolute alcohol in order to avoid taking account, in each case, of the strength of the brandy. The sum of these impurities gives the *coefficient of impurity*. As it is not sufficient to consider the coefficient of impurity to know the value of a brandy, the percentage of the products of simple oxidation, acids, and aldehydes, on the total impurities, is given as the *coefficient of oxidation*. It was found that all the samples of pure brandy, Anis, Charente, and Algeria, show—a coefficient of impurity higher than 340—a total of ethers and alcohols over 300—a coefficient of oxidation varying from 11 to 36 for products of 1 to 40 years without being exactly proportional to age. Other products (cognacs, eaux-de-vie, &c.) of good quality, the purity of which was not guaranteed, but which may be

considered as good, if not absolutely pure, gave coefficients of impurity ranging from 340 to 300, and a total of ethers and alcohols between 300 and 250.

The ordinary neuter alcohols of commerce of good flavour are 10 times purer than true brandies. Commercial products obtained from industrial alcohol rendered aromatic by brandy from natural wines are therefore less harmful than brandy itself, and as it is difficult to maintain that among good old cognacs the most impure are not beneficial, the conclusion cannot be avoided that the ravages of alcoholism are simply due to the abuse of alcohol itself.—L. J. de W.

**Fusel Oil, Bases contained in.** E. Bamberger and A. Einhorn. *Ber.* 30, 224—229.

THE authors call attention to the danger of pyridine bases being contained in fusel oil. They have examined the amyl alcohol with which they were working, and purchased as pure, and they have separated in a pure condition the two bases, pyridine and 2, 5-dimethylpyridine, and have indications of the existence of others of the same series.—A. L. S.

**Large Spirit Vats, The Cleaning of: A Warning.** *Zeits. für Spiritusind.* 22, 27.

See under XVIII. B., page 254.

PATENTS.

**Brewers' Refuse and other Materials or Substances Requiring Similar Treatment, Impts. in and connected with Machines for Drying.** R. Cunliffe, Weaste, Lanes. Eng. Pat. 2150, Jan. 30, 1896.

THE machines are of the type wherein the material or substance is dried in a cylinder adapted to rotate inside a casing over a furnace. Air is admitted, in regulated quantity, through doors *c* into two lateral chambers, and is heated in two separate volumes, one passing through the hollow fire-bars *d*, and the other through the hollow fire-bridge *f*, perforated partition *f'*, and tube *g'*. The heated air passes through the hot-air chamber *h*, lateral casing *c'*, and hollow trunnion *b'*, into the cylinder *b*, which is revolved by hand or power.

The furnace gases pass through the flues *i*, *i'*, into the space between the cylinder *b* and casing *c*, and are discharged through the flue *c''*, into which the air from the cylinder *b* also passes through the apertures *b''*. In the form shown, the cylinder is charged and emptied through doors in the cylinder and casing. In a modification, the material is fed automatically from a hopper, which is placed against the chimney of the apparatus, so that the material is heated before entering the cylinder. The chimney is bifurcated, the branches communicating separately with the cylinder and its casing.—R. A.

## XVIII.—FOODS; SANITATION, WATER PURIFICATION, & DISINFECTANTS.

### (A.)—FOODS.

*Albuminoids in Substances Rich in Starch, A Modification of Stutzer's Method for the Estimation of.* H. Tryller. Chem. Zeit. 1897. 21, 54.

See under XXIII., page 264.

### PATENTS.

*Lactic Acid Bacteria, An Improved Process for Raising Permanent Pure Cultivations of.* H. H. Lake, London. From L. v. Lorentz, Hamburg, Germany. Eng. Pat. 7898, April 14, 1896.

WITH a view of preserving cultivations of lactic acid bacteria such as are used for acidulating cream for the preparation of butter, the patentee mixes a pure cultivation with a solution of 4 grms. of milk sugar in 100 c.c. of water. Of this cultivation, called a "fluid cultivation," 200 grms. are mixed with 5 grms. of milk sugar and preserved in sterilised vessels, holding about 250 c.c., which are then sealed with sterilised stoppers or corks. In order to preserve the preparation in the form of powder, 200 grms. of potato starch, 50 grms. of milk sugar, and 75 grms. of the above fluid cultivation are mixed together and dried at 30° C., the powdered material being preserved in well sterilised glasses. The cultivation can also be kept in a solid compact form by preparing a porous cake from 60 grms. of gypsum, 20 grms. of milk sugar, and a sufficient quantity of distilled water. After drying and sterilising the cake by heating, it is cooled and impregnated in a sterilised space with 75 grms. of the fluid cultivation, dried at a temperature below 30° C., and preserved in sterilised filter paper.—T. A. L.

*Molasses of Raw Beet Sugar, Process for the Production of a Food of a High Nutritive Value from.* J. Hensel, Hermsdorf-Kynast, Germany. Eng. Pat. 24,038. Oct. 28, 1896.

See under XVI., page 252.

*Vegetable Extracts, and the Method of Obtaining the same, Impts. in.* A. J. Boulton, London. From L. Fromm and R. Schmidt, Dresden, Germany. Eng. Pat. 25,786, Nov. 16, 1896.

THIS process is for the production of an extract containing both fatty and albuminous substance from vegetables, beans, nuts, &c., in a form easily soluble and assimilable, as food, containing about 50 per cent. of fat, and 25 per cent. of albumin. The vegetable substance, after being ground to a flour, is made into a paste with cold water (containing sodium chloride in the proportion of 5–10 per cent. of the flour). It is kneaded between rollers, by which treatment the fat becomes thoroughly incorporated with the albumin, which is also converted into a soluble form. The mass is then dissolved in hot water of 50°–60° C., converted into an emulsion by stirring, separated from impurities in a centrifugal machine, and finally dried by steam to a thick mass.—J. J. K.

### (B.)—SANITATION; WATER PURIFICATION.

*Large Spirit Vats, The Cleaning of: A Warning.* Zeits. für Spiritusind. 22, 27.

IS a large distillery and cider manufactory in Saxony a serious explosion occurred in the autumn of last year under circumstances of some interest. A wooden fermenting vessel of a capacity of 18,000 litres had been standing full of 96 per cent. spirit for three months. It was then emptied and partly filled with water, and the workmen were preparing to enter it for the purpose of scrubbing the inside when a violent explosion occurred. Four workmen were burnt, two of them so severely, that death ensued in a short time.

An official inquiry showed that the timber of the vessel had absorbed a considerable quantity of spirit, of which the slight treatment with cold water had removed but little. The vapour arising from this spirit had formed an explosive mixture with the air, which had been ignited by a gas flame near at hand. The use of safety lamps in the vicinity of vessels of this description was recommended.—J. G. W.

### PATENTS.

*Filtration of Sewage, Impts. in Arrangements and Apparatus for.* R. E. von Leugker, London. Eng. Pat. 1038, Jan. 15, 1896.

THE filtering area is divided into four equal separate filter beds, all of which have their supply and discharge pipes radiating from a central chamber in which the valves are also contained. The outlet and inlet valves of each bed are connected, so that when the outlet valve is opened by the pressure of liquid in the bed, the inlet valve closes, and the valves belonging to the different beds are also connected with each other in such a manner that the opening of the outlet valve and closing of the inlet valve of one bed, closes the outlet valve and opens the inlet valve of the next, and so on in rotation. In this way each filter bed successively becomes charged with liquid, remains charged for a time, then discharges, and finally remains empty for a time.—L. A.

*Filtering and Purifying Liquids [Water, &c.], A New or Improved Method of and Apparatus for.* J. G. Lorrain, Norfolk Street, Strand, W.C. Eng. Pat. 2859, Feb. 7, 1896.

THE liquid is passed first through a finely perforated plate, which offers considerable resistance to the flow, then through a layer of purifying material (preferably platinised carbon, &c.) arranged so as to offer less resistance to the flow than the plate, and finally through a second perforated plate, which offers less resistance to the flow than the purifying material, air being at the same time supplied through a tube to the purifying material, in order that the oxygen of the air may combine with the oxidisable matters in the liquid. The apparatus may be provided with a straining device, through which the liquid is first passed to remove suspended matters.—R. A.

*Settling Tanks or Lodges used in the Purification of Sewage and other Foul Waters, and in the Clarification of Manufacturers' Liquid Compositions: Impts. in the Construction of.* J. Petrie, Rochdale, Lancaster. Eng. Pat. 3047, Feb. 11, 1896.

THE tanks are constructed with smooth sloping sides, down which the suspended solids readily slide and are removed from time to time by opening a valve or valves at the bottom.—L. A.

*Sewage, Impts. in Apparatus for the Treatment of.* W. P. Thompson, Liverpool. From E. de Harven, Antwerp, Belgium. Eng. Pat. 5690, March 13, 1896.

THE apparatus described is a cesspool composed of two separate pits, the first of which receives the whole of the liquid and solid substances, retains the solid ones, and delivers the liquid from or near its top to the second pit. The second pit is divided into four parts, by means of partitions of different height, and contains a siphon which automatically discharges a fixed proportion of the liquid into the sewer after it has circulated through all the subdivisions of the pit. At one end of this pit there is a receptacle for disinfectant, and a tilting ladle with a float, which, actuated by the rise and fall of the water level, automatically and gradually discharges a measured volume of the disinfectant into the pit while it is again filling up after the siphon has operated. This apparatus is intended to be used in connection with the water-closet system, the solid matters being retained by the first pit, and the liquid being disinfected in the second pit before passing into the sewers.—L. A.

### (C.)—DISINFECTANTS.

#### PATENTS.

*Disinfectants in Porous Cylinders, An Improved Method of using.* T. Grimstone, London. Eng. Pat. 2424, Feb. 3, 1896.

ANY suitable disinfectant or deodoriser is hermetically sealed within a porous pot which is placed in the w.c. flushing tank or similar receptacle. Solution of the disinfectant takes place by diffusion in a slow and regular manner. Permanganate crystals alone may be placed in the pot, but the

inventor prefers to employ "kresylene (or soluble creosote), eucalyptol, terpinol, or carbolic acid in liquid form, or any desired combination of these or their equivalents, to which is added as a basis, silica, to prevent volatile effusion," in proportions to form a thick paste.—L. A.

*Seaweed Matter, Composition for Disinfecting and Rendering it available for Agricultural or Fertilising Purposes.* P. O'Dowd, Westport, Ireland. Eng. Pat. 5381, March 10, 1896.

THE composition consists of a mixture of peat charcoal and sulphate of iron, suitable proportions being 90 to 95 parts of the former with from 10 to 5 parts of the latter.—L. A.

*Insecticide, A New or Improved.* J. N. Spence, Harrow, Middlesex. Eng. Pat. 5705, March 13, 1896.

THIS consists of a mixture of borax and sugar, preferably 3 to 1, with or without a trace of charcoal or lampblack, e.g. 8 oz. to 140 lb. of the borax and sugar mixture.—L. A.

## XIX.—PAPER, PASTEBOARD, Etc.

*Esparto Half-Stuff Manufactured in France.* Papier Zeit. 1897, 214

A FACTORY has been started at Fos-sur-Mer (Bouches-du-Rhône) by a company trading as the "Société Anonyme des Pâtes de Cellulose." This factory is now regularly supplying half-stuff to paper-makers in France. It is noted that the importation of esparto pulp from this country to Paris alone, amounted last year to the value of 1,000,000 francs.

The following notes on the method of using it are supplied to purchasers:—The half-stuff should be soaked before adding to the beater, from 2 to 6 hours, according to its condition. In the beating the finish should be very thick, especially in papers containing a very high proportion of the esparto. In mixing with other half-stuffs it is recommended to work up the esparto separately. In bleaching it is important to avoid acidity.—C. F. C.

*Parchment Paper. [Waste Waters Treatment.]* Papier Zeit. 1896, 21, 3390.

IN the preparation of parchment papers the waste waters are very strongly acid, and are therefore not allowed to be run into streams and rivers in England. For this reason the industry, although originated in England, is no longer carried on in this country. J. S. Rigby, of Wavertree (Liverpool), has just taken out a patent by which the more strongly acid water pressed from the paper is passed through towers filled with magnesite, and the more dilute washings are treated with crude calcium chloride. In this way he hopes to obtain the marketable products, magnesium sulphate, gypsum, and pure carbonic acid, and at the same time purify the waste waters sufficiently for their discharge into streams, &c.—L. T. T.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

*"Lunar Caustic," Separation of Nitrate of Copper from Nitrate of Silver in the Manufacture of.* C. J. H. Warden. Pharm. J. 1897, 58, [1387], 61.

IN the manufacture of lunar caustic at the Calcutta Medical Depot, the silver, which always contains a certain amount of copper, is dissolved in nitric acid, and, after separation of the gold, as much as possible of the nitrate of silver is crystallised out. The deep blue mother-liquor is evaporated to dryness and the residue powdered and placed in a glass funnel stopped with a plug of asbestos, where it is treated with nitric acid of sp. gr. 1.42. The nitric acid dissolves the whole of the nitrate of copper, while only a very small amount of silver nitrate is dissolved. The nitric acid can be recovered by distillation, and the small amount of silver separated from the nitrate of copper by precipitation with salt. By this method a salt is obtained practically free from copper.—A. S.

*Mercury Pyroborate.* Dupnoy. Bull. de la Soc. de Pharm. de Bord. 36, 269; and Pharm. J. 1897, 58, 82.

TOKAYER (Pharm. Post. 25,156) obtained, by precipitating an aqueous solution of mercuric chloride with borax, a brownish-red precipitate, which he regarded as mercury pyroborate,  $\text{HgB}_2\text{O}_7$ . This substance has recently been successfully employed as an antiseptic. The author, on examining the salt, found it contained no boric acid, but was a basic oxychloride of mercury having the formula  $\text{HgCl}_2 \cdot 3\text{HgO}$ . This oxychloride may also be prepared by treating a boiling solution of mercuric chloride with sodium carbonate, keeping the mercuric chloride in excess, to avoid formation of other oxychlorides.—A. S.

*Mercury Benzoate.* Rebière. Bull. de la Soc. de Pharm. de Bord. 36, 280; and Pharm. J. 1897, 58, 82.

THE author prepared this salt in a pure state by the following method:—A known quantity of pure mercuric chloride was precipitated by soda and the precipitate washed until free from chlorine. From the amount of mercuric chloride taken, the amount of oxide was calculated, and sufficient finely powdered benzoic acid mixed with it to leave a slight excess of  $\text{HgO}$ . The mixture, diluted with water, was left for 24 hours and then heated to boiling; a white amorphous powder resulted, which, when again heated with a large volume of boiling water, redissolved, and on cooling crystallised out in long silky needles, which were drained and dried at the ordinary temperature. These crystals had the definite composition  $\text{Hg}(\text{C}_6\text{H}_5\text{O}_2)_2$ .—A. S.

*Bismuth Benzoate.* Rebière. Bull. de la Soc. de Pharm. de Bord. 36, 272; and Pharm. J. 1897, 58, 82.

FOR the preparation of the basic benzoate of bismuth,  $\text{BiO}_2 \cdot \text{C}_6\text{H}_5\text{O}_2$ , which is the French official salt, the author uses the following method:—Freshly precipitated oxide of bismuth, thoroughly washed, is drained to a pasty consistence. The amount of anhydrous  $\text{Bi}_2\text{O}_3$  is determined in a portion of the paste, and to the rest is added the calculated quantity of finely powdered benzoic acid, to produce the salt  $\text{BiO}_2 \cdot \text{C}_6\text{H}_5\text{O}_2$ . The mixture is diluted with sufficient water to make it fluid, well mixed, and left in contact for 24 hours. The precipitate is then thrown on a cloth, drained, and dried in the air.—A. S.

*[Menthol and Menthone.] Researches in the Camphor Series.* E. Beckmann. J. Prakt. Chem. 1897, 55, 14.

THE menthol used had the melting point  $43^\circ \text{C}$ . and specific rotation  $[\alpha]_D = -49.3$  in 20 per cent. alcoholic solution.

Menthol sodium is obtained by heating the theoretical proportions of the components at  $200^\circ$  in an atmosphere of hydrogen. The mass becomes solid, melts at a higher temperature with partial decomposition, and soon changes in the air, even when cold.

Benzoic acid ester may be made by heating with benzoic anhydride at  $160^\circ$ – $170^\circ$  for 2–3 hours. The ester melts at  $54.5^\circ$ , in 20 per cent. alcoholic solution  $[\alpha]_D = -90.72$ . On the water-bath and with a current of steam the compound is very slowly volatile; menthol and menthone may thus be readily separated.

Stearic Acid Ester.—Stearic anhydride is obtained by the action of phosphorus oxychloride on dry sodium stearate (from commercial acid) suspended in benzene, and evaporation of the benzene after filtering. The stearic ester, prepared in a similar manner to the benzoic ester, may, on account of its difficult volatility, serve for the isolation of this alcohol (and others). Menthol stearate melts at  $39^\circ \text{C}$ .

Separation of Menthol and Menthone.—This may be accomplished by means of the oxime; the method may be used for the extraction of menthone from ethereal oils. After formation of the oxime by heating in alcoholic solution with hydroxylamine and sodium bicarbonate on the water-bath for 15 minutes, addition of water, extraction by ether, and evaporation of the solvent, a mixture of menthol and l-menthone oxime is obtained. From this mixture four extractions with dilute sulphuric acid (sp. gr. 1.17) extract the oxime and leave menthol of normal melting point and rotation. The oxime is obtained by saturation with soda

after addition of ice, and extraction by ether after passing carbon dioxide through the solution. The oxime is usually not quite solid, and melts at  $47^{\circ}$ – $49^{\circ}$ , instead of  $58^{\circ}$ : it probably contains a little menthol.—A. C. W.

*Camphor Series, Researches in.* [Borneol and Reduction of Camphor.] E. Beckmann. J. Prakt. Chem. 1897, 55, 31.

In the reduction of camphor, borneol is formed in quantities equal to or greater than those of isoborneol. The amounts of each were calculated from the observed rotation of the mixture. In the case of reduction in alcoholic solution (ethyl or amyl alcohols, phenol) isoborneol forms 16–21 per cent. of the product. In indifferent solvents (toluene, petroleum ether, ether) 43–47 per cent. of isoborneol is formed. The mixtures may be separated by the process described for menthone and menthol in the preceding abstract, or more simply by passing in carbon dioxide, shaking with ice-cold water, and separation of dissolved borneol, by acidifying with sulphuric acid and addition of alkali, or by standing 8–14 days. All mixtures produced in non-alcoholic media contain about 5 per cent. camphor-pinacone, which is left behind on steam distillation.

—A. C. W.

*Caffeidine-Carbonic Acid.* E. Fischer and O. Bromberg. Ber. 1897, 30, 219.

By agitating caffeine with dilute alkali at ordinary temperatures for three or four days in a mechanical agitator, the authors have been able to convert the alkaloid into caffeidine-carbonic acid in a materially shorter time than that required by the original method of Maly and Andreaseh (Monatsh. für Chem. 4, 369). The acid so formed is separated as a copper salt, the metal removed with  $H_2S$ , and the acid solution evaporated *in vacuo* at  $40^{\circ}$ . In small quantities the acid separates readily in crystalline form, but in larger quantities it remains uncrystallised in a syrupy condition; if this syrup be dissolved in glacial acetic acid, and this be treated with four times its volume of benzene, large colourless crystals, which melt between  $127^{\circ}$ – $130^{\circ}$ , are obtained; these appear to consist of a compound of caffeidine-carbonic acid and acetic acid. The pure acid is obtained from this body by dissolving in 30 parts of boiling acetone; on cooling, caffeidine-carbonic acid separates in long colourless prismatic needles, which have, after drying *in vacuo*, the formula  $C_{10}H_{12}N_4O_5$ . When heated in sealed tubes with phosphorus oxychloride in an oil-bath for three hours, the resulting syrupy liquid obtained by concentration on the water-bath gave, when treated with an excess of potash, a crystalline mass; this, on extraction with chloroform, proved to be caffeine.—J. O. B.

*Sparteine Derivatives.* F. Ahrens. Ber. 1897, 30, 195–209.

The fact that oxysparteine and dihydroxysparteine, the chief products of the oxidation of sparteine, differ markedly in their physiological action on the heart—oxysparteine imparting greater power to the pulsation, while the actual number of beats is decreased, whereas with dihydroxysparteine the action appears to be exactly contrary,—has induced the author to investigate the subject. He finds that an aldehyde group exists in oxysparteine and two hydroxyl groups in dihydroxysparteine. The hydrochloride of this base had the composition  $C_{15}H_{21}N_2 \cdot 2HCl + 3\frac{1}{2}H_2O$ , and occurred as large, well-formed, colourless crystals. The hydriodide,  $C_{15}H_{21}N_2HI$ , obtained by neutralising the alcoholic solution of the base with hydriodic acid, gave shining scales, which melted at  $225^{\circ}$ – $226^{\circ}$ ; excess of acid gave the corresponding acid salt,  $C_{15}H_{21}N_2 \cdot 2HI$ , in large, clear crystals, melting at  $256^{\circ}$ – $258^{\circ}$ .

The formula for oxysparteine is  $C_{14}H_{20}N_2CHO$ .

When treated with a large excess of hydrogen peroxide and left for some weeks, the result was a slow oxidation of oxysparteine and the formation of a crystalline acid, which melted at  $287^{\circ}$ – $289^{\circ}$ , and had the composition  $C_{10}H_{16}NO_2 + 2H_2O$ , giving crystalline soluble salts with alkalis and alkaline earths.—J. O. B.

*Piperidine Guaiacolate.* Schidrowitz. Pharm. J. 1897, 58, 81; Brit. Med. J., No. 1881, 136.

This compound,  $C_9H_{11}NC_7H_5O_2$ , was prepared by the action of piperidine on guaiacol dissolved in benzene or petroleum ether. It crystallises in prismatic needles or plates, melts at  $79^{\circ}$ – $81^{\circ}$  C., is soluble in water to the extent of 3.5 per cent., and also easily soluble in most organic solvents. Mineral acids and alkalis decompose it into its constituents. It is used in the treatment of phthisis.—A. S.

*Eckart's Rhodinol, Properties of, and its Technical Production from Pelargonium Oils.* R. Pfister. Chem. Zeit. 1897, 38.

MOXNET and Barbier have shown that the alcohol, rhodinol,  $C_{10}H_{17}OH$ , the odoriferous principle of otto of roses, is contained in the true geranium oils distilled from the pelargonium species. The name geraniol had already been given to an alcohol of unpleasant odour contained in palmarosa oil. According to Ger. Pat. 80,007, by the Société Chimique des Usines du Rhône, rhodinol is obtained from the essential oils of pelargonium (geranium) varieties. The pelargonium oil is carefully fractionated under as low a pressure as possible, when a rhodinol boiling within a few degrees, but not quite pure, is obtained. This is heated in an autoclave for eight hours at  $140^{\circ}$ – $150^{\circ}$  C. with acetic anhydride, by which quantitative esterification is brought about. By fractionation, the rhodinol acetate is now separated from the non-alcoholic impurities, which have the same boiling point as the alcohol. After saponification and further fractional distillation *in vacuo*, rhodinol is obtained as a colourless mobile oil of constant boiling point. For use, this rhodinol is diluted with citronellol, as in the natural rose oils, since in the pure state it rapidly alters and loses its pleasant odour. Mixed with citronellol, rhodinol may be distilled *in vacuo* and obtained free from other admixture, but if distilled alone, traces of decomposition products are formed, and render the product useless for perfumery.

For controversy as to the composition of rhodinol, geraniol, and réuniol, and the use of these names, see this Journal, 1896, 292, 373, 469, 827.—A. C. W.

*Otto of Roses, Methods of Examining.* R. Jedermann. Zeits. Anal. Chem. 1897, 96.

THE author, in common with most modern authorities, regards the physical characters of otto of roses, as well as its chemical reactions, of considerable value in its critical examination. He finds the pharmacopœial tests as given in the official works of most countries to be quite valueless, and specially comments on the fallacious deductions which may be made from the modification of Hager's test, contained in the United States Pharmacopœia; the author finds that perfectly pure samples of otto will not respond to this test, the disturbing substance being a trace of resinous matter, derived from the green sepals of the flowers, traces of which are sometimes carried over by the steam in the process of distillation; when the roses expand quickly, as was the case last year, the process of distillation has to be carried on so rapidly that time is not available for the elimination of the green outer portions of the rose flowers, so that the otto produced contains a minute trace of this resinoid body.

The preference shown for ottos having a high congealing point is regarded as fallacious, since the amount of odourless stearoptene in the oil is dependent on the conditions under which the otto is distilled; moreover, this preference on the part of buyers for an oil rich in stearoptene induces the distillers to produce the same at the sacrifice of the aroma. The optical rotation is a useful factor: pure oil will give a rotation of  $43.30'$  at  $30^{\circ}$  C. in a Wild's polaris-trobrometer. The specific gravity is also useful, lying between 0.8555 and 0.8645 at  $30^{\circ}$  C., the lighter oils being naturally rich in stearoptene.—J. O. B.

*Commercial Civet.* J. O. Braithwaite. Pharm. J. [4], 4, 101.

THE author has examined three samples of commercial civet, and finds them all to be grossly adulterated with either added fat, water, fecal matter, or sugar, or other

foreign organic matter. No published data of any value being available, a sample of the natural secretion from the civet cats in the Zoological Society's Gardens was obtained. Except for accidental impurities, mainly hairs of the animal and sawdust from its cage, this product was almost wholly soluble when extracted in a Soxhlet apparatus with light petroleum ether. The insoluble residue was almost free from odour, and dry. The commercial samples gave from 70 to 50 per cent. of matter soluble in this solvent, and the residues in all cases were stercoraceous in odour. One—the worst—also contained much sugar. Another lost 30 per cent. on drying, showing at the same time water globules under the microscope. The total acid number of the standard sample was 140, and the volatile acid number 32.3; all the commercial samples deviated markedly from these figures, that for the volatile acid being more than 60 per cent. too low.—J. O. B.

*Artificial Pulegone from Citronellal.* F. Tiemann and R. Schmidt. Ber. 30, 22—32.

In a previous paper (Ber. 29, 903) the authors showed that citronellol—

$(\text{CH}_3)_2\text{C}:\text{CH}.\text{CH}_2.\text{CH}_2.\text{CH}(\text{CH}_3).\text{CH}_2.\text{CH}_2\text{OH}$ ,  
citronellal—

$(\text{CH}_3)_2\text{C}:\text{CH}.\text{CH}_2.\text{CH}_2.\text{CH}(\text{CH}_3).\text{CH}_2.\text{CO}_2\text{H}$ ,  
and citronellie acid—

$(\text{CH}_3)_2\text{C}:\text{CH}.\text{CH}_2.\text{CH}_2.\text{CH}(\text{CH}_3).\text{CH}_2.\text{CO}_2\text{H}$ ,  
are compounds of the aliphatic series. They also pointed out that under the action of acetic anhydride, citronellal was converted into a secondary alcohol of the formula  $\text{C}_{10}\text{H}_{18}\text{O}$ , which they called isopulegol, and converted by oxidising agents into the corresponding ketone,  $\text{C}_{10}\text{H}_{16}\text{O}$ , designated isopulegone. The former compound is obtained by heating 150 grms. of citronellal with 100 grms. of acetic anhydride for 20 hours in an oil-bath to  $160^\circ\text{--}180^\circ\text{C}$ . The melt is taken up with alcohol, treated with 150 grms. of caustic potash and steamed, when isopulegol passes over, giving a yield of 66 per cent. on the weight of the citronellal. The oxidation to isopulegone is effected by emulsifying 100 grms. of isopulegol in 1 litre of water and gradually adding a hot solution of 150 grms. of potassium bichromate, 200 grms. of concentrated sulphuric acid, and 600 c.c. of water during about half an hour, after which the crude isopulegone is at once driven off with steam. For purification, it is dissolved in dilute alcohol and treated with semicarbazide hydrochloride in sodium acetate solution, when, after a few hours, isopulegone semicarbazone crystallises out and is further crystallised from benzene. This compound is then dissolved in alcohol, decomposed with sulphuric acid, filtered from semicarbazide sulphate, and the filtrate extracted with ether, the residue therefrom being steamed, when pure isopulegone passes over, distilling under 12 mm. pressure at  $90^\circ\text{C}$ . The product does not give a crystalline compound with sodium bisulphite, thus differing from pulegone. It is, however, converted into this latter compound by agitating 1 part by weight of it with 20 parts of a 5 per cent. barium hydrate solution for 50—60 hours, when it boils at  $99^\circ\text{--}103^\circ\text{C}$ . under 15 mm., and reacts in every way similar to natural pulegone obtained from oil of "Pennyroyal." Pulegone and isopulegone, as well as pulegol and isopulegol, possess a certain similarity in their physical and chemical properties, such as odour, specific gravity, and direction of rotation (the former rotating the plane of polarisation to the right, the latter to the left), and both are converted by boiling with formic acid, into acetone and methyl-1-cyclo-hexanone-5. Pulegone and isopulegone, however, give different oximes and semicarbazones, since a mixture of either of these two compounds has a lower melting-point than the pure compounds separately. Moreover, pulegone and pulegol are easily reduced by sodium and alcohol to menthol, but isopulegone and isopulegol have not been directly converted into this substance.—T. A. L.

## PATENTS.

*Remedial Serum [for Tuberculosis], The Manufacture of.* Impts. in. G. B. Ellis, London. From F. Niemann, Basel. Eng. Pat. 2014, Jan. 28, 1896.

THE object of this invention is the preparation of antitoxic serum, free from glycerin (the presence of glycerin being objectionable, because, as alleged, it prohibits, on account of its poisonous properties, the use of large injections of remedial serum), and possessed of greater curative powers than it has hitherto been possible to obtain. The process used, is described at length. Briefly, a healthy animal is injected (subcutaneously):—

(1.) 2—3 times with tuberculin, i.e., with a sterilised and filtered culture of the tubercle bacillus.

(2.) At intervals of 3—4 days with gradually increasing doses of the active principle of tuberculin, free from glycerin, until a quantity of about 2 grms. of active material per kilo. of body weight has been reached. The active principle is prepared by precipitating tuberculin with alcohol, &c., and dissolving the precipitate in water.

(3.) The final treatment consists in injecting a quantity of a boiled, but not filtered, culture of the tubercle bacillus, 3—4 weeks, subsequently, blood is drawn from the jugular of the animal, allowed to coagulate, and the serum filtered off, treated with a trace of carbolic acid and stored in sterilised bottles.—H. T. P.

*Artificial Musk. An Improved Production of.* J. W. Mackenzie, London. From C. Schmid, Brussels. Eng. Pat. 2205, Jan. 30, 1896.

A NEW benzenesulphonic acid having the constitution  $(\text{CH}_3)_2\text{C}_6\text{H}_3.\text{C}(\text{CH}_3)_2(\text{SO}_3\text{H})$ , a trimethylmethanedimethyl benzene sulphonic acid, is prepared from the following two solutions and subsequently nitrated:—

(a.) 1050 grms. of ordinary sulphuric acid and 460 grms. of pure sulphuric acid ( $66^\circ\text{B}$ ), are mixed in a vessel surrounded by ice and water and kept at from  $8^\circ$  to  $10^\circ\text{C}$ .

(b.) 130 grms. of trimethylmethane, 90 grms. of dimethyl benzene, 70 grms. of oil of turpentine, 20 grms. of ethyl benzene, and 10 grms. of dimethylethylmethane, are mixed, the mixture (a) is added in quantities of 10 grms. at a time, keeping the temperature below  $10^\circ\text{C}$ .

The whole is left in the cold bath for some hours; it is then poured cautiously in small quantities into a vessel containing 7.2 litres of water. After standing 12 hours, the floating oily layer is removed and the aqueous solution

poured into 29.5 litres of brine at 24° B., well stirred, and allowed to crystallise for 48 hours. The crystals are collected, washed, "heated in a water-bath to 125° C.," and filtered whilst hot. On cooling, the crystalline creamy mass of the new acid is formed. This is then nitrated in the usual manner, the resulting nitro product recrystallised from alcohol, neutralised with ammonia, pressed and dried. It smells intensely of musk.—J. O. B.

*Phenetidine and its Homologues, New Compounds from [Sulpho-phenetidides], The Manufacture of.* G. B. Ellis, London. From La Société Chimique des Usines du Rhône, anct. Gilliard P. Mounet and Cartier, Lyons. Eng. Pat. 3791, Feb. 19, 1896.

THE production of aromatic sulpho-phenetidides, by the action of the corresponding sulphonic chlorides on *p*-phenetidine, is claimed. In general, the aromatic sulphonic chloride (1 mol.), dissolved in some indifferent liquid, is mixed with an aqueous solution of *p*-phenetidine hydrochloride (1 mol.) and the whole thoroughly agitated with caustic soda (3 mols.) solution, added very gradually. After some time the aqueous layer, which contains the sodium salt of the new body, is acidified with a mineral acid, whereupon the phenetidine is precipitated. The reaction that takes place is as follows, taking toluene-sulphonic chloride as example:—

Similar condensation products may be formed under the same conditions by the action of benzene, naphthalene, and other sulphonic chlorides (and their nitro- and other derivatives) not only upon phenetidine, but also on anisidine and higher homologues of phenetidine. The products formed, are all more or less insoluble in water, but possess distinctly acid character and yield salts with alkalis, &c. The alkaline salts of toluene-sulpho-phenetidine and anisidine are soluble in water, and therefore suitable for medicinal and other purposes.—H. T. P.

*Oxygen Gas [for Lecturers chiefly], Impts. in and relating to Apparatus for the Production of.* F. J. Stedman, Strand. Eng. Pat. 4548, Feb. 29, 1896.

AN apparatus is described for producing oxygen, in which the application of a heating agent to a retort is so controlled automatically as to proportion the generation of gas to the expenditure thereof.—R. S.

*New Pharmaceutical Preparations [Tasteless Derivatives of Quinine, &c.], The Manufacture and Production of.* J. Y. Johnson, London. From The Vereinigte Chininfabriken, Zimmer and Co., Frankfurt-on-the-Main. Eng. Pat. 4991, March 5, 1896.

THE claim relates to compounds produced from quinine and other cinchona alkaloids by the action of carbonyl chloride, or of chloro-carbonic ethers. See under "Eu-Quinine," this Journal, 1897, 159.—H. T. P.

*Bismuthoxyiodide-methyl-gallate, Production of.* W. E. Heyes, Manchester, England. From The Chemische Fabrik vormals Sandoz, Basel, Switzerland. Eng. Pat. 15,295, July 10, 1896.

TEN kilos. of bismuth nitrate and five kilos. of sodium acetate are dissolved in a little water with the addition of 10 kilos. of acetic acid. A solution of 4½ kilos. of the methyl ether of gallic acid and 3.5 kilos. of potassium iodide in about 100 litres of lukewarm water is added at once, and the mixture is heated, at a temperature of about 40° to 50° C., until the precipitate, which was at first brownish-red bismuth oxyiodide, has turned a dark grey

colour. This precipitate, which is the new body, is then well washed, and dried below 100° C. It forms a light grey insoluble powder, and is introduced as a healing antiseptic dressing. It has the formula—

—J. O. B.

*Camphor and Isomers thereof, Impts. in the Manufacture of.* J. C. Richardson, London. Eng. Pat. 3555, Feb. 17, 1896.

THE reduction of turpentine hydrochlorides is effected by means of alkalis or alkaline earths, and the liberated camphene oxidised by means of hot air or oxygen to oxycamphor. If the reducing agent be a peroxide, the oxygen is supplied in the reaction. Or, turpentine is treated direct with oxides or peroxides of the alkaline earths, a current of steam or hot air passed through the mixture, and the products condensed in the usual way. The residual "uncrystallisable camphor" is used as a solvent for gums, resins, or, with sulphur, for vulcanisation of rubber. It is also emulsified with soap for a medicinal embrocation. Electrolytic reduction of the hydrochlorides is obtained either from the melted substance or from solutions, and a current of steam or air may be passed through at the same time.—J. O. B.

*A Pharmaceutical Product [Menthol Solutions], the Production of; Impts. in.* J. Y. Johnson, London. From The "Vereinigte Choinfabriken, Zimmer and Co.," Frankfurt-on-the-Main. Eng. Pat. 3706, Feb. 18, 1896.

A FLUID preparation of menthol for internal use, produced by dissolving 10—30 per cent. of solid menthol in one of its compound ethers. The valerianic ether of menthol is mentioned as being especially suitable for the purpose. In this way, it is claimed, the burning taste of the menthol is, to a great extent, masked, and at the same time its stimulating action on the system exalted.—H. T. P.

*Iodo-oxybenzoic Acid, Manufacture of Esters of.* O. Imray, London. From The Farbwerke vormals Meister, Lucius, and Brüning, Hoechst-on-the-Maine, Germany. Eng. Pat. 5496, March 11, 1896.

THE ester of iodo-oxybenzoic acid is produced by iodising salicylic acid ester, or by esterification of di-iodosalicylic acid. The alkyl-ester of di-iodo-oxybenzoic acid is described as being a white crystalline compound readily soluble in alcohol. The di-iodosalicylic acid methyl ester melts at 110°, and crystallises in long brilliant needles. The ethyl ester melts at 132°, and crystallises in square tablets. These new esters are to be employed therapeutically.—J. O. B.

*Musk, Process for the Manufacture of Substitutes for Natural.* M. Dinesman, Paris. Eng. Pat. 22,139, Oct. 6, 1896.

THE process comprises—

(1.) The conversion of any one of the isomeric butyltoluidines, or homologues thereof (butyl-xylidine, &c.), into the corresponding mono-nitro-hydrocarbon, either by diazotising and treating with a cuprous salt, or by nitrating and treating the nitrated base obtained, with nitrous acid and alcohol.

(2.) Nitration of the mono-nitro-hydrocarbon thus obtained with fuming nitric and sulphuric acids. A nitro-(tri-) body is thus produced, possessing a strong musk-like odour.—H. T. P.

*Acetyl and Lactyl Derivatives of Aniline and Phenetidine, Process for Preparation of.* L. Lederer, Munich, Germany. Eng. Pat. 28,969, Dec. 17, 1896.

THE patentee claims the cheap production of these lactyl and acetyl derivatives by heating the sulphates or chlorides of these bases, with or without pressure, with lactates or acetates, such as the lime salts of these acids. Double decomposition then results.—J. O. B.

## XXI.—PHOTOGRAPHY.

*Albumin, Action of Formaldehyde on.* A. Bach. *Monit. Scient.* 1897, 157.

THIS investigation, begun in 1893, is avowedly incomplete, but is published in order to retain the author's rights of priority; Blum having recently taken up the same subject.

The latter has shown that egg albumin treated with formaldehyde, while retaining all its other properties unaltered, yet loses the power of coagulating with heat. At first sight this does not seem very peculiar, for a similar result may be obtained in other ways. Dried in thin layers in the sun, albumin leaves a residue completely soluble in water, and not altered by heating, except after the addition of acetic acid. Desiccated at low temperatures also, white of egg will not coagulate on heating until it has been treated with a current of carbonic acid. After addition of formaldehyde, too, albumin is less easily precipitated by alcohol, as the following experiment proves:—Two equal portions (10 c.c.) of an albumin solution were placed in test-tubes, and one was treated with 0.5 c.c. of formalin, and heated for several minutes in a water-bath. 95 per cent. alcohol was then run into both from a burette till the liquid became turbid. The normal sample required 2.2 c.c.; the other, 63.5 c.c.

A fairly pure specimen of albumin, containing only a minute quantity of mineral matter, was prepared from eggs by Würtz's process, which consists in a precipitation of the body with lead acetate, and decomposition of the albuminate with  $\text{CO}_2$ . The last traces of lead were removed by  $\text{H}_2\text{S}$ ; but as the liquid would not filter, it was heated to incipient coagulation, and then allowed to settle. 750 c.c. of a solution containing about 6 per cent. of the purified albumin were mixed with 75 c.c. of 40 per cent. formalin, and the whole divided into different parts. It was found that these would bear a temperature of 92°, or even the boiling point, without decomposition; and they were apparently unaltered by exposure to sun and air for 14 months, when all odour had vanished. The liquid still gave all the reactions of albumin, and was found not to have been peptonised, as it seemed might possibly be the case. On the other hand, the formalin was not polymerised: for, on treatment with phenylhydrazine acetate in excess, no crystallisable osazone could be recovered.

With the view of isolating the compound of albumin and formaldehyde, Blum distilled the liquid till it no longer reduced ammoniacal silver nitrate and the distillate ceased to give Schiff's reaction. The present author has preferred to try repeated precipitation with alcohol and re-solution in hot water. In this way he obtained a colourless, opalescent fluid having a strong burnt sugar-like odour, and yielding, on evaporation *in vacuo*, pale yellow scales. They also possessed the ordinary properties of albumin; but on treatment with phenol or aniline, gave white precipitates soluble in alcohol.

—F. H. L.

*Aldehydes and Ketones, Development with, in Presence of Sodium Sulphite.* L. Lumière and Seyewetz. *Bull. Ass. Belge Phot.* 1896, 23, 770.

IN 1889, Schwartz and Mercklin showed that the reducing power of a developer is considerably increased by the presence of formaldehyde. The authors confirm this observation, and find that the accelerated action does not depend on the formaldehyde alone, but also on the presence of sodium sulphite. No other sodium compound, such as the acetate or neutral phosphate, can take the place of the sulphite. It is also stated that most aldehydes and ketones behave like formaldehyde. Such bodies not only hasten the development, but enable the use of alkali to be dispensed with; the developer consisting of an aldehyde or ketone, a phenolic reducing agent, and sodium sulphite. The authors believe that the phenol forms a salt with a portion of the alkali of the sulphite; the sulphite being changed into bisulphite, which in its turn forms a bisulphite compound with the ketone or aldehyde. The reducing power of quinol probably depends on this liberation of alkali.

The authors append the following developer, which has given good results:—Quinol, 3 parts; sodium sulphite, 10 parts; acetone, 10 parts; water, 100 parts.—J. L. B.

*Colour, The Production of, by Photographic Methods.* H. Trueman Wood. *J. Soc. of Arts*, 45, 278—287.

THE problem of producing a naturally coloured photograph demands a substance capable of being modified by light of different colours, so as to show the same colours permanently; and this susceptibility must be capable of being arrested or destroyed by some means, so as to fix the pictures and prevent further change.

Seebeck first discovered that silver chloride was darkened by exposure to light, and Senchier, in 1782—reported by Seebeck in 1810,—remarked that different parts of the spectrum affected it differently, producing colours roughly corresponding to their own. Herschel and Hunt, about 1810, exposed silver chloride paper first to diffused light and then under coloured glasses, reproducing thus approximately the colours of the glasses. Becquerel, in 1848, made copies of the spectrum by direct photography on Daguerreotype plates coated electrically with thin films of silver chloride, but did not succeed in fixing them. Warren de la Rue, Niepce de St. Victor, and others, worked on Becquerel's lines, but did not succeed in making any considerable advance. More lately (first exhibited in 1891) Lippmann produced photographs by his now well-known process, which depends on the formation of a striated structure in the film, produced by interference between the direct light and that reflected from a mercury surface at the back of the film. The defect of this process arises from the fact that the colours are not pigments, but interference results, and hence only visible in certain directions. Another recent invention is the photochromoscope of Mr. Ives, in which three separate pictures of the same object are taken, through blue, red, and green glass respectively; positives made from these negatives are then illuminated, each by light of the corresponding colour, and the three images so obtained are superposed, either on the eye or on a screen. In a modification of this instrument, the three positives are dyed, each of a colour complementary to the light by which the negative was taken, then superposed and viewed by transmitted white light. A somewhat similar idea, needing, however, only one positive, was worked out by Cross, Bevan, and Green. This depends on the fact that certain diazo derivatives will take up as dyes various coal-tar colouring matters, but lose the power when acted on by light. The film, then, washed with the mixture for producing a blue dye, is exposed under the blue-printing negative, the process repeated with the red dye mixture and red-printing negative, and again with the yellow dye mixture and the yellow-printing negative. A positive in colours is thus obtained, but the colours fade in a strong light. Yet another modification of Mr. Ives' method consists in taking a picture through a variously coloured screen of fine lines, and having a similar screen behind the positive when viewing it by transmitted light. The latest process is that of M. Chassagne, an account of which has quite lately appeared (*this Journal*, 1897, 161), and very remarkable results of which have been shown. The nature of M. Chassagne's solutions is still a secret, and speculations as to their mode of action are therefore premature.

Other recent researches in this direction seem to be all based on the process of Becquerel. Wiener, examining the Becquerel colours at various angles of view, has concluded that on chlorinised silver plates the colours are chiefly interference effects, but that with flocculent chloride they are pigmentary; and he has attempted to sketch the elements of a theory of the action of coloured light in producing similar colour. Graby has tried to develop Becquerel's process by using silver chloride in contact with various reagents, but no very definite results have yet been obtained. Mr. Bennetto has also shown some coloured photographs, but has not yet published his process.

—I. T. D.

## PATENTS.

*Painting and Colouring Photographs, Prints, Drawings, and the like, Impts. in and in Solutions therefor.* M. Williams, Liverpool. Eng. Pat. 2711, Feb. 6, 1896.

THE back of a photographic print is painted with a solution of a suitable "aniline" dye in alcohol containing a little glycerin, &c., the presence of water or saline matter being

avoided. The colour soaks into the paper, becoming visible from the front through the silver film, which softens the effect and provides the necessary light and shade.

—F. H. L.

*Photographic Developers.* J. Hauff, Feuerbach, Stuttgart, Germany. Eng. Pat. 27,931, Dec. 7, 1896.

The alkyl-o-amido substitution products of phenols, cresols, xylenols, and naphthols, also their derivatives, the carboxy-alkylamido substitution products of the same bodies, and their derivatives, and the molecular combinations of hydroquinone and pyrocatechol with these bodies, are claimed for the development of photographic negatives.—J. O. B.

*Drawings, Impt. in the Photographic Reproduction of.* E. Gay, Frankfurt-on-Main, Germany. Eng. Pat. 28,087, Dec. 8, 1896.

GLAZED drawing paper is treated with a mixture of gum arabic, 100 grms.; bichromate of potash, 40 grms.; water, 300 centilitres; half a gram. of washing soda is preferably added. The mixture is spread on the paper and dried in the usual way. The drawing, upon tracing paper, is placed over this and exposed to the light for 5 to 15 minutes. The print is first washed very delicately, and again a second time with a sponge until the lines of the drawing appear hollow, owing to the solvent action of the water. It is dried first with blotting paper, then in the air. When dry, the print is coated with a sponge with a mixture of shellac, 75 grms.; lamp black, 70 grms.; spirits of wine, 750 centilitres. It is then plunged in a bath of hydrochloric acid for 20 minutes, when the paper whitens and the drawing comes out black; it is finally cleaned by brushing in water, and dried.—J. O. B.

## XXII.—EXPLOSIVES, MATCHES, Etc.

### PATENTS.

*Explosives [Safety], Impts. in or relating to.* W. Greaves and E. M. Hann, both of Aberdare. Eng. Pat. 4509, Feb. 28, 1896.

THE object of this invention is to render ordinary gunpowder, or explosives of that class, safe for use in fiery or dusty mines, by adding one or more of the following salts: Oxalic, formic, tartaric, or acetic acids. The alums, carbonate of ammonium and soda, sulphates of ammonium, soda, or potash, chloride of ammonium, or, preferably, ammonium oxalate.—R. B. P.

*Measuring the Power or the Volume of the Gases resulting from the Explosion of Explosives, An Improved Method of and Apparatus for.* H. H. Lake, London. From the Sprengstoff Actien-Gesellschaft-Carbonit, Hamburg. Eng. Pat. 3023, Feb. 10, 1896.

See under XXIII., page 261.

*Matches, Manufacture of; Igniting Compound for.* G. Schwiening, Beltenhausen, Cassel, Germany. Eng. Pat. 6052, March 18, 1896.

AN igniting mixture for the heads of matches consisting of 15 parts of potassium chlorate, 0.5 part of sulphur, 4 parts of calcium plumbate, 4 parts of "terra sienna," 2 parts of glass, 1.5 parts of amorphous phosphorus, 1.5 part of gum or cementing matter, all by weight.

It is claimed that the above mixture ensures ignition of the match stem on being rubbed against any surface offering frictional resistance.—R. B. P.

*Explosives [Safety], Impts. in or relating to.* W. Greaves and E. M. Hann, both of Aberdare. Eng. Pat. 6937, March 30, 1896.

TO produce an explosive that can be used with safety in fiery or dusty coal mines, these inventors propose the addition in suitable proportions of borax or boric acid, either alone or mixed with one or more of the following salts:—To carbonite, dynamite, the gelatine explosives, &c., or to "ordinary gunpowder" "and explosives of that class."

The salts named are:—Oxalic acid, ammonium, sodium, and potassium oxalates, or the double oxalates of these. The salts may be used either in the hydrated or the anhydrous state.

The employment of various alums for the same purpose is also described in the provisional specification.—R. B. P.

*Gunpowder [Nitrate Mixture], Impts. in the Manufacture of.* C. Mortier, Bilbao, and H. A. Sandoz, Portugalete. Eng. Pat. 25,711, Nov. 14, 1896.

FOR sporting guns, pistols, and revolvers the powder consists of trinitrocresol, 25 parts; nitrate of potash, 65 parts; charcoal, 9 parts; and stearic acid, 1 part.

For military rifles ("Gras" system) and cannon of small calibre, it consists of trinitrocresol, 20 parts; nitrate of potash, 70 parts; charcoal, 8 parts; and stearic acid, 2 parts, all by weight, in both cases.

The three last-named ingredients are incorporated in a revolving iron cylinder containing bronze balls. The mixture is then transferred into a wooden revolving cylinder, with wood balls, and the trinitrocresol incorporated with it. The mixture is then pressed hydraulically into slabs, which are subsequently granulated by means of rollers. The granulated powder is then treated in a glazing drum in which the heat produced by friction is sufficient to melt the stearic acid, which then forms a water-proof coating on each grain.—R. B. P.

## XXIII.—ANALYTICAL CHEMISTRY.

### APPARATUS, ETC.

*Ultimate Organic Analysis under Pressure in an Autoclave.* Hempel. Ber. 30, (1897), [2], 202—211.

THE author has devised a rapid and easy mode of determining carbon, hydrogen, sulphur, and halogens in organic compounds by combustion in compressed oxygen in an autoclave similar to Berthelot's explosion-bomb, but smaller, so as to economise substance, save time, and admit of weighing the whole on an ordinary chemical balance.

The apparatus, shown half size in the figure, is bored and turned out of a block of iron or steel, is enamelled inside, is 2 mm. thick in the walls, will stand a pressure of 200 kilos. per

Fig. 1.

sq. cm., and holds 33 c.c., so that 800 c.c. of oxygen at atmospheric pressure will be contained in it at 25 kilos. per sq. cm. The cover is screwed on upon a lead ring packing, and the central screw for the valve is packed with vulcanised fibre. Through a passes (packed and insulated by india-

rubber) an iron rod, to which is attached the platinum wire *b*, while *c* is a platinum spoon attached to the cover, and in which stands the little open cylinder of fireclay.

Solids are compressed in a mould into little cylinders, a short length of cotton thread being first inserted, the ends of which, twisted round a fine platinum wire stretched between *b* and *c*, serve as a torch or wick. Liquids are dropped into the spoon from a small weighed pipette, a similar thread dipping into the liquid. The  $\text{CO}_2$  and  $\text{H}_2\text{O}$  yielded by combustion of a known length of this thread are determined once for all, and allowance made in each analysis.

Fig. 2.

chloride tube *B*, the soda-lime tube *C*, and the guard-tube *D*. The valve is opened, and the gases allowed to pass slowly out. When this ceases, *k* is connected to a water aspirator, and when exhaustion goes no further, purified air is admitted through *m* and the pump again set to work; the admission of air and exhaustion are repeated. The apparatus is taken apart, and autoclave, water-collector, and  $\text{CO}_2$ -collector separately weighed. The autoclave is now opened, rinsed with water, and the acidity determined by centinormal soda solution. Sulphur and halogens can now be determined in the usual way. Any carbon remaining in the spoon is burnt off in the air, the spoon being weighed before and after, and the weight of the carbon added to that calculated from the  $\text{CO}_2$ .

A specimen analysis and calculations are given in the paper. The autoclave used by the author weighs 250 grms. and costs about 50s.—J. T. D.

#### PATENTS.

*Measuring the Power or the Volume of the Gases Resulting from the Explosion of Explosives, An Improved Method of and Apparatus for.* H. H. Lake, London. From The Sprengstoff Actien-Gesellschaft-Carlbuth, Hamburg. Eng. Pat. 3023, Feb. 10, 1896.

The apparatus consists of two pistons *b*<sup>1</sup> and *b*<sup>2</sup> moving in two cylinders *a*<sup>1</sup> and *a*<sup>2</sup>, the latter, being closed at its upper

The substance is weighed, placed in the spoon, the autoclave closed, and the whole weighed. An adapter is then screwed on *d*, communicating with an oxygen cylinder and a pressure gauge, and oxygen allowed to enter till the pressure reaches 25 kilos. per sq. cm.; the valve is closed, and the oxygen bottle disconnected. The autoclave is then placed for safety in a strong outer cylinder of iron, the thin platinum wire heated by a current of electricity, and the combustion allowed to proceed. After half an hour (two hours if nitrogen acids, sulphur, or halogens be present) connection is made by the adapter *n* to the bulb-tube *f* containing a little strong sulphuric acid, the calcium

end by a cap *h*. *a*<sup>1</sup> is in communication with a chamber *c*, in which the material to be experimented upon is exploded by means of an electric detonator *d*. The piston *b*<sup>2</sup> is attached to a rod *f*, the lower end of which rests upon the top of *b*<sup>1</sup>, so that any movement of *b*<sup>1</sup> is communicated to *b*<sup>2</sup>. The lower end of *f* is guided by the block *g*, which slides in the tube *a*<sup>1</sup>. *a*<sup>1</sup> is attached by screwing to *a*<sup>2</sup> at one end and to *a*<sup>1</sup> at the other by means of *e*.

When the material being experimented on is exploded in *c*, pressure is set up and *b*<sup>1</sup> is forced outwards.

The motion of *b*<sup>1</sup> is communicated by *f* to *b*<sup>2</sup> and the air, or other gas, in *a*<sup>2</sup> is compressed until the total pressures acting on *b*<sup>1</sup> and *b*<sup>2</sup> are equal.

The dimensions of the various parts being accurately known, the pressure acting on *b*<sup>2</sup>, and therefore the pressure acting on *b*<sup>1</sup>, can be calculated from the distance moved through by the pistons. This distance can be recorded by attaching to the block *g*, a marking point *g*<sup>1</sup> (which is guided by a slot *a*<sup>1</sup> in the wall of *a*<sup>1</sup>) and allowing its outer end to trace a curve on the surface *g*<sup>2</sup> of a revolving drum *g*<sup>3</sup>.

In place of an elastic medium in the cylinder *a*<sup>2</sup>, an inelastic one, such as glycerin, may be used.

The cylinder *a*<sup>2</sup> is then provided with an opening of suitable size through which the inelastic medium is forced out. The quantity forced out serves as a measure of the power of the explosive.—R. B. P.

*Electric Device [Arc Lamp], for showing the Relation of Oxygen and Nitrogen in Mines and other places, Improved.* L. Cohn, Breslau, Germany. Eng. Pat. 28,609, Dec. 14, 1896.

See under II., page 231.

#### INORGANIC CHEMISTRY.—QUALITATIVE.

*Nitrous Acid, a Delicate Reaction for.* E. Riegler. Zeits. Anal. Chem. 1896, 35, 677.

In a small tube, place 0.02–0.03 grm. of crystallised naphthionic acid, add 5–6 c.c. of the liquid to be tested, shake well, add 2 or 3 drops of strong hydrochloric acid and shake thoroughly for a minute, now add 20 or 30 drops of ammonia, holding the tube in a slanting position. Traces of nitrous acid cause the appearance of a rose-coloured ring where the liquids meet: on shaking, the whole liquid becomes rose or dark red according to the quantity of nitrous acid present. Since very dilute solutions of naphthionic acid fluoresce, the colour should be examined by transmitted light. In rain water and tap water the presence of nitrous acid is well shown by this reaction. The coloration depends on the formation of diazonaphthalenesulphonic acid, which with ammonia and a second molecule of naphthionic acid produces a dyestuff.—A. C. W.

# INORGANIC CHEMISTRY.— QUANTITATIVE.

## Phosphoric and Arsenic Acid, Titration of: An Exact Method of. A. Christensen. Zeits. Anal. Chem. 1897, 36, 81.

THE author finds that by titration of the free iodine liberated on mixing an excess of solution of potassium iodide and potassium bromate with free phosphoric acid, the reaction which takes place is in accordance with the equation—

In conducting the determination, the diluted phosphoric acid solution not exceeding the equivalent of 40 c.c. of decinormal thiosulphate solution (1 c.c. of which = 0.007 grm.  $\text{P}_2\text{O}_5$ ), is placed in a flask with a well-ground stopper along with 3 grms. of potassium iodide and 10 c.c. of 5 per cent. potassium bromate solution diluted to 100 c.c. and either allowed to stand at normal temperature until the next day or warmed between 40° and 50° for half an hour, and the free iodine titrated. The end of the reaction is sharp, and far more delicate than in the methods of acidimetric titration with standard alkali. The method is applicable with modifications to bone meal, Thomas slag, and other commercial phosphates, the phosphoric acid being precipitated as silver or magnesium ammonium phosphate, from which it is liberated by means of sulphuric acid, and in the author's hands has given most satisfactory results. For details of the many experiments reference should be made to the original paper.

In the determination of arsenic acid by this method the results obtained were not quite so exact as in the case of phosphoric acid, but were sufficiently so to be of considerable value.—J. O. B.

## Sulphur in Pyrites, Determination of, by Means of Sodium Peroxide. C. Glaser. Chem. Zeit. 1897, 40.

IN the extraction of the melt (see this Journal, 1894, 1095) it sometimes occurs that the residue is more or less black, due to the formation of ferrous sulphide produced by interaction of iron oxide and still-present sodium sulphide. This is more likely to occur if the peroxide by frequent exposure has lost some of its oxidising power. The finely divided iron sulphide may without difficulty be oxidised whilst wet; let the liquid cool somewhat, and add sodium peroxide in small quantities until the colour of the residue becomes a pure brownish-red and a permanent foam forms, when this is the case all the sulphur is oxidised. The residue should be washed at the pump with boiling water. Since the iron oxide readily dissolves in a hydrochloric acid solution of bromine, it may readily be tested for sulphur, and if necessary any small amount of barium sulphate can be added to the main precipitate.

The difficulty mentioned by Asbóth (this Journal, 1895, 597), that in low grades of pyrites (30 per cent.), separation of silicic acid may increase the weight of the barium sulphate, has not been noticed by the author in analyses of 40–45 per cent. American pyrites, and moreover analyses made by his method agreed very well with results obtained by Fresenius's method. Possibly the explanation may be that the author only allows the precipitate to stand long enough for complete deposition, for which 15 minutes is ample when precipitating in hot solution with addition of the barium chloride in drops.—A. C. W.

## Ferric Chloride, Volatility of. H. P. Talbot. Amer. Chem. J. 1897, 19, 52–59.

THE author states that no loss of iron, in the form of ferric chloride, is to be feared under the conditions which prevail in ordinary analytical processes, unless residues containing also ammonium chloride are ignited, or such residues have contained traces of aqua regia, when a small, but appreciable loss of iron appears to be possible.—A. S.

## Caustic Alkali, Estimation of, in Presence of Alkaline Carbonates. G. Lange. Zeits. f. angew. Chem. 1897, [2], 41–42.

AN investigation by Küster into the volumetric methods of estimating caustic alkali in liquors containing carbonate shows that of six methods involving the use of barium chloride, only that of C. Winkler gives true results. The present paper gives a comparison of the results obtained on analysing various samples: (a) by the gas volumetric method; (b) by direct differential titrations using phenolphthalein and methyl orange as indicators; (c) by the Winkler method (direct titration with methyl orange as indicator, and in a second portion, titration, after the addition of barium chloride, using phenolphthalein), carefully following Küster's directions as to the very gradual addition of the  $\frac{1}{2}$  normal hydrochloric acid used for titration. When only small percentages of carbonate were present all three methods led to identical results, but when the quantity of alkali as carbonate became greater than that present as caustic alkali, whilst methods (a) and (c) gave correct, identical and true values, method (b) no longer yielded correct results.—J. T. C.

## Persulphates, Analysis of. F. Ulzer. Zeits. f. angew. Chem. 1897, 61.

IN the estimation of active oxygen, the author states that he obtained good results by heating a solution of about 0.3 grm. of the sample with an excess of ferrous ammonium sulphate solution (containing 1 to 1.5 grm. double salt solution) and dilute sulphuric acid in a current of carbonic anhydride, or using a Bunsen valve, for about half an hour, and titrating back the excess of iron salt with permanganate. To determine the total sulphuric acid, a solution, as concentrated as possible, of a weighed quantity of the sample, was heated for some time with hydrochloric acid to destroy the persulphuric acid, and after strong dilution, the sulphuric acid was precipitated as barium sulphate. A sample analysed gave 70.01 per cent. total sulphuric acid, 14.01 per cent. of ammonia, and a fixed residue of 0.61 per cent. The sample contained 45.61 per cent. of ammonium persulphate (3.2 per cent. active oxygen) and contained free acid, titrated by normal alkali, using methyl orange, equivalent to 18.93 per cent. of sulphuric acid. The composition of the sample is given as follows:—Ammonium persulphate, 45.61 per cent.; acid ammonium sulphate, 48.77 per cent.; residue, 0.61 per cent.; and water, 5.01 per cent.—J. T. C.

## Manganese, Electrolytic Determination of. C. Engels. Zeits. f. Elektrochemie, 1897, 3, [14], 286–289, and 305–308.

THESE are further communications on an electrolytic method for quantitatively estimating manganese described in a previous number of the same Journal (1895–6, Heft 19). An account of the method (abstracted from the *Berichte*) as applied to salts of manganese will be found in this Journal for 1896, 219. It is now stated that the method can be used for directly determining manganese in salts of manganic and permanganic acids. To a solution of the salt (say, potassium permanganate) add 5 c.c. of acetic acid (1:2), and enough hydrogen peroxide to decolorise the solution. The presence of even a small quantity of hydrogen peroxide prevents the formation of an adherent deposit. The excess must therefore be removed by adding a small amount of chromic acid: 0.2 to 0.4 grm. is generally sufficient. 2 grms. of chrome alum and 10 grms. of ammonium acetate are next added and the solution is made up to 150 c.c. The electrolysis is carried out with an E.M.F. of 3 to 3.4 volts and a current density of about 0.9 ampère per 100 sq. cm. The electrolysis is most satisfactorily performed at a temperature of 85°, the deposit then obtained being adherent. At lower temperatures it is brittle, and during the subsequent processes of washing with alcohol, drying, and heating, there is apt to be decrepitation and loss.—D. E. J.

## Nickel and Copper, Separation of, in Matte, and the Recovery of the contained Precious Metals. T. Ulke. Eng. and Mining J. 63, [5], 113–114.

IN this article the author gives a short review of the various electrolytic methods proposed for the above separa-

tion. In referring to Hoepfner's process (this Journal, 1897, 49), he mentions the chief objection as being due to the fact that a cheap and durable diaphragm of low electrical resistance has not yet been discovered. Rickett's method (1893) of precipitating the nickel as basic sulphate and separating the copper by electrolysis, is also spoken of as not showing promise. In mentioning the difficulty of depositing a thick plate of pure nickel owing to its peeling off, in consequence probably of thick films of oxide, it is said that plates  $\frac{1}{2}$  in. thick are now produced at the Balbach Works, which are very tough and elastic, and will not break or crack under the hammer. In these works, anodes containing about 95 per cent. of nickel, 0.55 of copper, 0.75 of iron, 0.25 of silica, 0.15 of carbon, and 3 per cent. of sulphur—the latter added to facilitate the casting—are used; and over 1,000 lb. of metallic nickel, containing less than 0.03 per cent. of arsenic and 0.02 per cent. of sulphur, are produced daily. The chief drawback to electrolytic processes appears to be the falling to pieces of the metallic or matte anodes, and the formation of large quantities of anode scrap, which sometimes amounts to 50 per cent. of the charge, and which consequently must be remelted into anodes and re-treated.

The process for treating Bessemer matte and recovering the precious metals therefrom, proposed by the author, is then described. The granulated matte is dissolved in dilute sulphuric acid, so that the electrolyte will contain about 8 per cent. of free acid. To this is added one-half per cent. of ammonium sulphate to retard the electro-deposition of arsenic, and a little hydrochloric acid to retain all the silver in the slime. Copper and nickel dissolve at the anode, while copper deposits at the cathode, and the precious metals with the anode scrap are deposited and settle down as slime. The copper is deposited from the solution first until the percentage is very small as compared with the nickel present, when the solution is separated from the electrolytic tank, and the remainder of the copper thrown down by sodium sulphide. The nickel solution thus obtained is freed from the small amount of iron present, and the nickel electrolytically deposited therefrom. For this purpose the liquid is kept neutral or slightly ammoniacal, and insoluble anodes of carbon or lead, or soluble anodes consisting chiefly of nickel, are used. With the former anodes the nickel will be of great purity, whilst with the latter it will be practically pure until the other metals in the nickel anode accumulate to an appreciable extent in the bath. With insoluble anodes the solution gradually becomes acid, and with soluble anodes it becomes alkaline, so that it is suggested both anodes be used in the same bath to preserve its neutrality.

A method of determining copper and nickel in the same portion of matte is then described as follows:—5 grms. are treated with 2.5 c.c. of sulphuric acid (1:1) and 10 to 15 c.c. of hydrochloric acid. After 10 minutes digestion, 5 c.c. of nitric acid are added, and the solution is evaporated to dryness. The mass is dissolved in water with a few drops of nitric acid, diluted to 100 c.c., and connected with the battery to deposit the copper, allowing about  $\frac{1}{2}$  ampère for each assay, the deposited metal being washed with alcohol and dried. To obtain the nickel, 0.5 to 1 gm. of sodium peroxide is then added to the solution, and the iron precipitated with ammonia, redissolved, and reprecipitated four times. The four solutions are mixed and evaporated to about 200 c.c., made strongly ammoniacal, and placed in connection with a Grove's battery. Two ampères per solution are allowed, and the temperature should be 70° C. In about 1 to 1½ hours the nickel is deposited, and is washed with water and alcohol, and weighed.

—A. W.

#### *Molybdenum and Vanadium, Volumetric Estimation of.* C. Friedheim. Ber. 29, 2981—2985.

This paper is a reply to some criticism by Gooch and Fairbanks of a method for estimating molybdenum, previously described by Friedheim and Euler, depending on the reaction  $2\text{MoO}_3 + 2\text{HI} = \text{Mo}_2\text{O}_3 + \text{H}_2\text{O} + \text{I}_2$  (See this Journal, 1896, 220).

The determination, as previously described, is carried out in a Bunsen apparatus, and one objection raised by Gooch

and Fairbanks is that error is introduced through oxidation of distilled hydriodic acid by atmospheric oxygen present in the receiver. They accordingly recommend that the reaction be carried out in an atmosphere of carbonic acid; this the present author condemns as unnecessarily complicating the process, and he reasserts that correct results are readily obtained provided that the first heating in the distillation is a gradual one, and that the solution is not raised to boiling until the retort is filled with iodine vapour. The reaction is ended when the iodine colour has vanished and the solution has become light-green; and the author shows that a statement by Gooch and Fairbanks that these indications are not sufficient, is based on insufficient grounds, and that the iodine found by these authors in the distilling flask is due to oxidation by air of the contained hydriodic acid.

For the reduction of vanadium pentoxide to the tetroxide (or, in presence of syrupy phosphoric acid, to the trioxide) by means of hydriodic acid, to obviate the use of the Bunsen apparatus, Browning has proposed to reduce the vanadate with hydriodic and sulphuric acids in an open vessel, and, after boiling off the iodine and nearly neutralising with caustic alkali, to add sodium bicarbonate and tartaric acid, and then to estimate the vanadium tetroxide with excess of standard iodine solution, titrating back with arsenious acid.

The author regards the use of two standard solutions as undesirable, and states that the Browning process renders the estimation of bases (lead and barium) in the distillation residue exceedingly difficult. A similar objection holds for Gooch and Fairbanks' proposal to apply Browning's process to the estimation of molybdenum.—J. T. C.

#### *Mercury in Ammonio-Mercuric Chloride, Estimation of.* J. R. Thompson. Chem. and Druggist, 1897, 50, 231.

The author has reported the examination of five samples of ammonio-chloride of mercury obtained from different sources. He found the following percentages of Hg estimated as  $\text{Hg}_2\text{Cl}_2$  in the five samples respectively:—A = 71.53, B = 71.56, C = 73.05, D = 75.01, E = 76.80. The B.P. standard is 77.5. He also found that the method of estimating the mercury as a metal was open to error on account of the loss in drying the metallic mercury. To reduce it to sub-chloride  $\text{Hg}_2\text{Cl}_2$ , he dissolved a weighed quantity of ammonio-mercuric chloride in hydrochloric acid in a beaker. To this an acidified solution of potassium hypophosphite was added, when a precipitate of  $\text{Hg}_2\text{Cl}_2$  was almost immediately thrown down. This was set aside for 12 hours, then washed with hot water till free from chloride, pressed, dried at 100° C. till constant, and weighed.—A. S.

#### ORGANIC CHEMISTRY.—QUANTITATIVE.

##### *Fatty Acids, Note on Wechsler's Method for the Separation of.* A. W. Crossley. Proc. Chem. Soc. 1897, [174], 21—22.

WECHSLER (Monatsh. 1893, 14, 462) has described a method for the separation of fatty acids, the principle of which method is contained in the following statement:—

If to a mixture of two fatty acids four-fifths of the caustic soda necessary to neutralise them be added, and the whole steam-distilled, the distillate contains the pure higher boiling acid. From the residue of the distillation a further three-fifths of the acids are set free by addition of sulphuric acid, and the whole is distilled with steam. Finally, the remaining fifth of the acids is set free, and in this case the distillate contains the lower boiling acid in a pure condition.

The purity of the acids contained in the various distillates was proved, by converting them into silver salts and subsequent analysis of these salts.

After experimental trial, it is concluded that Wechsler's method does not give such good results as its author suggests, nor can it in any way be looked upon as a satisfactory method for separating mixtures of fatty acids.

##### *Prussian Blue: Commercial Analysis.* E. J. Parry and J. H. Coste. Analyst, 1896, 21, [246], 223.

TUR authors adopted the following scheme of analysis:—The moisture was determined by drying at 100° C., and the

water of combination by combustion with lead chromate. The nitrogen was estimated by boiling with sulphuric acid and then determining the ammonia in the ammonium sulphate formed. For the estimation of the total iron, a weighed quantity was ignited, care being taken that the temperature was sufficiently high to decompose the last traces of the blue, but not high enough to render the oxide of iron difficult of solution. In all cases, on adding hydrochloric acid to the "ash," a marked effervescence showed that alkaline carbonate was present. The acid solution was filtered, if necessary, from barium sulphate or other insoluble matter, and the iron (and alumina) precipitated with ammonia. The iron in the (weighed) mixed oxides was determined by titration with potassium bichromate, after reduction with stannous chloride, the alumina being estimated by difference. A portion of the filtrate was evaporated to dryness, and, after volatilisation of the ammonium salts, the alkaline salts were weighed, and the chlorine therein determined by titration with silver nitrate. In another portion of the filtrate, the sulphuric acid was determined, and from these data—*viz.*, the weight of the alkaline salts, chlorine, and sulphuric acid—it was shown that in all cases the alkali-metal was almost entirely potassium or sodium, and in no case a mixture of the two metals. Another weighed quantity of the pigment was boiled for a few minutes with aqueous potash, and the resulting precipitate of oxide of iron weighed, after ensuring its complete conversion into  $\text{Fe}_2\text{O}_3$ . This, multiplied by 0.7, represents the "extra-radicle" iron.

Pigments sold as Prussian blue should contain at least 20 per cent. of nitrogen and 30 per cent. of iron, calculated on the dry matter, and, after burning, should be entirely dissolved by hydrochloric acid. The sulphuric acid used in the nitrogen determination should not be blackened; this, if it occurs, indicating the presence of organic adulterants.

—A. S.

*Carbonyl Compounds. Determination of Aniline in Quinoline.* C. Liebermann and J. Flatau. Ber. 30, 234.

See under IV., page 233.

*Glue, Viscosity of. A New Process for Determining the.* J. Fels. Chem. Zeit. 1897, 21, 56 and 70.

THE author discusses the commercial valuation of glues, and offers a criticism and list of the principal chemical and physical methods. He adopts in principle Lipowitz's method (Neue chem. techn. Unters. Berlin, 1861, 37–42), which is based on the fact that the consistency of a glue is equivalent to the quality—that is, to its adhesiveness. The glue under examination is powdered, and a portion dried at 100° C. for two hours, to determine the water. 100 grms. are treated with 400 c.c. of cold water for 24 hours, and finally dissolved by warming on a water-bath; it is then diluted so that 15 per cent. of dry substance is in solution. The viscosity determination is made with this solution at 30° C. using an Engler's viscosimeter; the viscosity of water at the same temperature being taken as unity. The viscosity period, divided by that of water, gives a number expressing the consistency of the glue in question.

—J. L. B.

*Albuminoids in Substances Rich in Starch, A Modification of Stutzer's Method for the Estimation of.* H. Tryller. Chem. Zeit. 1897, 21, 54.

WHEN albuminoids are estimated by Stutzer's method, dealing with substances rich in starch, considerable difficulty is experienced in filtering and washing the copper hydroxide compound. Stutzer himself has proposed to warm such substances on the water-bath for only 10 minutes, so as to prevent, as far as possible, the gelatinisation of the starch. The author employs malt extract to transform the starch, and carries out the determination in the following manner:—1 gm. of the substance is well incorporated with 100 c.c. of water, placed in a beaker, and heated on a boiling water-bath for 10 minutes; it is then cooled to 65° C. and 10 c.c. of malt extract (100 of malt to 500 c.c. of water) added, the above temperature being maintained for 20 minutes. The alum and copper hydroxide are next introduced, and the contents of the beaker heated for 10 minutes in a boiling

water-bath. The precipitate is collected on a filter, well washed, and the nitrogen determined by Kjeldahl's method in the precipitate *plus* the filter. The result is corrected for the nitrogen present in the malt extract. A list of results show that the numbers obtained by this modification and by Stutzer's method agree closely.

—J. L. B.

*Optically Active Substances in Beetroots, Presence and Estimation of.* F. Herles. Zeits. Zuckerind. Böhmen, 1897, 21, 302–305.

WHEN the yield of sugar does not agree with the polarisation of the beetroots worked up, the task of the chemist is often to ascertain if, along with sugar, there are not other dextro-rotatory substances present in the roots. In factories where the basis of control is the polarisation of the juice and not the direct polarisation, the discrepancy is to be sought in this circumstance, but it also occurs when hot-water digestion is used, and in this case the difference between the alcoholic and water digestion is regarded as a proof of the presence of optically active non-sugars.

The author had occasion to examine a sample of halved beetroots which had given a difference of 2.2 per cent. between the alcoholic and water digestion. By digestion with 96 per cent. alcohol, 90 per cent. alcohol, and with water, he obtained 13.30, 13.60, and 13.90 per cent. respectively. The normal weight of expressed juice, when made up to 100 c.c. with 93 per cent. alcohol and with water, read 14.90 and 15.10 per cent., showing the effect of alcohol in lowering the reading. He attributes larger differences to bad sampling, imperfect subdivision of the pulp, and consequent imperfect extraction, or inaccurate tests, and suggests as the direct proof of the presence of active bodies the Clerget inversion (this Journal, 1897, 67).

—L. J. de W.

*Reducing Sugars, Determination of, in Terms of Cupric Oxide.* G. Defren. J. Amer. Chem. Soc. 1896, 18, 749–756.

THE author employs O'Sullivan's method (J. Chem. Soc. 1876, ii., 130) for the determination of the reducing powers of sugars. The Fehling's solution is prepared according to Soxhlet's formula, with a slight modification:—69.278 grms. of crystallised copper sulphate are dissolved in water and the solution made up to one litre. 356 grms. of Rochelle salt, and 100 grms. of sodium hydroxide are dissolved in water and made up to a litre. The two solutions are kept in separate bottles. The cuprous oxide may be collected on paper in a Soxhlet tube, or Gooch crucible; the last two being packed with prepared asbestos. It is then well washed, ignited, and weighed as cupric oxide.

It has been stated by O'Sullivan (*loc. cit.*) that 1 gm. of glucose produces 2.205 grms. of cupric oxide. The author, however, finds that this value is not a constant for all weights of glucose, the amount varying from 2.27 grms. of cupric oxide for small quantities, and 2.22 grms. for large; this is the case also with maltose and milk sugar. The weights of dextrose, maltose, and milk sugar respectively, corresponding to a given weight of cupric oxide, are obtained by the following formulae, in which W = the weight of cupric oxide:—

$$D = (0.4400 + 0.000037 W) W$$

$$M = (0.7215 + 0.000061 W) W$$

$$L = (0.6270 + 0.000053 W) W.$$

Tables are given in which the weights of dextrose, maltose, or milk sugar, corresponding with given weights of cupric oxide, are obtained. A supplementary table is added for application to mixed products such as commercial glucose, in which the weights of cupric oxide and equivalent weights of dextrose, as obtained by the 3.86 divisor, have the relation 386:381 to the absolute equivalents.

—J. L. B.

*Starch, Conditions affecting the Volumetric Estimation of, by Means of a Solution of Iodine.* F. T. Littleton. Amer. Chem. J. 1897, 19, 44–49.

THE author concludes, as the result of a series of experiments, that on account of the dissociating effect of water on starch iodide, the iodometric method is available only with

substances containing a large amount of starch, and is best used when the substances compared, contain starch in proportions not widely differing. The solutions to be colorimetrically compared must be in all respects under conditions very nearly identical.

The so-called iodide of starch, if a chemical compound, is one very easily dissociated, e.g., by rise of temperature, by increase of the amount of solvent water, and by the introduction of another liquid, such as chloroform, carbon bisulphide, &c., having a superior solvent power for iodine.

—A. S.

*Aldehyde in Alcohol, Estimation of.* J. Paul. Zeits. anal. Chem. 1896, 35, 647.

In Mohler's method of using Schiff's reaction for the colorimetric estimation of aldehyde in alcohol (Ann. Chim. Phys. 1891, 121), a solution of magenta decolorised by fixed quantities of sodium bisulphite and sulphuric acid is used. The coloration is, however, different when different sulphite solutions are used, probably because solutions of the same specific gravity have not always the same composition. The author overcomes this difficulty by the use of sulphurous acid solutions, the strengths of which can be iodometrically determined. The reagent contains 0.05 gram of magenta and 0.5 gram of  $\text{H}_2\text{SO}_3$  in 100 c.c., and is made by mixing a solution of the purest "Diamant Fuchsin" of known strength (filtered, whether clear or not) with the corresponding quantity of sulphurous acid, and making up to the volume given. After an hour or two the solution is colourless. It may be kept in well stoppered bottles for a few days, but long keeping is to be avoided.

When alcohol free from aldehyde is required, the author finds that Mohler's method—boiling 1 litre of absolute alcohol with 10 c.c. of aniline and 10 c.c. of phosphoric acid of 45° B. for an hour with return-condenser—gives an alcohol containing both aldehyde and aniline. All attempts to purify alcohol by chemical methods were unsuccessful; finally the following process was adopted:—A 10-litre flask was connected with a fractionating column inclined at an angle of 45° with the horizon, and this with a reflux condenser through which water at 50°–60° C. slowly flowed. The flask contains 8 litres of about 95 per cent. alcohol, not too rich in aldehydes, which is kept boiling on the water-bath. Aldehyde escapes at the open end of the condenser; its exit is facilitated by inserting in the condenser to the level of the water, a tube connected with an aspirator. After several days of such treatment the alcohol was slowly distilled off, a second condenser being connected to the first. The first fraction of 3 litres was rejected; the second, also of 3 litres, was used for the preparation of the typical solutions. In most cases the colorations are sufficiently intense when the alcohol is diluted to 30 per cent.; only when the liquid would contain after such dilution less than 15–20 mgrms. of aldehyde per litre, is dilution to 50 per cent. necessary. The typical solutions contain 25, 50, 100 mgrms. of acetaldehyde in 1 litre of alcohol of 30 volume per cent. For alcohols very poor in aldehyde a solution containing 10 mgrms. in 50 per cent. alcohol, was used. The observations were carried out with the Krüss's polarisation colorimeter and Duboseq's colorimeter. The following is a detailed description of the process with a solution of known strength:—10 c.c. of the alcohol to be tested and 10 c.c. of the typical solution of 25 mgrms. content were placed in two dry test tubes swimming in a large vessel of water at 16° C., where the temperatures were equalised. 1 c.c. of the reagent was added to each tube as rapidly as possible, the contents mixed, and the tubes again placed in the water. After 25 minutes the two liquids were poured at the same time into the cylinders of the colorimeter, 10 observations were made rapidly, the height of the solution under investigation being 25 mm. The mean of the 10 observations of the height of the typical solution was 24.1 mm.; thus the aldehyde content of the alcohol is  $25 \times \frac{24.1}{25} = 24.1$  mgrm. per litre. In practice, the aldehyde content of the unknown alcohol will not be so nearly equal to that of the typical solution: a rapid preliminary experiment is made, using a typical solution of less strength than that of the unknown alcohol, and from

the result of the test the alcohol is diluted to such an extent as to give about the required tint. When the polarisation colorimeter of Krüss is employed, the typical solution of 100 mgrms. is unusable, and that of 50 mgrms. to the litre gives intense colorations with which it is difficult to work.

If the greatest accuracy is not required, the colour comparisons may be made in test-tubes of equal diameter. The author finds, in agreement with Mohler and in opposition to Bornträger, that acetal may be estimated by this method, being apparently entirely split up by the sulphurous acid. 70 parts of furfural give only the same coloration as 1 part of acetaldehyde.

Of other triphenylmethane colours, Crystal Violet does not give the reaction, Methyl Violet BB from Meister, Lucius, and Brünig, and Methyl Violet 1 B conc. from Farbentabriken vorm. F. Bayer and Co. are both decolorised by sulphurous acid and give bluish violet colorations proportional to the quantity of aldehyde, but the intensity is much inferior to the magenta coloration. Methyl Violet 5 R from the last-mentioned firm gives very favourable results, almost surpassing those with magenta. In the experiments quoted, using magenta, the maximum error is 8 per cent.

—A. C. W.

*Alkaloids and their Salts, Note on the Estimation of Water in.* D. B. Dott. Pharm. J. 1897, 58, 21.

Drying on the water-bath is recommended as the most convenient course in the case of the alkaloids and their salts, when these are being estimated by pharmacopœial methods, and should be adopted when not contra-indicated. But as the temperature of a water-bath varies according to its size, ventilation, and the amount of water contained in it, a substance which does not readily part with its water a few degrees below 100° C. should not be dried in the water-bath but in an air-bath, or otherwise at a temperature over 100° C. Morphine hydrate is such a substance. In an ordinary copper water-bath, 10 ins. internal measurement, pure morphine hydrate in fine powder lost, after two hours, 3.31 per cent.; after three hours, 3.56 per cent.; the bath being well-filled with water briskly boiling. The morphine was then heated in an air-bath for an hour at 120° C., when it indicated a loss of 6.35 per cent., and lost nothing farther. Another sample dried in the water-bath containing very little water, had lost after two hours only 0.17 per cent., then on drying at 120° C., a loss of 6.49 per cent. was indicated. The formula,  $\text{C}_{17}\text{H}_{19}\text{NO}_3 \cdot 9\text{H}_2\text{O}$ , requires 6.63 per cent. loss on complete desiccation. The morphine precipitates of the Pharmacopœia should therefore be dried either at a low temperature (as U.S.P.), or at 110° to 120° C. When an alkaloid has been extracted by alcohol or chloroform, it is much more convenient to dry at 110° to 120° C., assuming that there is no decomposition at this temperature, as the alkaloid may only slowly attain a constant weight in the water-bath. In the case of salts which lose only a proportion of their water under 100° C., and the remainder at a higher temperature, it is preferable to dry at the higher temperature so as to estimate the total water of hydration.—A. S.

*Morphine in Opium and its Preparations, Assay of.* A. Grandval and H. Lajoux. J. Pharm. Chim. 1897, [6], 5, 153.

*Opium.*—10 grms. of opium are triturated in a glass mortar with 40 c.c. of water until thoroughly disintegrated, then thrown on a small pleated filter, washing the mortar with another 40 c.c. of water, which is poured over the filter. This is thoroughly drained, the filter and its contents again rubbed down with a third portion of water and filtered, and washed until the filtrate is free from bitterness. The washings and the filtrates are evaporated together until reduced to 13 grms., the same weight of alcohol (95 per cent. by volume) added, and the mixture allowed to stand for half an hour to permit the sulphate or meconate of lime to separate; the liquid is then filtered through a small filter previously moistened with 60 per cent. alcohol. The precipitate is washed with (60 per cent.) alcohol, which is dropped gradually on to the edge of the filter, kept carefully covered with a glass disc to prevent drying of the

edges. To the filtrate, ammonia is added cautiously until a slight ammoniacal odour persists, stirring is continued for some minutes, when the morphine is gradually precipitated in the tracks of the rod. The mixture is allowed to stand for 12 hours in the cool, and the precipitated alkaloids collected on a tared filter, thoroughly drained, and cautiously washed with 40 per cent. alcohol until the filtrate is colourless; this should require about 25 c.c. The filter and its contents are then well drained, dried at 100°, and weighed. The weight of morphine and narcotine is thus obtained. The filter is again placed in the funnel and washed first with 5 grms. of ether and then with 10 grms. of chloroform, which latter solvent removes the narcotine. The filter is again dried and the morphine weighed as hydrated morphine. It is stated that chloroform does not dissolve hydrated morphine, although it acts as a solvent upon the anhydrous alkaloid.

*Extract of Opium.*—5 grms. of extract are dissolved in 5 c.c. of water, 5 grms. of alcohol of 95 per cent. added, allowed to deposit, and filtered through a small filter, moistened with alcohol of 60 per cent. The precipitate is washed with 40 c.c. of alcohol of 40 per cent., and the assay continued as described above.

*Tincture of Opium.*—26 grms. of the Codex tincture (corresponding to 2 grms. of the extract) are evaporated to 7 grms., 5 grms. of alcohol of 95 per cent. are then added drop by drop and a slight excess of ammonia. The assay is completed as above.

Special minutie for manipulation in the case of assaying Rousseau's laudanum, Black drop, and Sydenham's laudanum, are given.—J. O. B.

*Antipyrine, Chemical Estimation of.* C. Kippenberger. *Zeits. Anal. Chem.* 1896, **35**, 659.

On the addition of a solution of iodine in an iodide, to solutions of antipyrine in water, acidified or not, there is produced antipyrinehydriodic periodide,  $C_{11}H_{12}N_2O \cdot HI \cdot I_2$  (compare this Journal, 1896, 223, 747), this is a brown tarry mass which does not crystallise on standing, is insoluble in water and in dilute hydrochloric and sulphuric acids, soluble in alcohol and chloroform, and especially in acetone. Hydriodic acid and its salts increase the solubility of the precipitate in water; it separates quantitatively in the presence of sufficient iodine solution, and may be used for the separation of antipyrine from phenacetin, sulphonal, acetanilide, and aniline salts, if acid be present, hydrochloric acid being most suitable. In the presence of aniline salts the filtration of the separated periodide should be accomplished as rapidly as possible. The details of the process are as follows:—To the solution of antipyrine, which should be as concentrated as possible, there is added in a stoppered flask an iodine solution, made by mixing 100 c.c. of  $\frac{1}{20}$  N iodine solution, containing 10 or 20 grms. of potassium iodide to the litre, with about 4 c.c. of hydriodic acid of sp. gr. 1.7 (52 per cent. HI). Only a small excess of iodine solution is added and the flask is then shaken until the liquid becomes clear, the precipitate adhering to the sides of the flask. The liquid is filtered through a small asbestos filter, the filtrate being best collected in a dry burette. In an aliquot part of the filtrate the iodine is determined by  $\frac{1}{20}$  N thiosulphate. 21.3 c.c. of  $\frac{1}{20}$  N iodine solution are equivalent to 0.1 gm. of antipyrine. The error due to solubility of the periodide in solutions of iodides is negligible unless absolute accuracy be required, in which case the iodine solution should be standardised against an antipyrine solution of known strength. Iodine solution in large excess would hinder this solvent action of hydriodic acid or its salts, but irregularities in the action of the iodine occur. Instead of the iodine solution containing hydriodic acid, as described above, a solution containing more potassium iodide may be used, but in that case hydrochloric acid must be added, and the reaction takes longer time. Salipyrine (antipyrine salicylate) and other antipyrine salts may be estimated in the same way.—A. C. W.

*Oil of Lemon, Analysis of.* A. Soldini and E. Berto. *Chem. and Druggist*, 1897, **50**, [872], 25.

The authors state that in using the method of fractional distillation and subsequent polarisation of the distillate, for

detecting adulteration of oil of lemon with oil of turpentine and oil of orange (Schimmel and Co.'s Bericht, Oct. 1896, this Journal, 1896, **15**, 925), they have found that the distillate from pure lemon oil invariably has a higher rotation than the original oil, and not a lower, as is stated to be the case.

For the estimation of citral, the following method is used:—A solution of bisulphite of potash is shaken up with the oil of lemon, whereby the whole of the citral in the oil is fixed and separated from the limonene and other compounds that have no aldehyde function. The decrease in volume is then estimated under identical conditions of temperature, and the volume of citral calculated. When relatively large quantities of turpentine or orange oils and even limonene are present, a correction must be made. The greater the proportion of citral to be estimated, the larger is the difference between the ascertained and the calculated percentage, but oils do not generally contain more than 7.5 per cent. of citral. The presence of turpentine, oil of orange, and even limonene somewhat falsifies the results. An oil containing less than 5.5 per cent. by weight of citral should be viewed with suspicion, but should not be described as adulterated if neither oil of turpentine nor any other foreign matter can be found present.—A. S.

*Guaiaol and Creosotes, Rapid Method of Analysis.* L. Adrian. *Bull. de Therapeut. [Sec. Pharmacol.]*, 1897, **2**, 1.

The method is a colorimetric one, based on the solubility of guaiaol in water and the colour reaction afforded by that body with nitrous acid. From 5 to 6 grms. of the guaiaol or creosote to be tested, are placed in a flask of about 200 c.c. capacity along with some water, shaken for two minutes and filtered; this filtrate will contain more or less guaiaol, according to the quality of the substance tested; it is diluted with twice its volume of water, and 1 c.c. of this liquid is placed in a test-tube, which is then filled to one-third with more water, and the mixture is well shaken; in the meanwhile a 10 per cent. aqueous solution of sodium nitrite is prepared, 2 drops of which are added by means of a dropping tube to the mixture, followed by a drop of nitric acid, when the colour reaction is slowly developed. Commercial guaiaol containing less than 50 per cent. of the pure body will give by this test a yellowish coloration, quite distinct from that obtained with a rich sample. The guaiaol content of a sample may be approximately determined according to this method, by preparing artificial mixtures of guaiaol free from creosote, containing from 10 to 90 per cent. of that body subsequently added. These types are treated with water and sodium nitrite as above described; the intensity of the colour of the sample under examination is then matched by means of these preparations of known guaiaol strength.—J. O. B.

*Mask-Pouches, Identification of Adulterated, by Means of the Röntgen Rays.* Wolff. *Pharm. Centr. H. N. F.* 1896, **17**, 827.

The transparency of mask-pouches under the Röntgen rays allows of the ready detection of the presence of fragments of lead used for adulterating and adding weight. A photograph is unnecessary, as the adulterant stands out quite plainly on the dark background.—J. L. B.

## XXIV.—SCIENTIFIC & TECHNICAL NOTES.

*Onocerin.* H. Thoms. *Ber.* **29**, 2985—2991.

This body is obtained from the roots of *Ononis spinosa* L. (*Papilionaceae*) by boiling out with 90 per cent. alcohol. The residue, on cooling, is treated with 60 per cent. alcohol, when the onocerin is left behind. By dissolving in absolute alcohol and passing the solution through animal charcoal, very small colourless prisms are obtained on evaporating off the alcohol. The solubility of onocerin in alcohol is very slight (0.25 per cent. in hot absolute alcohol). It is also only slightly soluble in acetic ether, ether, and chloroform, but is readily soluble in amyl alcohol and turpentine. The author shows, from a number of analyses made of the compounds formed by onocerin with acetic anhydride,

bromine, &c., that the formula of the body is  $C_{26}H_{44}O_2$ . On oxidation with potassium bichromate a ketone is formed, and from this a hydrazone by treating with phenylhydrazine. Analyses of these bodies lead the author to the conclusion that there is present in onocerin a dihydroxy-secondary alcohol, which on oxidation is converted into a diketone. Experiments were made to see whether this ketone is further oxidised by chromic acid mixture. A substance was obtained, the smell of which resembled butyric acid, but the yield was so small that it could not be chemically examined. The above-mentioned secondary alcohol ( $C_{26}H_{44}O_2$ ) only differs from cholesterol by one atom of oxygen.—W. P. S.

**Stannous Iodide, Apparent Action of Light in Inducing Crystallisation of.** C. J. H. Warden, *Pharm. J.* 1897, 58, [1387], 61.

A sample of stannous iodide, prepared by acting on stannous chloride with potassium iodide, was placed in a stoppered flint-glass bottle and exposed to diffused daylight, a piece of thin white paper cut in the shape of a cross being gummed to the bottle by the top of the cross. After some weeks, that portion of the contents not protected by the cross, was coated with ruby-coloured needles, while the salt behind the paper cross was apparently amorphous.

—A. S.

**Linseed Meal or Mustard Flour, Adulteration of with Colza Marc.** Jaworow-ki. *Pharm. Zeits. für Russ.* 1896, 35.

THE presence of colza-seed marc in linseed or mustard flour may be detected by boiling 2 or 3 grms. of the sample with a solution of 10 grms. of salt, 20 grms. of water, and 30 centigrms. of dilute hydrochloric acid. Care should be taken not to add the powder to the solution until the latter has reached the temperature of  $70^\circ$ ; on cooling, the mixture is filtered and neutralised with sodium carbonate, and two or three drops of a 1 per cent. solution of ferrieyanide of potassium are then added. If the powder is pure no coloration takes place, but if colza marc is present, a brown, red, or violet reaction is obtained.

—J. O. B.

**Luciferase, a Light Producing Zymase.** L. Dubois. *J. Pharm. Chim.* 1897, [6], 5, 81.

THE light produced by glow-worms, by putrifying fish, and other organised light giving structures, is stated to be derived from a peculiar ferment, which the author has named luciferase. From his experiments it appears that this physiological light results neither from combustion nor directly from slow oxidation, although oxygen is necessary for the production of the light, luciferase acting as a carrier of oxygen. The luminous organs of glow-worms as well as the eggs in the ovary of the female insect, give a blue coloration with tincture of guaiacum. The same reaction is given by the mucus obtained from the body of dead fish, when treated with chloroform water and filtered.—J. O. B.

#### PRIZES.

**Chemical Prizes by the Belgian Government.** *Chem. and Druggist*, March 13, 1897, 416.

THE Belgian Government offer several prizes, ranging in value up to 20,000 fr., for the best solutions of questions of industrial and scientific interest. The questions relating to chemistry are the following:—(1.) The determination of the constitution of camphor by means of analytical and synthetical reactions, and the differentiation of the optic isomers with the aid of chemical reactions. (2.) A practical method for the cheap conversion of atmospheric nitrogen into  $NH_3$ . (3.) A practical method for the preparation of chlorine from calcium chloride at a less cost than that now in use. (4.) A new process, better than the methods now known, for dyeing various textile yarns. (5.) A simpler method for the preparation of HI. (6.) Improvements in fractional distillation. Full details concerning these questions may be had upon application to the General Commissary of the Belgian Government, 17, Rue de la Presse, Brussels.

## New Books.

**TRAITÉ ÉLÉMENTAIRE DE CHIMIE, à l'usage des Candidats au Certificat d'Aptitude des Sciences Physiques, Chimiques et Naturelles et des Candidats aux Baccalauréats Scientifiques. CHIMIE MINÉRALE. 1<sup>re</sup> PARTIE.** Par A. HALLER et P. TH. MÜLLER. Georges Carré et C. Naud, 3, rue Racine, Paris. 1896. Price 6 fr.

8vo volume containing 336 pages of subject-matter, illustrated with 50 wood engravings, and an alphabetical index of subject-matter.

The term "Chimie Minérale" is clearly intended to represent what we usually term "Inorganic Chemistry."

**CHIMIE ORGANIQUE. 2<sup>me</sup> PARTIE.** Par A. HALLER et P. TH. MÜLLER. Georges Carré et C. Naud, 3, rue Racine, Paris. 1896. Price 4 fr.

8vo volume containing 205 pages of subject-matter, illustrated with two woodcuts. There is an alphabetical index of subjects treated of.

**RECUEIL DE PROCÉDÉS DE DOSAGE, pour l'Analyse des Combustibles, des Minerais de Fer, des Fontes, des Aciers et des Fers.** Par G. ARN, Professeur de Chimie Industrielle à la Faculté des Sciences de Nancy. Georges Carré et C. Naud, 3, rue Racine, Paris. Price 8 fr.

8vo volume, containing 313 pages of subject-matter, illustrated with 61 wood engravings. There is no alphabetical index, but the work closes with a classified table of contents.

The text is divided into three parts:—Part I., devoted to the Assay and Analysis of Fuels and Combustibles; Part II., to the Analysis of Minerals; and Part III., to that of Metallic Products, Iron, Cast Metal, and Steels.

**PRÉCIS D'ANALYSE CHIMIQUE. Première Partie. I. Analyse Qualitative.** Par E. FINK, Chef des travaux pratiques d'Analyse à l'École Municipale de Physique et de Chimie Industrielle de la Ville de Paris. Georges Carré, 3, rue Racine, Paris. 1896. Price 3.50 fr.

THIS little work on Qualitative Analysis contains 190 pages of subject-matter, and is illustrated with 13 wood engravings. At the end of the book is given a blank form of the record of curriculum to be followed and filled up by each laboratory pupil of the École Municipale. The classification of the work is developed in the table of contents, which is placed at the end, but there is no alphabetical index.

**PRÉCIS D'ANALYSE CHIMIQUE. Deuxième Partie. II. Analyse Quantitative.** Par E. FINK, Georges Carré et C. Naud, 3, rue Racine, Paris. 1896. Price 5 fr.

THIS small 8vo volume contains 312 pages of subject-matter, and is illustrated with 60 wood engravings. A table of contents is given at the end of the work, so classified as to render an alphabetical index unnecessary.

**LES NOUVEAUTÉS CHIMIQUES POUR 1897. Nouveaux Appareils de Laboratoires, Méthodes Nouvelles des Recherches Appliquées à la Science et à l'Industrie.** J. B. BAILLIÈRE ET FILS, 19, rue Haute-fueille, Paris. Poulenc Frères, 92, rue Vieille-du-Temple, et boul. St. Germain 122. 1897. Price 2.50 fr.

THIS is an illustrated volume of small 8vo size, containing a descriptive account of new laboratory apparatus and methods of research applied to science and industry, for the year 1897. It is illustrated with 160 wood engravings, contains 235 pages of subject-matter, preface, classified table of contents, and alphabetical index.

**SHORT STUDIES IN PHYSICAL SCIENCE, MINERALOGY, CHEMISTRY, AND PHYSICS.** By VAUGHAN CORNISH M.Sc. 1897. Price 5s.

8vo volume, containing frontispiece, preface, table of contents, and text nearly filling 225 pages, with an alphabetical

index. There are three illustrative engravings. One chapter of the work is devoted to "Chemical Manufacture." It contains three sections:—Sect. I. The Fuel of Blast Furnaces; Sect. II. Explosives; and Sect. III. By-Products and Waste Products.

**A HANDY BOOK FOR BREWERS**, being A Practical Guide to the Art of Brewing and Malting. Embracing the conclusions of Modern Research which bear upon the Practice of Brewing. By HERBERT EDWARDS-WRIGHT, M.A. Second Edition; thoroughly revised. Crosby, Lockwood, and Son, 7, Stationers' Hall Court, Ludgate Hill, 1897. Price 12s. 6d.

THIS work contains prefaces to first and second editions, table of contents, and subject-matter extending to page 503; then follow two Appendices: A. A list of the Hop-growing Parishes of Kent; and B. A Synoptic Table of the Various Processes in Malting and Brewing, with some operative details and abstract of the Chief Physical and Chemical changes. The work ends with an alphabetical index of subjects. The text is subdivided into thirteen sections or chapters, respectively headed as follows:—I. Introductory. II. Barley, Malting, and Malt. III. Water for Brewing. IV. Hops and Sugars. V. The Brewing Room. VI. Chemistry as applied to Brewing. VII. The Laboratory. VIII. Mashing, Sparging, and Boiling. IX. Ferments in General. X. Fermentation with Commercial Yeast: its Science and Practice. XI. Culture from a Single Cell. XII. Yeasts. XIII. Treatment of Beer. XIV. The Brewery and Plant.

**TABELLEN FÜR GASANALYSEN, GASVOLUMETRISCHE ANALYSEN, STICKSTOFFBESTIMMUNGEN**, &c. Von Prof. Dr. G. LUNGE, Friedrich Vieweg und Sohn, Brunswick, Germany. 1897. Price M. 2. H. Grevel and Co., 33, King Street, Covent Garden, London.

THESE tables are five in number, and are arranged in sheets, which could be detached from the book-cover and hung upon the walls of a laboratory. The chief tables, I. and II., were calculated out by the author in 1879, and published in Dinger's *Polyt. J.* **231**, 522. A supplement to Table II., embracing the pressures from 680 to 708 mm., was given by Lwoff in the *Zeits. f. angew. Chem.* 1893, 433 (see also this Journal, 1893, 1030).

Table I. is for the Reduction of the Volume of Gas found, to zero Centigrade; whilst Table II. is for the "Reduction of the Volumes of Gas found to the Normal Barometric Pressure of 760 mm."

Table III. is for the Tension of Aqueous Vapour at Temperatures from 10 to 25° C.

Table IV. serves specially for "Nitrometric" Analyses in which nitric oxide is to be measured. It equally serves in the interpretation of the results of the Schlösing-Grandeaun process.

Table V. is for the "Conversion of the e.c. read off into Milligrams of Substance," and may be used for the gasometric determinations involved in Dumas' Method of Nitrogen Determination, in that of the Nitrometer and similar Apparatus when used for Determinations of Carbonic Acid, Active Oxygen (from Permanganate-), Manganese Peroxide, Chlorine (from Hypochlorites), Nitrogen or Ammonia (according to the Sodium Bromide Method, the numbers being so calculated as to render dispensable Dietrich's Table).

**CHEMISCH-TECHNISCHES REPERTORIUM**. Uebersichtlicher Bericht über die neuesten Erfindungen, Fortschritte und Verbesserungen auf dem Gebiete der technischen und industriellen Chemie, mit Hinweis auf Maschinen, Apparate und Literatur. Herausgegeben von Dr. EMIL JACOBSEN. 35. Jahrgang. 1896. Erstes Halbjahr. Zweite Hälfte. R. Gaertner's Verlagsbuchhandlung, Hermann Heyfelder, Schönebergerstrasse 26, Berlin, S.W. 1897. H. Grevel and Co., 33, King Street, Covent Garden, London.

THE second issue for the first half-year of 1896 of Jacobsen's Repertory of Chemical Technology, containing reports

of the progress of the following branches of chemical industry:—I. Foods. II. Paper. III. Photography. IV. By-Products, Residues, Manures, Sanitation, Disinfectants, &c. V. Soaps. VI. Explosives, Matches, &c. VII. Preparation and Purification of Chemicals. VIII. Chemical Analysis. IX. Apparatus, Machinery, Electro-technology, Thermo-technology, Appendix, and New Books.

**THEORIE UND PRAXIS DER ANALYTISCHEN ELEKTROLYSE DER METALLE**. Von Dr. BERNHARD NEUMANN. W. Knapp, Halle a/S. 1897. Price M. 7. H. Grevel and Co., 33, King Street, Covent Garden, London.

THIS work contains preface, table of contents, subject-matter filling 216 pages, short appendix, and alphabetical index. The text is illustrated with 65 engravings, and is subdivided into three Sections:—I. THEORY OF ELECTROLYSIS. II. THE PRODUCTION, MEASUREMENT, AND REGULATION OF CURRENT; and III. CARRYING OUT THE ELECTROLYSIS. A. General. B. Separation of Metals from Solutions of Pure Salts. C. Separation of Metals; and D. Technological Examples.

**ELEKTROCHEMISCHE ÜBUNGS-AUFGABEN FÜR DAS PRAKTIKUM, SOWIE ZUM SELBSTUNTERRICHT**. Zusammengestellt von Dr. FELIX OETTEL. W. Knapp, Halle a/S. 1897. Price M. 3. H. Grevel and Co., 33, King Street, Covent Garden, London.

8vo volume containing preface, table of contents, and subject-matter covering 53 pages, illustrated with 20 engravings. This series of Exercises in Electrolysis is classified according to the following scheme:—General Instructions as to the necessary arrangements, apparatus, &c. I. Testing the Apparatus for Measurements. II. Dependence of the Resistance of the Bath on the Factors: Current Density; Concentration and Temperature of the Solution; Distance of Electrodes. III. Influence of Current Density and Concentration on the Course of Electrochemical Reactions. IV. Employment of Gas Analysis in carrying out Electrochemical Reactions. V. Experiments with Diaphragms. VI. Precipitations of Metals with Soluble and Insoluble Anodes. VII. Introduction of Contributory Reactions. VIII. Experiments with Glowing and Fused Electrolytes. IX. Experiments with Double-pole Electrodes. X. Organic Electrolyses.

**THE CHEMISTRY OF DAIRYING**. An Outline of the Chemical and Allied Changes which take place in Milk, and in the Manufacture of Butter and Cheese; and the Rational Feeding of Dairy Stock. By H. SNYDER, B.S., Professor of Agricultural Chemistry, University of Minnesota, &c. Chemical Publishing Co., Easton, Philadelphia. 1897. Price \$1.50.

SMALL 8vo volume, with preface, table of contents, and subject-matter filling 137 pages. Supplementary tables with Average Composition of American Feeding-Stuffs, &c., and appendix with Questions for use in the Class-room, and an alphabetical index. The pages are illustrated with 21 woodcuts. The book, as the author says, has "been prepared with the object of furnishing useful information to a class of young men who intend to become farmers and dairymen, rather than scientific experts." The character of this information will appear in the following excerpt of the table of contents:—I. General Composition of Milk. II. Milk-testing. III. Milk Fats. IV. Milk Sugar and Lactic Acid. V. The Lactometer and the Detection of Adulterated Milk. VI. The Chemistry of Butter making. VII. The Chemistry of Cheese-making. VIII. The Ash, and Miscellaneous Compounds of Milk. IX. Dairy Salt and Commercial Problems relating to Milk. X. The Sanitary Condition of Cows' Milk, and that of other Domestic Animals. XI. Preserving Milk. XII. ## Trade Report.

### TARIFF CHANGES AND CUSTOMS REGULATIONS.

(From the Board of Trade Journal.)

#### FRANCE.

##### Tariff Decision.

Thorium salts are to pay a specific duty of 20 francs per kilo., instead of the previous *ad valorem* rate.

#### TUNIS.

##### Reduction of Export Duty on Halfa Grass.

Mr. Haggard encloses copy of a decree published in the *Journal Officiel Tunisien* of the 16th February 1897, reducing the export tax on halfa grass from 1 fr. 25 cts. to 50 cts. a metric quintal.

#### ITALY.

##### Tariff Decision.

According to the *Gazette Ufficiale* of 9th January last, alcoholic solutions of colours are assimilated to spirit varnishes, and should be classified under No. 81x of the Customs tariff.

#### UNITED STATES.

##### Tariff Decisions.

Carbonate of strontia is assessed for duty at 25 per cent. under paragraph 60, Act of 1894.

Lysidine, a medicinal coal-tar preparation, is dutiable at 25 per cent. under paragraph 443.

Perfumed smelling salts are dutiable at 25 per cent. as chemical salts.

#### QUEENSLAND.

##### Exemptions from Duty.

Under an Act recently passed by the Legislature of Queensland, the following articles will be exempted from duty from the specified dates:—

30th September 1896.	31st March 1897.
Alkaline earth.	Artists' colours.
Alumina.	Asbestos (unmanufactured).
Antifermentine.	Asphalt.
Cotton-seed oil.	Bark for tanning.
The following drugs and chemicals:—	Castor oil in bulk.
Cyanide of potassium.	Chalk.
Sulphate of soda.	Cylinders and tubes containing gas and ammonia.
Nitrate of soda.	Drugs and chemicals (except those already exempted).
Caustic soda.	Explosives.
Sulphate of baryta.	Electro-plating materials.
Sulphate of iron.	Gold and silver leaf.
Sulphate of magnesia.	India-rubber solution.
Sulphate of potash.	Leather.
Sulphide of sodium.	Scientific instruments and materials.
Fish oil.	Photographic instruments and materials.
Infusorial earth.	Paper.
Linotype metal.	Resin.
Liquid stain for leather.	Sheep dip.
Myrobolans (unground).	Stockholm tar.
Phosphorised pollard.	Tin foil.
Pottery materials.	
Preservatives.	
Sizeoline and hydra-size.	
Scap colouring.	
Valonia (unground).	

## OFFICIAL NOTICES.

### CARBIDE OF CALCIUM.

The following is the memorandum which has been issued by Colonel Sir Vivian Majendie, Her Majesty's Inspector of Explosives, under date of March 1:—

With a view to assisting local authorities in dealing with applications for licences to keep carbide of calcium, the following observations as to the character and prevention of the risks attending to such keeping have been drawn up:—

1. Carbide of calcium is a solid substance which, while not itself inflammable, evolves, when brought into contact

with moisture, a gas (acetylene) which is of a highly inflammable character.

2. This gas, when mixed with air, or when under even slight compression, becomes powerfully explosive.

3. Carbide of calcium, unless carefully manufactured from suitable materials, is liable to contain impurities which, when the carbide is acted on by water, evolve phosphoretted or silicoretted hydrogen-gases which, when evolved in appreciable quantities, would render the acetylene produced liable to spontaneous ignition.

4. In addition to the risks indicated above, acetylene gas is capable of forming an explosive compound when brought into contact with copper.

5. The character of the apparatus to be used in connection with the production of acetylene gas from carbide of calcium is intimately connected with the question of safety; for example, grave risk may arise from the heat developed by a too rapid conversion of the carbide into acetylene gas; or from the apparatus permitting escape or leakage of gas which is being formed, or not allowing a free passage of the gas from the generator into the holder, and so causing excess of pressure in the generator or other part of the apparatus.

6. Risk might also arise if proper provision were not made for dealing with the residue of the carbide of calcium which has been used for making acetylene gas (*viz.*, lime), as such residue might contain carbide of calcium which has escaped decomposition.

It will therefore be obvious that local authorities, in granting licences for carbide of calcium, should have regard to the foregoing risks, and with that view should make provision:—

(a.) For the exclusive use of hermetically closed packages for the keeping and conveying of carbide of calcium.\*

(b.) The adequate ventilation of the place where the carbide of calcium is present.

(c.) The prohibition of any powerful compression of the gas produced in the apparatus or receptacles employed.

(d.) The keeping and use of pure carbide of calcium only, and the establishment of efficient arrangements for the sampling and testing of the carbide.

(e.) The exclusion of copper from all vessels or apparatus used with or for carbide of calcium and the gas produced therefrom.

(f.) The use only of an apparatus which the local authority have satisfied themselves, under competent advice, is of a safe and suitable character, and the prohibition of the employment for the manipulation of such apparatus of any person other than a properly instructed and capable operator.

(g.) The safe disposal of the residue and the prohibition of its introduction into sewers, cesspools, &c., unless mixed with at least ten times its bulk of water.

It will, in all cases, be for the local authority very carefully to determine whether the premises proposed to be licensed are themselves suitable for the purpose, regard being had to the formidable consequences (from fire or explosion) which might result from the careless or imperfect observance of any of the imposed conditions, especially in dwellings or in places or premises where large numbers of persons are liable to assemble.

### ACETYLENE.

*Chem. and Druggist, March 6, 1894.*

The Associated Fire Offices have drawn up the following regulations in regard to insurance of premises in which the generation or storage of acetylene is carried on:—

(1.) That the storage of calcium carbide, liquid acetylene, and (or) acetylene gas, and every apparatus, whether portable or otherwise, for the generation of such gas, must be only in a building detached at least 10 ft. at the nearest point from every other building.

\* The 9th section of the Petroleum Act specifies, among the conditions which may be included in a licence under that Act, the mode of carrying within the district of the licensing authority.

(2.) That suitable valves or devices for controlling the pressure of the gas must be placed inside the detached building, and a cut-off provided between such building and the building supplied with the gas.

(3.) That in addition to the above, the piping in the building in which the gas is used must be provided with a pipe-outlet into the open air, controlled by a safety device so arranged as to let the gas escape outside the building whenever the pressure of the gas exceeds 4 oz. to the square inch.

It should be understood that fire insurance offices will not admit liability for explosion of acetylene gas occurring elsewhere than in any building which is, or the contents of which are, the subject of the insurance effected under the above rules, which, however, are under revision, as they have been found to be practically prohibitive of the use of acetylene.

### STATISTICS.

#### GERMAN TRADE RETURNS FOR 1896.

*Ch. of Comm. J., Feb., 39.*

The trade returns issued by the Imperial Statistical Office provide the following statement by classes of the values (in 1,000's of marks) of imports and exports during 1895 and 1896:—

Classes of Goods.	Imports.		Exports.	
	1895.	1896.	1895.	1896.
Lead and leadware .....	7,440	6,487	10,805	11,641
Drugs, dyestuffs, &c. ....	243,810	232,913	318,114	298,809
Iron and ironware .....	463,987	307,765	322,785	301,792
Earths, ores, precious metals, &c. ....	373,494	233,341	282,584	152,883
Glass and glassware ....	10,705	9,659	43,381	46,956
Hides and skins .....	170,299	186,378	75,659	81,823
Hops .....	9,884	6,612	24,866	27,291
Caoutchouc and gutta-percha and wares of. ....	42,903	35,736	30,460	27,432
Copper and copper wares ..	69,517	55,537	84,546	72,990
Hardware, cutlery, &c. .	39,897	36,117	116,997	73,500
Leather and leather wares. ....	57,518	54,808	151,316	165,807
Candles .....	102	115	658	581
Oils and fats .....	114,205	136,518	27,140	26,394
Paper and paste goods ..	12,626	10,754	101,172	104,354
Petroleum .....	89,959	76,321	1,325	1,151
Soap and perfumery ....	1,850	2,628	12,450	10,734
Stone and stoneware ....	31,915	31,756	25,577	21,890
Coal and other fuel .....	117,150	110,742	157,395	145,769
Tar, pitch, resin, and asphalt. ....	37,720	33,353	9,751	8,312
Potteryware .....	6,141	5,527	43,136	38,646
Oilcloth, &c. ....	973	1,235	1,310	1,149
Zinc and zincware .....	5,487	5,294	11,528	25,038
Tin and tinware .....	18,038	13,927	5,273	4,923
Total value (1000 m.) .	4,573,448	4,246,111	3,631,629	3,424,976

#### THE MINERAL PRODUCTION OF CANADA.

*Eng. and Mining J., March 6, 1897, 232.*

The total value of the mineral output of Canada for 11 years past has been reported as below:—

	Dols.
1886 .....	12,000,000
1887 .....	12,500,000
1888 .....	13,500,000
1889 .....	14,500,000
1890 .....	18,000,000
1891 .....	20,500,000
1892 .....	19,500,000
1893 .....	19,250,000
1894 .....	20,300,000
1895 .....	22,000,000
1896 .....	23,627,395

In the table below, which gives the production in 1896, the figures show the quantity or value of the product marketed. Where tons are used, they are short tons of 2,000 lb.

#### Summary of the Mineral Production of Canada in 1896.

Product.	Quantity.	Value.
<b>METALLIC.</b>		
Copper (fine, in ore, &c.).....	Lb. 9,385,556	Dols. 1,021,148
Gold .....	.....	2,810,206
Iron ore .....	Tons 88,206	181,513
Lead (fine, in ore, &c.).....	Lb. 241,999,977	721,384
Nickel (fine, in ore, &c.).....	Lb. 3,500,009	1,155,000
Silver (fine, in ore, &c.).....	Oz. 3,205,343	2,147,589
Total metallic .....	..	8,631,640
<b>NON-METALLIC.</b>		
Asbestos.....	Tons 12,250	429,858
Chromite .....	" 2,362	25,982
Coal .....	" 3,743,234	8,006,395
Coke .....	" 49,817	111,560
Felspar .....	" 480	1,368
Fireclay .....	" 667	1,427
Graphite .....	" ..	9,455
Grindstones .....	" 3,663	32,510
Gypsum .....	" 205,293	174,403
Manganese ore .....	" 12	900
Mica .....	..	60,000
<b>Mineral pigments:—</b>		
Baryta .....	Tons 145	715
Ochres .....	" 2,950	10,925
Mineral water .....	Galls. 796,372	111,736
Natural gas .....	.....	276,301
Petroleum .....	Bbls. 726,882	1,155,646
Phosphate (apatite) .....	Tons 570	3,900
Pyrites .....	Tons 33,715	101,153
Salt .....	" 49,956	169,677
Soapstone .....	" 410	1,230
Tripolite .....	" 664	9,950
<b>STRUCTURAL MATERIALS AND CLAY PRODUCTS.</b>		
Bricks* .....	..	1,600,000
Building stone* .....	..	1,000,000
Cement, natural .....	Bbls. 69,705	60,500
" Portland .....	" 78,085	111,005
Flagstones .....	.....	6,710
Granite .....	Tons 18,717	106,769
Lime* .....	..	650,000
Marble .....	Tons 74	905
Pottery* .....	..	163,995
Sands and gravels* .....	Tons ..	129,000
Sewer pipe .....	..	158,875
Slate .....	..	53,370
Termi-cotta .....	..	110,855
Tiles* .....	..	225,000
Total non-metallic .....	..	15,087,665
Total metallic .....	..	8,631,640
Estimated value of mineral products not returned.	..	500,000
Total value .....	..	23,627,395

\* Partly estimated.

In this table the copper includes the contents of ore and matte, and is valued at 10·88 c. per lb. Lead, which includes that in ores and bullion, is valued at 2·98 c. per lb. Nickel, all of it in ores and matte, is rated at 33 c. per lb. Silver is taken at an average of 67 c. per oz. The value given for natural gas is the gross return from the sales of the gas. In arriving at the quantity of petroleum, the barrel of 42 galls. is taken, but the value is computed at an average of 1·59 dols. per barrel of 35 galls.; 42 galls. refined oil are assumed as equal to 100 galls. crude oils.

The increases shown, in comparison with 1895, are:—Coal, 229,738 tons, or 278,859 dols.; copper, 596,394 lb., or 71,919 dols.; lead, 1,124,085 lb., increase in quantity, but 28,582 dols. decrease in values; silver, 1,129,660 oz., or 988,956 dols.; gold, 899,306 dols. The decreases were:—Iron ore, 14,595 tons, or 53,757 dols.; nickel, 338,525 lb., 205,904 dols.; natural gas, 146,767 dols.

The gain in coal is altogether due to Nova Scotia, which produced 296,153 net tons more than in 1895, but this increased output is offset in a large measure by a decrease of 104,629 tons in the production of British Columbia. Copper shows a large decrease in Ontario and a small increase in Quebec, while British Columbia's contribution is 3,818,556 lb., which amount is 1,848,193 lb. more than in 1895. In gold large increases are to be credited to Nova

Scotia and Ontario, but British Columbia heads the list with an increase over the previous year of 197,675 dols. .

The production of lead is altogether that of British Columbia, and has increased in the year by over 1,100,000 lb., but a decrease in the market price of some 8 per cent., lessens the total value by 25,582 dols. Natural gas shows a decrease in value of 116,761 dols., or about 31 per cent., which would seem to be due to a heavy falling off in the production of the Welland gas field. Ontario's nickel production is reduced during the year by nearly 100,000 lb., and shows a decrease in the value of over 200,000 dols. British Columbia shows an output of silver amounting to 3,135,343 oz., valued at 2,100,689 dols., an increase over 1895 of 1,429,660 oz. in quantity, and in value of nearly a million dollars.

### GENERAL TRADE NOTES.

#### SALE OF EDIBLE OILS IN BELGIUM.

*Ch. of Commerce J., Feb., 36.*

A Royal decree, made December 28, will come into force on April 1, regulating the sale of edible oils in Belgium. Thenceforward the receptacles in which edible oils are to be sold, exposed for sale, stored or transported for sale or delivery, must bear an inscription comprising, immediately after the word "oil," in identical character of an equal size to those used for that word, an exact indication of the raw material or raw materials from which the oil has been obtained (olive oil, poppy oil, earthenut oil, sesame oil, cotton oil, olive and sesame oil, &c.). The receptacles must also bear the name or firm as well as the address, or at least the mark of the manufacturer or seller; while the descriptive particulars of the oil must also appear in the invoices, carriers' notes, or bills of lading. The sale or exposure for sale for food purposes of damaged (*gâtées*) or adulterated (*corrompues*) oils is prohibited, as well as sale, exposure for sale, storage for sale or for delivery in the same premises or in premises communicating other than by the public thoroughfare; the carriage simultaneously in the same vehicle, for sale or delivery, of edible condiments and vegetable oils not intended for food, unless the receptacles of the latter bear a label such as "non-edible oil," indicating in distinct characters that it is not intended for use as food. The Minister of Agriculture and Public Works is to put the law into operation, infractions being punishable by penalties provided under the law of August 1, 1890, without prejudice to the penalties established by the Penal Code.

#### WINDOW GLASS IN TURKEY.

*Ch. of Commerce J., Feb., 40.*

The French Chamber of Commerce in that city reports that Constantinople requires annually 24,000 to 40,000 cases of window glass, which is almost exclusively imported from Belgium. The quality of this glass is as bad as possible, greenish and defective, and is only preferred on account of its cheapness. The price varies from 15 to 25 francs per case, according to size. There are only a few small glass factories at Constantinople.

#### A NEW TURPENTINE DISTRICT.

*Chem. and Druggist, 1897, 50, 337.*

The pine forests of Georgia and Carolina, which have hitherto supplied most of the turpentine of commerce, becoming worn out, the industry is being transferred further south towards Florida.

Seven large turpentine "farms" have been established within the past two months in Alachua County, Florida. U.S.A.—A. S.

#### LEAD SHIPMENTS FROM THE UNITED STATES.

*Eng. and Mining J., Feb. 27, 1897, 205.*

Shipments of a considerable quantity of lead have recently been made from the Colorado smelters to Europe by way of Galveston, Tex., going to that port by rail from Pueblo.

At present prices of the metal abroad, there is probably more profit in shipping lead in this way than in marketing it in the East, where demand is at present light and sales are made below the European quotations. It is a question, however, how far this trade can be carried on without causing lower prices on the other side. A good deal of Mexican lead, refined in bond, has also been going abroad, and there is a limit to the demand there. The Spanish mines were very active last year, under the stimulus of higher prices, and supplies have been increased until there is some risk that they may exceed the demand; although business is very active all over Europe.

#### SULPHUR PRODUCTION IN SICILY.

*Eng. and Mining J., Feb. 27, 1897, 214.*

According to the *Rassegna Mineraria*, the exportation of sulphur from Sicily in long tons (2,240 lb.) for the year 1896 was 396,745 tons, as compared with 347,636 tons in 1895 and 328,930 tons in 1894. Notwithstanding the gain last year of 49,109 tons in the exports, the stocks on hand at the shipping ports show an increase of 19,243 tons. These stocks amounted to 222,999 tons on December 31st, 1896, as compared with 203,756 tons at the close of 1895 and 198,513 tons at the close of 1894. As the consumption at home is comparatively nothing, a comparison of the exports and the stocks shows that the total production in 1896 was 415,988 tons. Of the exports the United States took last year 121,923 tons, a quantity which compares with 99,227 tons in 1895 and 105,773 tons in 1894. The average price at shipping port showed a considerable improvement; in 1894 it was 56.50 lire (10.85 dols.), and fell to 52.10 lire (10 dols.) in 1895, but in 1896 the effect of the combination of producers was shown, and the average rose to 68 lire (13.05 dols.) per ton.

Exports to all countries from Sicily showed an increase in 1896, with the exception of Great Britain, where there was a falling off of 2,000 tons. This was more than made up by an increase of 9,000 tons in the shipments to Sweden, Norway, and Denmark.

#### RUSSIAN PETROLEUM EXPORTS.

*Eng. and Mining J., Feb. 27, 1897, 214.*

The exports of oil from Russia during the year 1896 are reported as follows:—Residuum and crude oil, 199,300 bbls.; lubricating oil, 726,200 bbls.; distillate, 846,700 bbls.; illuminating oils, 5,481,400 bbls.; making a total of 7,253,600 bbls. Of this total, Batum shipped 5,243,500 bbls., and Novorossisk the remainder. A Belgian company has been organised to develop the Grosni oil field on a more extensive scale. The work on the pipe line between Baku and Mikalovo, or half the distance between Baku and Batum, will commence as soon as the weather opens. Drilling operations are being pushed actively at Petrovsk.

#### THE EXPORT OF PETROLEUM FROM THE UNITED STATES.

*Imp. Inst. J., March, 93.*

It appears from recent returns that the petroleum exported from the United States during the year 1896 was the largest in the history of that important commodity. The shipments of the crude product reached a total of 117,921,276 galls., which shows an increase of 1,967,145 galls. over the exports during 1895. Of naphthas, there were exported last year 13,420,769 galls., being an increase of 662,829 galls. The shipments of illuminating oil amounted to the enormous total of 749,305,844 galls., showing the increase to have been 71,805,197 galls. The exports of lubricating oils have increased by 3,859,578 galls., the total shipments having amounted to 50,629,143 galls. There was a sudden and rapid increase by 364,140 galls. in the exports of residuum, which amounted for the year to 507,990 galls. The total shipments of all petroleum products reached a total of 931,785,022 galls., the increase over 1895 being 78,658,892 galls.

## PETROLEUM IN SUMATRA.

*Eng. and Mining J., Feb. 20, 1886.*

The Royal Netherlands Petroleum Company has completed a well at Langkat, Sumatra, which exceeds any drilled so far on that island. Its daily production is 4,800 bbls. None of the older wells produced at any time more than 500 barrels. If the production of the new well keep up, it will be able to furnish 3,000,000 cases of refined oil a year.

## THE PETROLEUM COMMITTEE.

*Chem. and Druggist, Feb. 27, 1897, 351.*

The Government have reappointed the Select Committee to inquire into and report upon the sufficiency of the law relating to the keeping, selling, using, and conveying of petroleum and other inflammable liquids, and the precautions to be adopted for the prevention of accidents with petroleum lamps. The members of the Committee are Sir Thomas Sutherland, Mr. Jesse Collings, Mr. Alexander Cross, Mr. Flannery, Sir Edward Hill, Mr. Wootton-Isaacs, Mr. Kenyon, Mr. McKillop, Mr. Mundella, Mr. Pollock, Mr. Harold Reekitt, Mr. Compton Rickett, Sir Benjamin Stone, Mr. Tully, and Mr. Ure.

## GERMAN PATENTS IN 1896.

*Chem. and Druggist, Feb. 27, 1897, 336.*

The returns of the Imperial German Patent Office for 1896 show that the applications in the year amounted to 16,486, an increase of 1,423 on the previous year. The number of patents granted, however, was smaller—viz., 5,410 against 5,720 in the year before. The great severity with which applications for patents are scrutinised by the German Patent Office is shown by the fact that only one-third of the applications are successful. Eighty applications were made last year for patents relating to alkali and the wholesale preparation of chemicals generally, and 51 of these were granted. The applications for patents for hygienic inventions numbered 3,317, of which 135 were granted; and those for chemical processes and apparatus generally 478, of which 198 were successful.

## GERMAN CHEMICAL TRADE.

*Chem. and Druggist, March 13, 1897, 416.*

The German trade returns for 1896 show that although the gross weight of chemicals and other articles for use in chemistry and pharmacy imported from abroad exceeds considerably the weight of similar articles exported from Germany, the opposite is the case with regard to the value of the goods. This is apparent from the following figures relating to the imports and exports of drugs, pharmaceutical goods, and dyestuffs:—

	1896.		1895.	
	Tons.	Value.	Tons.	Value.
		M.		M.
Imports .....	1,021,537	243,819,000	1,001,905	232,913,000
Exports .....	642,425	318,414,000	609,983	289,809,000

The imports show an increase of 1.9 per cent. in weight and 1.6 per cent. in value; the exports an increase of 5.3 per cent. in weight and 6.5 per cent. in value.

## THE PROPOSED NEW UNITED STATES TARIFF.

The *Times* has printed a synopsis of the new Tariff Bill as published in the *Philadelphia Press*, from which the following details relating to chemicals and pharmaceutical goods may be taken as substantially correct, although they are not official. The comparisons are with the existing Wilson tariff:—

Acids.—Acetic, 3 c. per lb. (20 per cent. *ad val.*); boracic, 3 c. (3 c.); chromic, lactic, 4 c. (4 c.); citric,

8 c. (25 per cent. *ad val.*); salicylic, 10 c.; sulphuric, or oil of vitriol, not specifically provided for,  $\frac{1}{4}$  c.; tannic, 50 c. per lb. (60 c.); gallic, 10 c.; tartaric, 7 c. (20 per cent. *ad val.*); all other acids not specifically provided for, 25 per cent. *ad val.*

All alcoholic perfumery, 45 c. per lb. and 45 per cent. *ad val.* (against 2 dols. per gallon and 50 per cent. *ad val.*).

Alkalis and all chemical compounds and salts not specially provided for, 25 per cent. *ad val.*

Alumina, alum, alum cake, patent alum, sulphate of alumina, and aluminous cake, and alum in crystals or ground,  $\frac{1}{2}$  c. per lb. (against  $\frac{1}{7}$ ths of 1 c. per lb.).

Ammonia, carbonate of,  $\frac{1}{4}$  c. per lb. (20 per cent. *ad val.*); muriate of,  $\frac{3}{4}$  c. per lb. (10 per cent.); sulphate of,  $\frac{1}{2}$  c. per lb. (20 per cent.); argols or crude tartar,  $\frac{1}{2}$  c. per lb.; tartars and lees crystals or partly refined argols, 4 c. per lb.; cream of tartar, 6 c. per lb.

Borax, crude, or borate of soda, or borate of lime, 2 c. per lb. (against 2 c. for borate of soda and  $1\frac{1}{2}$  c. for borate of lime); refined borax, 3 c. (2 c.).

Camphor, refined, 4 c. per lb. (10 per cent.). Chloroform, 20 c. per lb. (25 c. per lb.).

Collodions, rolled or in sheets, 50 c. per lb.; if unfinished or partly finished articles, including celluloid articles, 75 c. per lb. and 45 per cent. (45 per cent. *ad val.*).

Ethers, sulphuric acid spirits, nitrous ether, 25 c. per lb.; fruit ethers, oils or essences, 2 dols. per lb.; other ethers, 1 dol., provided no article pays less rate than 25 per cent. *ad val.*

Iodine, resublimed, 20 c. per lb.

Malt extract, fluid, in casks, 35 c. per gallon (15 c.); in bottles or jugs, 40 c. per gallon (25 c.); solid or condensed, 40 per cent. *ad val.* (30 per cent. *ad val.*).

Potash, bichromate and chromate, 3 c. per lb. (25 per cent.); caustic, 1 c.; chlorate, 3 c.; prussiate of red, 8 c.; cyanide of, 6 c.; prussiate of yellow, 4 c. (25 per cent.).

Quicksilver, 10 c. per lb. (7 c. per lb.).

Soda bicarbonate,  $\frac{3}{4}$  c. per lb. ( $\frac{1}{2}$  c.); bichromate and chromate, 2 c. (25 per cent.); crystal carbonate,  $\frac{1}{2}$  c.; caustic,  $\frac{1}{2}$  c.; nitrate, 2 c. and  $2\frac{1}{2}$  c.; crystals, not concentrated, and soda ash,  $\frac{1}{4}$  c. (against  $\frac{1}{2}$  c. for crystals); sulphate of soda, 1 dol. 25 c. per ton.

Sulphur, refined, 8 dols. per ton (20 per cent.).

Bay rum or bay water, whether distilled or compounded or first proof, and in proportion for any greater strength than first proof, 1 dol. 50 c. per gallon (against 1 dol. per gallon).

Waters (aerated and mineral).—Ginger-ale, ginger-beer, lemonade, soda-water, &c., in bottles containing each not more than three-fourths of a pint, 18 c. a dozen; in  $\frac{3}{4}$  to  $1\frac{1}{2}$  pint bottles, 28 c. per dozen; but no separate or additional duty shall be assessed on the bottles (against ginger-beer or ginger-ale, 20 per cent. *ad val.*).

All mineral waters, all imitations of natural mineral waters, and all artificial mineral waters not specially provided for, in bottles up to 1 pint, 30 c. per dozen bottles; if containing more than 1 pint and not more than 1 quart, 40 c. a dozen bottles, but no separate duty shall be assessed upon bottles (against 20 per cent. *ad val.*).

## METHYLATED SPIRIT IN INDIA.

*Chem. and Druggist, March 20, 459.*

The quantity of spirit methylated in Bengal last year shows a considerable increase. In 1894-95 it was 54,282 gallons; in 1895-96, 59,854 gallons. Methylated spirits are, of course, professedly imported or prepared for use in arts and manufactures and in chemistry, and in this idea the duty thereon is fixed at a low rate of 5 per cent. *ad valorem*. It has lately been shown, however, that spirit methylated with wood-naphtha can be manipulated into a drinkable spirit, and the Bengal administration have therefore taken under consideration a scheme for denaturing the spirit in a more effective way. The medium with which the spirit is to be rendered "completely and permanently unfit for human consumption" is "caoutchoucine," with which it is to be mixed.

# BOARD OF TRADE RETURNS.

## SUMMARY OF IMPORTS.

Articles.	Month ending 28th February.	
	1896.	1897.
	£	£
Metals.....	1,669,857	1,839,334
Chemicals and dyestuffs.....	917,247	673,474
Oils.....	777,085	711,181
Raw materials for non-textile industries.....	2,746,428	2,795,651
Total value of all imports.....	5,899,597	6,959,639

## SUMMARY OF EXPORTS.

Articles.	Month ending 28th February.

## Monthly Patent List.

\* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

### I.—PLANT, APPARATUS, AND MACHINERY.

#### APPLICATIONS.

3999. F. Evelyn and P. H. Mellor. Improved fuel economiser or apparatus for heating the feed water of boilers by means of the waste products of combustion. Feb. 15.

4095. H. Howell. Improvements in valves more especially adapted for use in self-discharging saturator used in the manufacture of sulphate of ammonia from gas liquor or ammoniacal liquor. Feb. 15.

4221. A. W. T. Hülsmar and P. Rohrig. Improvements in clearing or clarifying and filtering apparatus. Complete Specification. Feb. 16.

4249. J. Bryson. See Class III.

4348. C. Bourdon. Improvements in condensers. Filed Feb. 17. Date applied for July 18, 1896, being date of application in France.

4612. D. A. Blair. Improvements in and relating to "Coffey's" distilling apparatus and the like. Feb. 20.

4690. J. R. Wright. An improvement in means or apparatus for carbonating liquids. Feb. 22.

4744. R. Moodie. Improvements in apparatus for washing or leaching granular or powdered substances and separating the same from the liquids used. Feb. 22.

4762. R. Matchett. Improved apparatus for reducing the pressure of liquids and gases. Complete Specification. Feb. 22.

5045. F. Berdal and V. Ducoulombier. Apparatus for preventing the scaling or incrustation of boilers. Feb. 25.

5066. O. Herrmann. New or improved process and apparatus for heating, concentrating, evaporating, and drying gaseous liquid and solid substances. Feb. 25.

5588. W. L. Wise.—From F. J. Brischar. Improved closing-device for bottles and the like designed to contain gas or other fluid under high pressure. March 2.

5589. W. L. Wise.—From F. J. Brischar. Improved closing device for bottles and the like designed to contain gas or other fluid under high pressure. March 2.

5823. Maignen's "Filtre-Rapide" and "Anti-Calcéaire" Co., Ltd., and A. A. Ellis. Improvements in apparatus for the treatment of water or other liquids with powdered materials. March 4.

6083. M. Crawford. Improvements in apparatus for charging liquids with gas. March 8.

6086. J. Kent and W. Lingley. Improvements in minimum thermometers. March 8.

6087. J. Kent and W. Lingley. An improved electric circuit-closing thermometer. March 8.

6157. L. Maiche. Improvements in apparatus for heating and cooling fluids by fluids. March 9.

6415. T. Bennett. An improved milk-testing apparatus. March 11.

6423. H. McV. Miller. Improvements in stills or condensers. March 11.

6550. L. Baseque. Centrifugal galactometer and analysing process connected therewith. March 12.

#### COMPLETE SPECIFICATIONS ACCEPTED.\*

1896.

4725. W. L. Wise.—From Solvay et Cie. Apparatus for filtering, washing, and drying, suitable for the treatment of bicarbonate of soda. March 3.

5849. F. H. Tyacke and C. E. Gittins. Water softening and purifying apparatus. March 10.

6934. F. Jurschina, Z. Schnitzer, and F. Herseh. An improved filtering material and process of making same. March 10.

15,374. J. Pogson. Surface condensers. March 3.

1897.

746. C. Gautier and X. Wehrle. Carburetting apparatus. March 3.

853. T. B. Lightfoot.—From The Gesellschaft für Linde's Eismaschinen. Safety and regulating appliance for apparatus for compressing vapours of ammonia and other volatile liquids. March 3.

1138. H. H. Lake.—From D. H. Burrell and E. J. Burrell. Centrifugal liquid separators. Feb. 24.

### II.—FUEL, GAS, AND LIGHT.

#### APPLICATIONS.

4125. J. R. Wigham. Improvements in apparatus for the production of artificial light applicable for lighthouse and ordinary illumination. Feb. 16.

4209. M. Horwitz. Improvements in the manufacture of incandescent bodies for incandescent lighting. Feb. 16.

4282. E. L. Carr. A new or improved portable acetylene gas generator. Feb. 17.

4302. C. E. Melville, J. Horne, and H. Roantree. An improved method of obtaining oxygen gas from atmospheric air. Feb. 17.

4424. E. Gossart and H. Chevallier. Improvements in or relating to means for producing and burning acetylene. Filed Feb. 18. Date applied for Sept. 10, 1896, being date of application in France.

4426. J. H. W. Stringfellow. Improvements relating to the manufacture of luminous and non-luminous gas. Feb. 18.

4428. K. Stattler and A. Strejz. An improved process for producing gas for burning and lighting purposes. Feb. 18.

4488. T. R. Fowler. Improvements in and connected with apparatus for the manufacture of acetylene gas. Feb. 19.

4583. W. P. Thompson.—From The Continental Gas Glühlicht Actien Gesellschaft Meteor vormals Kroll Berger and Co. Improvements in or relating to incandescence burners. Feb. 20.

4613. A. T. Fletcher and J. S. Marsland. Improvements connected with inclined gas retorts. Feb. 20.

4734. E. Barillot and C. C. Leclaire. Improvements in or relating to the storage of acetylene gas. Feb. 22.

4764. P. A. M. Lacroix. An improved automatic apparatus for producing acetylene gas. Feb. 22.

4775. H. H. Lake.—From P. Octure and A. Desmazures. An improved burner applicable more especially for incandescence lighting. Feb. 22.

4781. A. J. Boulton.—From E. Melin. Improvements in or relating to the production of acetylene gas. Feb. 22.

4790. F. H. Smith. An acetylene gas lamp. Feb. 23.

4791. C. W. Kemp. Improvements in or relating to incandescence gas lighting. Feb. 23.

4826. R. Cremer. Bottle for compressed gases. Feb. 23.

4870. E. J. Frost and B. Middleditch. Improvements in devices for automatically regulating the quality of gas. Complete Specification. Feb. 23.

4987. G. A. E. Ronset and A. Cobler. Improvements in apparatus for the production of "acetylene." Feb. 24.

5044. F. Missire and M. L. Missire. Improvements in burners for incandescence lighting. Feb. 25.

5051. A. W. Holden and F. W. Brown. Improvements in acetylene gas generators and outlets. Feb. 25.

5149. A. Roedel. Process and apparatus for removing graphite crusts from the interior of gas retorts. Complete Specification. Feb. 25.

5180. S. J. Farnsworth. Improvement in apparatus for condensing smoke and producing liquor carboline. Feb. 26.

5182. F. A. E. Samuelson. Improvements in the construction of coke ovens. Feb. 26.

5236. C. B. v. Franco. Improvements in means for generating, holding, and burning acetylene gas. Complete Specification. Filed Feb. 26. Date applied for July 27, 1896, being date of application in Spain.

5250. T. H. Gittins and A. Forshaw. Improvements in the manufacture of fuel. Feb. 26.

5297. H. Emmett. Improvements in incandescence gas and other burners. Feb. 27.

5445. G. Baldwin and C. Crastin. Improvements in the apparatus for the manufacture of acetylene gas. March 1.

5669. J. Kohndorfer. A process for producing a solid or consistent fuel containing petroleum. Complete Specification. March 3.

5756. H. R. Bean and H. Ringwood. An improved combined automatic generator, condenser, and holder for acetylene and other gases. Complete Specification. March 4.

5786. H. Hansen. Process for the solidification of refined petroleum and mineral oils for heating and lighting purposes. March 4.

5817. Comte de Hamel de Manin. Improvements in the manufacture of incandescence bodies for illuminating purposes. March 4.

5913. H. E. Alexandre. An improved apparatus for the manufacture of acetylene gas. Complete Specification. March 5.

6016. A. Mengers, H. Hurwitz, and A. Franke. Improvement in the treatment of incandescence bodies for gas lighting. March 6.

6033. J. W. Roberts and E. C. Theedam. The use of gunpowder, gun-cotton, or any explosive used in firearms, whether of a chemical or mechanical mixture, in stationary and portable engines, as a motive force. March 8.

6078. A. J. Boulton.—From F. Jausseus. Improvements in or relating to apparatus for the production of acetylene gas. March 8.

6132. W. Clinie and A. Watson, jun. Improvements in gas producers. March 9.

6159. J. Moeller. Improvements in oil lamps for incandescence lighting. March 9.

6271. A. Guasco. An improved apparatus for producing acetylene gas. March 10.

6292. A. Stowell. Incandescence lamp. March 10.

6404. P. Muschamp and S. Burridge. Improvements in manufacture of coke, and in apparatus and appliances connected therewith. March 11.

6538. W. R. Biss. An improved apparatus for generating and storing acetylene gas. March 12.

6548. R. E. Faure. Improved apparatus for producing acetylene gas. March 12.

6658. W. W. Strode and G. H. White. Improvements in or relating to the manufacture of acetylene. March 13.

6659. W. W. Strode and G. H. White. Improvements in or relating to illuminating apparatus. March 13.

6673. J. Hamilton. An improved mantle for incandescence gas lamps. March 13.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

4980. W. Wheatley and G. Kros. Apparatus for the production of carburetted water-gas. March 10.

5291. A. Kitson. Apparatus for the manufacture of gas, partly applicable to other purposes. March 10.

5813. T. Holliday. Apparatus for use in the production and application of acetylene gas. March 3.

6254. W. Parlyby. Apparatus for quenching or cooling coke produced in the manufacture of coal-gas. Feb. 24.

6380. Sir E. Green, Bart. Fuel economisers. March 17.

6408. A. Sweetser. Apparatus for the manufacture of oxygen gas. March 10.

6719. R. Reitmeyer.—From A. Cerekel. Apparatus for lighting and heating by means of acetylene gas. Feb. 24.

6739. J. C. Bayley. Apparatus for generating and storing acetylene gas, especially suitable for use in portable installations. March 3.

7286. C. Billington, jun. An improved method of and means for removing "scum" or "retort carbon" from gas retorts. March 3.

7559. W. Hampson. Apparatus for separating mixed gases by refrigeration, especially applicable to the separation of oxygen from air. March 10.

9681. H. L. P. Boot. Street lighting by glow lamps. Feb. 17.

12,662. A. Tobler. Apparatus for the automatic generation and distribution of acetylene gas. March 3.

17,644. R. Goodwin. A gas plant and system to make and produce acetylene gas, or acetylene and carbonic acid gas combined. March 24.

23,591. G. Trouve. Apparatus for producing and storing acetylene gas. March 17.

26,516. G. Tresenreuter. Method and apparatus for producing gas from liquid combustible materials. Feb. 24.

29,613. A. Rommoser and A. von Hake. Incandescence lights. March 3.

29,966. J. Y. Johnson.—From The Electric Rectifying and Refining Co. Apparatus for producing ozone. March 3.

1897.

139. F. Trendel and J. Mucke. Process and apparatus for producing acetylene gas. March 10.

328. J. Zimmermann. Processes and apparatus for forming and burning acetylene and similar gases. Feb. 24.

1653. G. de R. de Sales. Process for the agglomeration of carbides. March 17.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

#### APPLICATIONS.

4249. J. Bryson. Improvements in or relating to retorts for the distillation of shale and other bituminous substances, or for the calcining of ironstone, lime, and other substances. Complete Specification. Feb. 17.

5698. A. Basch and H. Graepel. An improved process for carbonising, charring, or coking combustible substances. Complete Specification. March 3.

### IV.—COLOURING MATTERS AND DYES.

#### APPLICATIONS.

4086. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of paranitraniline red having very bluish tints fast to washing and light. Feb. 15.

4369. W. H. Claus, A. Ree, and L. Marchlewski. Production of new polyazo dyes. Feb. 18.

4446. B. E. R. Newlands and J. A. R. Newlands. Improvements in the preparation of a colouring matter for and its application in the manufacture of sugar. Feb. 18.

4657. J. Turner and Co., Ltd, and P. Schidrowitz and O. Rosenheim. Manufacture of new products from piperidine. Feb. 20.

4703. W. G. Heyes.—From The Chemical Works, Sandoz. The manufacture or production of substantive disazo colouring matters. Feb. 22.

5119. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. A method for dyeing half-wool with basic azo dyestuffs in an acid bath. Feb. 25.

5259. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. A process for dyeing fast tannin antimony lakes of polyazo dyestuffs and basic safranine azo dyestuffs on the vegetable fibre. Feb. 26.

5351. A. G. Green, A. R. Wahl, and The Clayton Aniline Co., Ltd. The manufacture of derivatives of diphenylethane and of diphenylethylene. Feb. 27.

5535. H. R. Vidal. New carboxylated products derived from amido or phenolic compounds and amides and phenolics of triphenylmethane. March 2.

5689. H. R. Vidal. Improvements in the manufacture of colouring matters. March 3.

5690. H. R. Vidal. Improvements in the manufacture of colouring matters. March 3.

5691. H. R. Vidal. Improvements in the preparation of paradioxythiazine and paramidoxithiazine. March 3.

5697. H. R. Vidal. Improvements in the preparation of paramidophenol and the like. March 3.

5924. I. Levinstein and Levinstein, Ltd. Production of new sulphonic acids which may be used in the manufacture of colouring matters. March 6.

6581. W. Majert. Method of producing and purifying orthotoluol-sulpho-chloride. Complete Specification. March 12.

6694. H. R. Vidal. Improvements in manufacture of colouring matters. March 13. Date applied for March 10, 1897, being date of application in France.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

7538. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of anthracene compounds and of dyestuffs derived therefrom. March 3.

7709. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of new derivatives of amido-1, alphy-2, alkyl-5 pyrazolones. Feb. 24.

7766. J. Y. Johnson.—From The Badische Anilin and Soda Fabrik. The manufacture and production of new colouring matter from dinitronaphthalene. March 17.

8582. H. H. Lake.—From Lepetit, Gausser, and Co. Manufacture of dyestuffs and tanning extracts. March 17.

8857. C. D. Abel.—From The Aetien Gesellschaft für Anilin Fabrikation. Manufacture of colouring matters of the rosinduline series. March 17.

15,294. W. E. Heyes.—From The Chemische Fabrik vormals Sandoz. The manufacture or production of polyazo colouring matters. March 3.

16,039. J. J. M. Ville. New red colouring matters—rodazines—of the triphenylmethane group, and method of producing the same. March 17.

### V.—TEXTILES, COTTON, WOOL, SILK, Etc.

#### APPLICATIONS.

4165. R. J. Eke. Improved machinery for the treatment of textile vegetable fibres. Feb. 16.

5350. M. Beck. Improvements in connection with apparatus for finishing, stretching, mordanting, and drying textile fabrics. Feb. 27.

5414. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Improved method of mereerising vegetable textures and yarns. March 1.

6038. J. Morton. Improvements in the manufacture of figured fabrics. March 8.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

877. J. J. Maan. Manufacture of impermeable fabrics. Feb. 24.

6519. J. Ingleby and E. Otlere. Manufacture of linoleum, cork carpets, and the like fabrics, and apparatus therefor. March 17.

### VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

#### APPLICATIONS.

4540. A. Sokoloff. Improved process for dyeing by means of electricity and the X-rays. Complete Specification. Feb. 19.

4953. A. Schmidt. Dyeing apparatus for carded wool. Feb. 23.

5122. S. Pitt.—From L. Cassella and Co. Producing fast dyeings upon the fibre by means of direct-dyeing colouring matters. Feb. 25.

5573. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. New process for dyeing cotton. March 2.

6112. W. E. Kay and The Thornliebank Co., Ltd. Improvements relating to the fixation of pigments or metallic powders in printing on textile fabrics or similar surfaces. March 9.

6498. J. Waugh.—From The Neue Augsburger Kattun-fabrik. Improvements in the method of washing and boiling off, and in the preparation of fabrics to be dyed or printed. March 12.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

8491. B. Thies. Process of and apparatus for bleaching, dyeing, washing, &c., spun fibres and stuffs of every kind. March 10.

22,823. J. Kent. Bleaching cotton and other vegetable textile materials. March 3.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

4179. A. J. Boulton.—From S. Gaudin and J. Block. Improvements in the method of making chloride of lead. Complete Specification. Feb. 16.

4227. T. Ryan, jun., A. Dyson, and The United Alkali Co., Ltd. Improvements in the manufacture of caustic soda or caustic potash from carbonate of soda or carbonate of potash. Feb. 16.

4675. F. Bosca. Improvements in the manufacture of calcium carbide. Feb. 20.

4721. H. Walker. Improvements in the method of and means for manufacturing calcium carbide. Feb. 22.

4747. A. Knop. Manufacture of nitrites. Feb. 22.

5483. R. N. Lennox. Process for the separation and purification of nitrate of ammonia. March 2.

5564. T. Jennings. An improved process for the production of magnesium hydrate. March 2.

6082. M. Crawford. Improvements in the production of carbonic acid and in apparatus to be employed therein. March 8.

6648. T. Keene. Improvements in furnaces for the manufacture of calcium carbide or the like. March 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1896.

4489. G. Craig. Improvements in obtaining alkaline salts, and apparatus therefor. March 3.

4725. W. L. Wise.—From Solvay et Cie. See Class I.

7464. A. MacNab. Treatment of bay salt. March 10.

7796. W. Shedlock. Apparatus for obtaining salt from brine and for similar purposes. March 17.

15,489. F. H. Haviland, A. Holoway, J. B. Collier, and W. H. Mureh. Method and apparatus for the production of calcium carbide. Feb. 24.

28,199. H. H. Lake.—From C. Pieper. Process of treating substances containing nitrogen for the manufacture of ammonia. March 10.

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATIONS.

4085. H. G. Harris. An improvement in the manufacture of plate glass and apparatus for that purpose. Feb. 15.

4141. T. W. Horn. Improvements in window glass. Complete Specification. Feb. 16.

4304. E. Masquelier. Improvements in the manufacture of glass face plates. Feb. 17.

4527. C. Paulus and H. Heim. Improvements in the manufacture of ceramic ware and in machinery or apparatus for the same. Complete Specification. Feb. 19.

4539. C. C. Schirm and O. Lessing. Improved process for producing ceramic masses. Complete Specification. Feb. 19.

4885. T. Detal-Thiran. Improvements in and relating to the manufacture of mosaic tiles. Feb. 23.

6104. H. Heckert. Improvements in glass hollow-ware. Complete Specification. March 8.

6184. E. Walsh, jun. Improvements in plate-glass annealing kilns. Complete Specification. March 9.

6347. A. H. Moore and J. W. Moore. Equable firing kilns. March 11.

COMPLETE SPECIFICATION ACCEPTED.

1896.

4093. G. H. Grindy and G. A. Lioyard. Method or means of decorating tiles, plates, and other articles of ceramic ware. Feb. 24.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

4048. W. S. Robinson and S. M. Brookfield. Improvements in cement and concrete. Complete Specification. Feb. 15.

5290. T. Parker.—From G. W. Parker. An improved means of crystallising gypsum for commercial use. Feb. 27.

5439. W. S. Wilkinson. Improvements in the manufacture of paving blocks, tiles, and the like. Complete Specification. March 1.

6413. D. Burness and J. Burness. Improvements in concrete paving and the like. March 11.

6459. W. C. Reid and F. Crosland. Improvements in lime or cement kilns. March 11.

6525. C. Christie. Improvements in the method of and means for making artificial stone. March 12.

COMPLETE SPECIFICATIONS ACCEPTED.

1896.

3597. A. Hannemann and G. Boily. Process of manufacture of artificial asphalt. Feb. 24.

7567. W. C. Lawton. Process of manufacturing ornamental strips of soft clay. March 17.

18,990. A. J. Boulton.—From Tortorici and Grasso. Process and apparatus for the treatment of articles of cement, plaster, chalk, and the like. March 17.

19,047. A. L. C. Nodon and L. A. Bretonneau. Process and means for drying or scilicet wood. March 10.

X.—METALLURGY, MINING, ETC.

APPLICATIONS.

4136. W. B. Johnson.—From The Pennsylvania Salt Manufacturing Co. Improvements in apparatus for casting metals. Complete Specification. Feb. 16.

4202. A. F. M. V. Baron. Manufacture of an alloy of copper and iron. Complete Specification. Feb. 16.

4218. E. Dode. Process of separating metals from ores. Feb. 16.

4309. S. Neffgen. Process of treating granular or pulverulent iron ores and slag, or other residues containing iron, to facilitate the extraction of the same. Complete Specification. Feb. 17.

4358. A. Phillips. A plunger for the purifying or mixing of molten metals or other bodies liquid at high temperatures. Feb. 18.

4377. T. Twynam. Improvements in the manufacture of iron and steel. Feb. 18.

4655. W. H. Hyatt. Improvements in the extraction of gold. Feb. 20.

4857. W. A. Koneman and W. H. Hartley. Improvements in or relating to the treatment of ores. Complete Specification. Feb. 23.

5011. P. Dronier. Improvements in apparatus for the manufacture of magnesium. Feb. 24.

5340. The Lu-minum Manufacturing Co., Ltd., and J. G. Accles. Improvements in and connected with the casting of metals such as aluminium and alloys of the same. Feb. 27.

5670. B. H. Thwaite and H. V. Holden. An improvement in the manufacture of armour plates. March 3.

5732. T. Millward. An improved plant for planishing, flattening, blueing, and tempering iron and steel, sheets, plates, and the like. March 4.

5796. T. Korovine, N. Klatshko, and J. Berthenson. Improvements in treating iron and steel. March 4.

5850. W. Sawyer. Improvements in the manufacture of alloys of metal capable of receiving and retaining a high polish. March 5.

5926. J. de Moya. Improvements in the manufacture of steel. Filed March 6. Date applied for Aug. 10, 1896, being date of application in France. Complete Specification.

6051. J. E. Preston. Improved method and apparatus for treating refractory ores containing gold, silver, nickel, &c. March 8.

6151. F. A. Gooch. Improvements in processes for reducing aluminium. Complete Specification. March 9.

6489. J. Davies and A. Sanders. Improvements in fluid furnaces for heating or smelting or refining metals. March 12.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

4165. E. L. Oppermann. A new or improved process for amalgamating and extracting gold or other suitable metals from dry crushed ore. March 3.

4899. J. C. Bull. Improvements in alloys. March 3.

6033. W. Pearson and J. A. Bott. Manufacture of aluminium alloys. March 3.

7783. W. P. Thompson.—From E. Wohlwill. Process for obtaining chemically pure gold from fine gold and alloys rich in gold. March 3.

8595. T. Smith. Improvements in or connected with readily fusible metal or alloy and the manufacture of articles therefrom, or from other metals or alloys. March 3.

12,106. E. Govett. An improved process for treating refractory ores. March 3.

14,330A. A. G. Brown. Manufacture of rods and tubes mainly from aluminium and aluminium alloys. March 17.

27,899. H. Imray.—From La Com. Anonyme des Forges de Chatillon et Commentry. Method of pouring steel ingots. Feb. 24.

1897.

94. J. D. Grey and T. Gwynne. Treatment of sheet iron and steel in the manufacture of polished sheets. March 17.

#### XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

##### APPLICATIONS.

4046. E. Zappert.—From T. Bergmann. Improvements in electric batteries. Feb. 15.

4353. J. B. Seammell. Improvements in electrical storage batteries or accumulators. Feb. 18.

4375. W. Rowbotham. Improvements in and relating to accumulators or storage batteries. Feb. 18.

4429. J. L. Dobell. Improvements in or connected with electric batteries. Feb. 18.

4434. A. B. Pescatore. Improvements in or relating to secondary batteries. Feb. 18.

4442. J. L. Dobell. Improvements in or connected with electric batteries. Feb. 18.

4616. E. Heyl. Improvements in electric accumulators. Feb. 23.

5102. W. S. Squire. Improvements in the construction of secondary batteries. Feb. 25.

5165. D. Neale. Improvements in primary and secondary electric batteries. Feb. 26.

5383. S. F. Walker. Improvements in primary galvanic batteries. March 1.

5687. M. M. Bair. Improvements in electric batteries. March 3.

5805. D. G. FitzGerald. Improvements in and in the manufacture of elements for secondary batteries. March 4.

5826. A. Schauschiff. Improvements in the active material of secondary batteries. March 5.

6188. J. Hargreaves. Improved means applicable for use in the electrolysis of salts. March 9.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

1905. H. Maxim. Improvements in furnace blasts, and in process and in means or apparatus for electro-thermally treating materials, for the reduction of metals, production of carbides, acetylene, cyanogen, cyanides, nitrides, and the fixation of nitrogen. March 10.

5263. H. A. V. Worth. Improved process for the electroplating or metallisation of wood. March 10.

5584. A. Cohen. Treatment of carbon in electro-chemical or electrolytic processes, and apparatus therefor. March 17.

7255. H. H. Lake.—From J. Julien. Secondary batteries. March 10.

8410. J. C. Graham. Electro-deposition of metals, particularly applicable to the deposition on wires. March 10.

10,095. P. Schmidt. Electric batteries. March 3.

13,690. A. Le Royer, A. E. Bonna, and P. van Berchem. Electrolytic apparatus. March 3.

20,035. D. Mathieu. Electrical batteries. March 17.

23,868. L. Honig. Insulating compound. March 3.

1897.

251. G. W. Harris and R. J. Holland. Secondary batteries, and process of forming same. March 10.

1535. A. James. Electric precipitation of gold and silver from their cyanide solutions. March 10.

1657. G. A. Webb and W. A. Thoms. Electro-deposition of metals and alloys. March 17.

#### XII.—FATS, OILS, AND SOAP.

##### APPLICATIONS.

4830. F. L. Bartelt. Improved washing and cleansing compound. Feb. 23.

5256. H. H. Lake.—From F. W. Klever. A method of dissolving iodine in mineral oils. Feb. 26.

5750. R. E. Green. Improvements in the production of glyceriu. March 4.

5820. A. F. Dunn and A. Waithman. Manufacture of an anti-septic soap powder. March 4.

5889. E. G. Scott. Improvements connected with the concentration or distillation of glycerin. March 5.

6564. P. Cullen. The manufacture of an improved cleansing composition. March 12.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

5791. P. R. de F. d'Humy. Production of lubricants. March 17.

5792. P. R. de F. d'Humy. Manufacture of soap. March 17.

7269. The Fish Utilisation Syndicate, Ltd, and J. C. W. Stanley. Liberation or recovery of oils and the like. March 17.

1897.

123. G. Rezek. An improved washing material, and process for making the same. March 10.

1208. W. P. Thompson.—From J. Van de Bucken and S. Gattfeld. Soap for carpets. March 17.

#### XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, Etc.

##### APPLICATIONS.

4947. W. Peel. A new paint or composition for ships' bottoms and submerged works. Feb. 24.

5121. J. G. Ingram. Improvements in the manufacture of parti-coloured india-rubber. Feb. 25.

5289. C. R. Lindsey. The manufacture of a pigment from aniline waste products. Feb. 26.

5577. W. W. Horsburgh and T. Macintosh. A new or improved composition of india-rubber or the like with other material. March 2.

5909. W. Negus.—From J. B. Gualco. Improvements in the manufacture of zinc white or oxide of zinc. March 5.

6222. E. B. Day. Improvements in india-rubber for pneumatic tyres and other purposes. March 9.

6324. T. C. Sanderson. Improvements in and relating to the manufacture of white lead. March 10.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

6830. W. J. Clapp and F. S. Dauncey. Manufacture of india-rubber, and machinery and apparatus therefor. March 3.

7785. J. Sanders. A new or improved composition applicable for covering or protecting ships' bottoms and other structures. March 3.

1897.

28,950. F. Beindorff. A process for making colours for water-colour painting. March 17.

#### XIV.—TANNING, LEATHER, GLUE, AND SIZE.

##### APPLICATIONS.

4439. C. H. O. Collins and J. Hoar. Improvements relating to the manufacture of artificial leather. Feb. 18.

5762. A. J. Boulton.—From G. L. Lippold. An improved substitute for leather or like material and the method of manufacturing the same. Complete Specification. March 4.

6217. P. G. Sanford. Improvements in the treatment of tanning liquids for clarifying, bleaching, or decolorising them. March 9.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

8582. H. H. Lake.—From Lepetit, Dollfus, and Gansser and Co. See Class IV.

14,293. G. W. Adler. An improved process of and compound for tanning hides and skins. March 3.

1897.

2746. A. J. Boulton.—From C. M. Higgins. Improvements in or relating to adhesive compounds. March 17.

#### XV.—AGRICULTURE AND MANURES, Etc.

##### APPLICATIONS.

4542. C. Tejero. Process and apparatus for the fabrication of dissolved leather, its enrichment and transformation into an azotised product for manure. Feb. 19.

5974. H. E. Newton.—From A. Caron. New process for increasing the growth of cereals and their yield by means of bacteria, and a method for developing and conserving the latter on a large scale. March 2.

#### COMPLETE SPECIFICATION ACCEPTED.

1896.

10,109. O. G. Blunden. New or improved artificial manure or fertiliser, and process for manufacturing the same. March 17.

#### XVI.—SUGARS, STARCHES, GUMS, Etc

##### APPLICATIONS.

4446. B. E. R. Newlands and J. A. R. Newlands. See Class IV.

4467. E. R. Savigny. A new or improved sweetening substance and a process for its manufacture. Feb. 19.

5242. E. D. Smythe. Improvements in apparatus for reclaiming crystallised syrups. Feb. 26.

#### XVII.—BREWING, WINES, SPIRITS, Etc.

##### APPLICATIONS.

4089. L. Maiche. An improved process for the purification of spirit. Feb. 15.

4441. A. J. Boulton.—From K. E. N. Fryklind. Improvements in the treatment of spirituous liquors and the products obtained therefrom. Feb. 18.

4612. D. A. Blair. See Class I.

4902. E. Guillaume. Improvements in distilling and rectifying processes and in apparatus therefor. Complete Specification. Feb. 23.

4926. C. Amey. A machine for aerating wine, beer, and other fermented and unfermented liquids. Complete Specification. Feb. 23.

5582. L. Prochazka and E. Frischauer. Improvements in the process of and apparatus for mashing and brewing. Complete Specification. March 2.

5953. A. R. Swift. The beer preserver. March 6.

6082. M. Crawford. See Class VII.

6083. M. Crawford. See Class I.

6278. F. Billing and W. E. Partridge. Improvements in apparatus and process for extracting the properties from hops and other such like purposes. March 10.

6343. E. G. Major-Lucas. Improved apparatus for separating beer from yeast. March 10.

6463. F. W. H. Hempel. Process for producing luminous spirit. Complete Specification. March 11.

6605. D. B. Bentley. Improvements in the method of and means employed for maturing wines and spirits. March 13.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

6147. F. B. Pike. Method of treating brewers' and distillers' grains. March 17.

1897.

1162. F. C. Haack. A new or improved process and apparatus for rapidly and economically ageing or maturing alcoholic beverages. March 10.

#### XVIII.—FOODS, SANITATION, Etc., AND DISINFECTANTS.

##### APPLICATIONS.

###### A.—Foods.

4117. J. Imray.—From La Soc. Anonyme des Matières Colorantes et Produits Chimiques de St. Denis and D. A. Rosenstiehl. A process for preserving alimentary substances. Feb. 18.

4395. J. Hogarth. Improvements in and relating to the treatment of alimentary substances. Feb. 22.

4730. B. L. Ryder. Improvements in method and apparatus for the preservative desiccation of vegetable and animal substances. Feb. 22.

5072. S. Griffin. Improvements in apparatus for conserving animal and vegetable food and other substances. Feb. 25.

6064. H. Humbser. Improved process for preserving substances. Complete Specification. March 8.

6065. H. Humbser. Improved process for drying substances. Complete Specification. March 8.

6346. W. Dodds. Improvement in preserving meat. March 11.

###### B.—Sanitation.

4040. F. P. Candy. Improvements in the purification of sewage and polluted water and in apparatus therefor. Feb. 15.

4406. T. Cosham. Improvements in sewage precipitating tanks. Feb. 18.

5005. W. J. Dibdin. Improvements in the treatment of sewage and appliances for that purpose. Feb. 24.

5007. L. Maiche. Improvements in apparatus for sterilising water. Feb. 24.

5793. P. Altmann. An improved process for rendering drinking water free from germs. Complete Specification. March 4.

5803. W. M. Ducat. Improvements in or connected with the purification of water, sewage, and other foul liquids. March 4.

6316. A. Apps. Improved method of sterilising, purifying, and deodorising receptacles for beverages and other materials. March 10.

### C.—Disinfectants.

4145. R. Stewart. Improvements in the manufacture of detergent fluids. Feb. 16.

5820. A. F. Dunn and A. Waithman. See Class XII.

5853. J. H. Peace. An improved antiseptic fluid for destroying microbes and other bacteria. March 5.

### COMPLETE SPECIFICATIONS ACCEPTED.

#### A.—Foods.

1896.

7480. A. J. Boulton.—From F. Fritzsche and Co. Preservation of organic substances. March 17.

26,506. H. Pape and W. Henneberg. Method and apparatus for producing fresh water from water containing salts. Feb. 24.

#### B.—Sanitation.

1896.

6132. H. B. Sharp. Manufacture of materials or compounds for use in the treatment of sewage and impure waters. March 17.

7268. The Fish Utilisation Syndicate, Ltd., and J. C. W. Stanley. Treatment of fish and other offal or similar refuse. March 10.

### XIX.—PAPER, PASTEBOARD, ETC.

#### APPLICATIONS.

4084. E. J. Pape. An improvement in blotting paper. Feb. 15.

4099. A. A. Hunting and E. A. Leigh. An improved method of and apparatus for drying paper and similar materials. Complete Specification. Feb. 16.

6054. J. S. Rigby, H. Sweetapple, and J. Clarke. Improvements in or connected with apparatus or machinery for the manufacture of vegetable parchment paper. March 8.

### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

4497. O. Tietze. Process for increasing the suppleness or pliability of paper. March 10.

### XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

#### APPLICATIONS.

4073. A. Mosticker. Improvements in the manufacture of vanillin. Feb. 15.

6220. J. C. Fell.—From W. J. Matheson and Co., Ltd. Process of producing acetanilid or acetolnids. Complete Specification. March 9.

6475. J. Y. Johnson.—From The Badische Anilin and Soda Fabrik. Improvements in the manufacture and production of acetylanthranilic acid. March 11.

6653. H. Oppermann and R. Goehde. New formic aldehyde compounds and processes of preparing the same. March 13.

6686. E. H. C. Durkopf. Improvements in the manufacture of methyleneditannic acids from formaldehyde and tannin. March 13.

### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

6858. C. D. Abel.—From E. Bonnet and T. Schlumberger. Manufacture of solution of tetranitro-cellulose (collodion pyroxyline). March 3.

1897.

28,968. L. Lederer. New or improved process for manufacturing oxyphenoxacetic acids. Feb. 24.

### XXI.—PHOTOGRAPHY.

#### APPLICATIONS.

5026. A. Rateau. Improvements in chromo-photographic apparatus. Complete Specification. Feb. 24.

6593. W. B. Ferguson. A new process of toning photographic prints and transparencies. March 13.

### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

15,852. E. P. Schoenfelder and E. Kehl. Chemical compositions for preparing the surface of suitable material for photographic prints. Feb. 24.

25,980. J. Liddle.—From The International Photographic and Supply Co. Process of printing photographs on textile fabrics, and solutions connected therewith. March 3.

### XXII.—EXPLOSIVES, MATCHES, ETC.

#### APPLICATIONS.

4062. S. A. Rosenthal.—From J. S. von Romoeki. Improvements in the manufacture of safety explosives. Feb. 15.

4279. P. S. D. Dunn. Improvements in or connected with matches. Feb. 17.

4566. R. Crooke, jun. Improvements in the manufacture of explosives especially applicable for use in coal mines. Feb. 19.

4672. L. Ronx. Improvements in the preparation of explosives. Feb. 20.

5003. H. L. Robinson and E. J. Ryves. An improved smoke-producing mixture for use with explosives. Feb. 24.

5399. G. de Wolf. From B. C. Pettingell. An improved blasting and gun powder. March 1.

6140. R. N. Lennox. Process for the separation and purification of nitrate of ammonia. March 9.

6409. H. Maxim. Improvements in explosive propelling compounds and methods of manufacture. March 11.

6438. W. F. Brown. Improvements relating to matches. March 11.

6461. M. van Look. Improvements in or relating to explosives. Complete Specification. March 11.

6610. C. O. Lundholm and J. Sayers. Improvements in the manufacture of explosives. March 13.

### COMPLETE SPECIFICATION ACCEPTED.

1896.

6431. A. V. Newton.—From A. Nobel. Improvements in explosive compounds. March 3.

## NOTICES.

### ANNUAL GENERAL MEETING.

The Annual General Meeting will be held in Manchester on the 14th, 15th, and 16th July next. Tickets of Membership will be issued in time for the Meeting, and will form, as heretofore, vouchers for visits to works and excursions. A draft programme will be issued with the May number.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those Members whose names are placed in italics in the list of Council will retire from their respective offices at the forthcoming Annual General Meeting.

Prof. F. Clowes, D.Sc., has been nominated to the office of President; Dr. Edward Schunck, F.R.S., has been nominated Vice-President under Rule 11; Mr. A. Gordon Salamon and Dr. Wm. Jay Schieffelin have been nominated Vice-Presidents under Rule 24; and Mr. D. Howard, Mr.

Ivan Leviostein, and Mr. Wm. Thorp have been nominated Vice-Presidents under Rule 8.

The Hon. Treasurer and Hon. Foreign Secretary have been nominated for re-election to their respective offices.

Members are hereby invited to nominate fit and proper persons to fill four vacancies among the Ordinary Members of Council under Rule 18. Nomination forms for this purpose can be obtained from the General Secretary upon application.

*Extract from Rule 18:*—"No such nomination shall be valid unless it be signed by at least ten Members of the Society who are not in arrear with their subscriptions, nor unless it be received by the General Secretary, at the Society's Office, at least one month before the date of the Annual General Meeting, to the election to take place at which it refers. Nor shall any such nomination be valid if the person nominated be ineligible for election under Rules 12 or 15. No member shall sign more than one nomination form."

#### COLLECTIVE INDEX.

In reply to numerous inquiries, the compilation of the Collective Index is in active progress, part of the work being already in the printers' hands. The labour of revision and correction must, however, of necessity, take time; and it is hoped that those members who have already subscribed will extend their indulgence to the Indexer, who is making every effort to complete this vast work.

The prices are as follows:—

To Members (see Rules 25 and 27) and Past Members (see Rule 30); Libraries, Corporations, and Exchanges on the Society's List

Each copy 10s.

To Subscribers ..... " 12s. 6d.

To others ..... " 15s.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SPOTTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed. The circulation of the Journal is now more than 3,000 per month.

#### LIST OF MEMBERS ELECTED 23rd APRIL 1897.

Aspinwall, H. C., Pempton Lakes, Passaic Co., N.J., U.S.A., Explosives Manufacturer.  
 Berry, Albert E., c/o Bouke, Roberts, and Co., Chemical Works, Stratford, E., Works Manager.  
 Brown, W. D., Know Mills Printworks, Entwisle, Lancashire, Colourist.  
 Canfield, F. D., jr., c/o National Sugar Refining Co., Yonkers, N.Y., U.S.A., Sugar Refiner.  
 Carnell, Wm. C., 4232, Wabash Avenue, Chicago, Ill., U.S.A., Chemist.  
 Clarke, Wm. B., Edison-Swan Electric Works, Ponders End, N., Electro-Chemist.  
 Cooper, Wm. R., Carisbrooke, Upper Tulse Hill, S.W., Electrical Engineer.  
 Farmer, John E., Salford Sewage Works, Weaste, Salford, Assistant Manager.  
 Gamble, Chas. W., Photo-Process School, 6, Bolt Court, E.C., Director.  
 Harris, W. D., Lanebeg, Lishurn, Co. Antrim, Ireland, Bleach and Dyeworks Manager.  
 Hill, George, Barton-on-Humber, Chemical Works Manager.  
 Israel, Louis A., c/o T. Wavell, California Street, San Francisco, Cal., U.S.A., Manufacturing Chemist.  
 Jansen, Dr. Robt., 43, Plymouth Avenue, Longsight, Manchester, Technical Chemist.  
 Jones, Chas. H., Rua Figueroa 7, Minas de Rio Tinto, South Spain, Chemist and Assayer.

Jorissen, Dr. Wm. P., 168, Oostzee dijk, Rotterdam, Holland, Editor.

Jowett, Wm. Hall, Ardencraig, Grassendale, near Liverpool, Chemist.

Lloyd, G. Hamilton, 7, St. Mildred's Court, London, E.C., Civil and Mining Engineer.

Low, Albert H., P.O. Drawer 1537, Denver, Colo., U.S.A., Metallurgical Chemist.

Miller, Jas., 2, Ailsa Terrace, Hillhead, Glasgow, Metallurgical Chemist.

Pickert, Leo W., American Sugar Refining Co., Granite Street, South Boston, Mass., U.S.A., Chemist.

Power, Dr. Fred. B., Wellcome Research Laboratories, 42, Snow Hill, E.C., Director.

Prentice, Dr. Bertram, Royal Technical Institute, Salford, Lecturer on Chemistry.

Raper, Thos. H., 18, Victoria Embankment, Darlington, Analytical Chemist.

Smith, Allan, 100, Bury Road, Edenfield, near Bury, Lancashire, Paper Mills Chemist.

Verity, Victor, 83, Lexington Street, East Boston, Mass., U.S.A., Chemical Works Foreman.

Wahl, André R., 331, Ashton New Road, Clayton, Manchester, Technical Chemist.

Walker, Henry V., 21, Cliff Street, New York City, U.S.A., Chemist.

Yates, Wm. H., 327, Bolton Road, Stoneclough, near Manchester, Lecturer on Chemistry.

#### CHANGES OF ADDRESS.

Barden, Sam, 1/o Far Bank Farm; Woodhouse Mills, Shelley, near Huddersfield.

Beanes, Edw.; Journals to Moatlands, Paddock Wood, Kent.

Brown, Jas., 1/o Bloomfield; 30, Castlereagh Avenue, Mountpottinger, Belfast.

Bumby, H., 1/o Askam; Coltness Ironworks, Newmains, N.B.

Burn-Murdoch, J. V., 1/o Pembroke; 23, Cadogan Gardens, S.W.

Clennell, J. E., 1/o New York; 501, Dooley Building, Salt Lake City, U.S.A.

Ewen, E. D.; Journals to c/o West Indian Tobacco Co., Ltd., Port of Spain, Trinidad, B.W.I.

Fawcett, J. H., 1/o Perth; c/o Mrs. Jamieson, 31, Queen Street, Melbourne, Victoria.

Green, J. Wilberforce, 1/o Hayle; 36, Crystal Palace Park Road, Sydenham, S.E.

Haigh, De Lagnel; Journals to Avenue A and 13th Street, Bayonne, N.J., U.S.A.

Hamilton, Oswald, 1/o Northfleet; Lancaster Cottage, Old Stratford, near Stony Stratford.

Handy, J. O.; Journals (temp.) to c/o Mrs. Maars, 10, Martensen's Allée, Copenhagen, Denmark.

Hawkins, J. D., 1/o Gillett; c/o Colo. Phila. Reduction Co., Colorado City, Colo., U.S.A.

Hennin, A., 1/o Monongahela Furnaces; National Tube Works, McKeesport, Pa., U.S.A.

Hotson, A. E., 1/o Union Square; 147, East 125th Street, New York, U.S.A.

Hunt, B., 1/o Stevenson Street; 216, Sansome Street, San Francisco, Cal., U.S.A.

Littell, R. Ballantine; Journals to Setanket, Long Island, N.Y., U.S.A.

Lynn, A. H., 1/o Nottingham; 11, Henry Street, Warrington.

Mahery, Prof. C. F.; Journals to Case School of Applied Science, Cleveland, O., U.S.A.

McEwen, A. F., 1/o Rossland; Lillooet, Laurie, C.P.R.R., British Columbia.

Manoukian, Wahan, 1/o Manchester; 9, Torrington Square, W.C.  
 Pethybridge, Walter, 1/o Clarendon Road; 3, Rhodesia Road, Clapham Rise, S.W.  
 Sinclair, Dr. Wm., 1/o Uphall; 18, Chumy Drive, Edinburgh.  
 Smith, Wm., 1/o 10; 38, Corn Street, Bristol.  
 Swan, David, 1/o Glasgow; Joppa Lodge, Innellan, N.B.  
 Waterhouse, Col. J., 1/o Calcutta; retain Journals until further notice.  
 Watson, Jno., 1/o Johannesburg; c/o Lancaster G.M. Co., P.O. Box 144, Krugersdorp, S.A.R.  
 Welch, J. Cuthbert, 1/o Reading; Kaslo, British Columbia.  
 White, W. Gilchrist; Journals to The Hodge, Broadbottom, near Manchester.  
 Wright, Lewis T., 1/o London; The Mountain Copper Co., Keswick, Cal., U.S.A.

## CHANGE OF ADDRESS REQUIRED.

Currie, Stanley C. C., 1/o 45, Broadway, New York, U.S.A.

## Deaths.

Ascough, Jesse, The Grange, Handsworth. April 11.  
 Mead, Frank, Gasworks, Sutton, Surrey.

## London Section.

THE CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE, W.

Chairman: R. Messel.

Vice-Chairman: Boverton Redwood.

## Committee:

B. Blount.	H. de Mosenthal.
C. F. Cross.	B. E. R. Newlands.
W. J. Dibdin.	S. Rideal.
R. J. Friswell.	F. G. Adair Roberts.
S. Hall.	F. Napier Sutton.
D. Howard.	Wm. Thorp.
E. Grant Hooper.	T. Tyrer.

Hon. Local Secretary:

John Heron, 110, Fenchurch Street, E.C.

The names in italics are those of Members of Committee who retire at the end of the current session.

The following have been elected to fill the vacancies, and will take office in July next:—Committee: F. J. Ewan, Otto Helmer, J. B. Knight, A. R. Ling, and Lewis T. Wright.

## SESSION 1896-97.

May 3rd, 1897:—

Dr. W. S. Squire, "On a New Slow-Combustion Arc Lamp suitable for Factories and Street Lighting."

Dr. J. Lewkowsitch, "On the Conversion of Oleic Acid into Candle Material."

Meeting held on Monday, April 5th, 1897.

DR. R. MESSEL IN THE CHAIR.

## THE CHEMICAL STABILITY OF NITRO-COMPOUND EXPLOSIVES.

BY OSCAR GUTTMANN, ASSOC. M. INST. C.E., F.I.C.

I do not think it is necessary for me to explain the meaning of the term "nitro-compound explosives," nor their chemical composition, as this is now well understood by technical men, and has, moreover, been fully set forth by me in the treatise on the Manufacture of Explosives which I published in 1895. I can therefore at once proceed to the subject of my paper, namely, the "chemical stability" of such explosives.

Chemically speaking, they may be described as somewhat loosely bound. If exposed to a heat of about 180° C., they will almost without exception explode, but far below this temperature there is a splitting up of the molecules going on, which results in the development of nitric peroxide, and this in its turn will, if once formed, rapidly promote decomposition. In speaking therefore of the chemical stability of nitro-compound explosives, we have chiefly to deal with the question of the circumstances under which these explosives are liable to be decomposed with the development of nitric peroxide.

At present the chief nitro-compound explosives are nitro-cellulose—be it made of cotton, wood, or other cellulose material—and nitroglycerin, or mixtures of these two; and also nitrobenzene, nitrotoluene, picric acid, pierates, &c. All these are manufactured nowadays in such a perfect way that the only possible cause of decomposition is the action of heat. But in some cases additions made to these explosives, either for the purpose of neutralising any free acid, or for the purpose of moderating or increasing the explosive effect, and sometimes also the mechanical treatment given may influence the stability.

In order to ascertain whether an explosive is liable to decomposition at temperatures that may occur under ordinary circumstances of storage and use, various means have been proposed, all of which should show the presence of nitric peroxide. In Austria it is still compulsory by law to keep a piece of litmus paper in each box of dynamite, so that on opening it the storekeeper can see whether the dynamite has become acid or not. Colonel Hess, of the Austrian Military Committee, heated the explosive, and carried the vapours into a solution of potassium iodide. In some other countries the explosive is subjected to a temperature varying between 100 and 135° C. for periods ranging from a day to a week, and the absence of red fumes is taken as an indication of the stability of the explosive. In this country the Home Office has, I believe upon the proposition of Dr. Dupré, prescribed a test which is familiar to everybody who has had to deal with explosives, since it has been adopted in almost every country, and has undoubtedly been the direct cause of great progress in the manufacture. It consists of heating the explosive in a test-tube at a given temperature (at present 170° F. for gun-cotton, and for most other explosives 180° F.) and noting the number of minutes which elapse before a brown line of a certain depth of tint appears on a piece of potassium iodide starch-paper that has been moistened with a solution of equal parts of glycerin and water, and which is suspended from a hooked glass rod passing through an india-rubber cork. In Germany zinc iodide starch-paper is used instead of potassium iodide paper. I shall deal with this test later on, and will now enumerate the various possibilities of decomposition, both during manufacture of the constituent nitro-compounds and the finished explosive.

Starting with gun-cotton, it was first recognised by Sir Frederick Abel that the various accidents with the original product of Schönbein and von Lenk were due to the imperfect removal of the acids that served to nitrate the cotton. Sir Frederick devised the pulping of gun-cotton in beating engines, whereby the fibres of the gun-cotton were thoroughly opened, and the washing water could easily penetrate. This process gives a gun-cotton of such high stability that there is now no difficulty of making it to comply with the Government heat test. Now and then, through imperfectly wringing out the acids in the centrifugal machine, a larger quantity of acids than usual remains in the gun-cotton, and as a definite number of washings are generally given, it may happen that, after the gun-cotton has gone through the whole process of boiling and washing, it is still sufficiently acid to give a bad heat test. Of course, this can be easily remedied with a little attention.

The practice of adding alkaline matters, such as carbonates of soda, lime, or magnesia, &c., is gradually dispensed with, and in this country the Government do not prescribe it. I believe I was the first to point out that the addition of alkaline matters to either gun-cotton or nitroglycerin is quite unnecessary, and in fact a deception. If there is a real decomposition going on in an explosive, the

small quantity of alkali will soon be consumed, whilst some of these alkalis have a direct tendency to decompose the nitro-compounds, thereby doing more harm than good. A properly purified explosive will, under ordinary circumstances of storage, keep practically for ever without showing the least sign of decomposition, and there is no better example than the bottle of nitroglycerin kept at the Nobel factory at Avigliana, which was the first nitroglycerin made by Prof. Sobrero in 1847, and which has been tested every year since, but has not yet shown any deterioration in stability. That the various alkaline substances added for neutralisation act differently has been shown by Dr. Dupré in the report of H.M. Inspectors of Explosives of 1887. He found that adding calcium or magnesium carbonate to gelatine dynamite does not appreciably affect the heat test, but the sodium carbonate has an uncertain effect, tending to increase the duration of the heat test in bad samples and to decrease it in good samples. This is quite consistent with what I said before, because in a bad sample the sodium carbonate would neutralise the acid already developed, whilst it would tend to decompose a good sample. In my own experience the addition of ammonium carbonate to blasting gelatine for the purpose of neutralising any acidity, has caused decomposition to such a degree that the guncotton partly disappeared, and the nitroglycerin was sweating out from the cases of blasting gelatine, so that the walls and the floor of the magazine were literally wet with it. The ammonia, which is so easily liberated from the carbonate of ammonia, acts very readily on nitro-compounds, and more readily on guncotton than on nitroglycerin.

In the case of picric acid and picrates, nitrobenzene, nitrotoluene, &c., similar remarks apply as to guncotton. When properly washed and freed from acid, they are stable, and the degree of stability will simply depend upon the complete removal of acids. In some of these nitro-compounds greater purity can be obtained by recrystallising, in others by repeated washing, if necessary with the addition of alkaline matters, so as to attack more readily the free acids.

Nitroglycerin, being an oily liquid, is not so easily purified, because it is more difficult to get it into small particles that can be attacked by the means employed for purification. Formerly very crude methods of washing, such as a petroleum barrel sunk into the ground to hold the nitroglycerin, and a churn-like perforated board to agitate the liquid, were used. Nowadays compressed air has been taken into requisition for thoroughly agitating the nitroglycerin with the washing liquids, and it serves at the same time to oxidise the lower nitro-compounds that generally accompany the impure product. With nitroglycerin it may also happen that a larger amount of acid is drawn off to the nitroglycerin in separating the latter, and then more frequent washing will have to be resorted to. In order to neutralise the bulk of the acid, sodium carbonate or soda in powder is added to the washing water, and the remaining acid is taken out by repeatedly washing with either hot or cold water or very weak soda solution. Some years ago a case came under my notice, where for days it was found impossible to make any nitroglycerin charge pass the heat test, although most careful and frequent washing was resorted to. Suspicion rested upon the glycerin and the sulphuric acid. The purity of the nitric acid, which had been made by my process, was above suspicion. However, careful examination with absolutely pure glycerin and sulphuric acid on the same large scale showed that the materials used were not at fault. The simple suggestion that I made from the beginning proved to be correct, namely, that the apparatus had not been sufficiently cleaned. As you know, nitroglycerin is made in leaden apparatus, and, although one would think that from the mixture of nitric and sulphuric acid only lead sulphate would be formed, yet the lead sulphate is of spongy, porous character, and will retain nitrous impurities mechanically. This is especially the case on the line of contact between the air and the surface. In testing small quantities of lead sulphate from different parts of an apparatus, and adding minute quantities to samples of nitroglycerin of undoubted excellence, the heat test at once went down in an alarming

degree. The explanation now came as a matter of course: small particles of lead sulphate are always detached from the lead apparatus and suspended in the nitroglycerin; through the washing with compressed air they are thrown up and get little time to settle. The water alone does not remove the nitrous impurities, except in the course of long treatment, and therefore minute particles will find their way into the samples tested.

A similar possibility, although of an opposite character, was suggested by me and proved experimentally by washing nitroglycerin with soda. In adding soda in powder instead of in solution, soda mud is thrown down. If a small quantity of such mud is taken up, it will be distinctly alkaline to litmus paper, yet if a drop of nitroglycerin is put on the top of it, and allowed to stand for some time, there will be an acid reaction on the line of contact between the nitroglycerin and the soda mud, showing that the nitroglycerin is attacked.

From these comparatively simple nitro-compounds I pass to mixtures such as blasting gelatine, for instance. It must not be assumed that because two nitro-compounds are very stable under the influence of heat, a mixture of the same will have equal stability. There are many circumstances that may occur to the contrary. Blasting gelatine, for instance, is made by dissolving soluble guncotton in nitroglycerin with the aid of gentle heating. I will show later on that nitric peroxide can be developed from some nitro-compounds at much lower temperatures than that of the official heat test, and it will therefore depend much upon the temperature at which the solution of blasting gelatine is made, and upon the mechanical treatment it has undergone, whether the finished product will retain the degree of stability of its components or have it reduced. The same may occur with mixtures of picrates, solutions of nitrobenzene and guncotton, molten masses of nitro-compounds of low melting point, &c. In the manufacture of smokeless powder in flakes, the paste is frequently rolled into sheets by means of steam-heated rolls. With other smokeless powders the paste is made by prolonged treatment in kneading machines, whereby the temperature of the paste is increased. These operations, in my opinion, reduce the duration of the heat test, since, as I said before, treatment at elevated temperatures will result in the local development of nitric peroxide, and, if once started, it will develop more rapidly than before.

What I have said so far is perhaps of more interest to the manufacturer only, and not so much to the general consumer, who has a right to demand that the finished explosives, whether they be simple or composite products, should be of reasonable safety of handling. A good many of the explosives in use are mixtures of a number of constituents sometimes of a most complex nature, and the influence of these constituents has to my knowledge so far not been sufficiently studied. I have, in my long experience with explosives, often had an opportunity of investigating some of the questions at issue. Recently I had occasion to go fully into the matter, and will now give you the results of my experiments as far as I have yet carried them.

The finished explosives of most interest are guncotton, dynamite, blasting gelatine, gelignite, and the many smokeless powders, whether they contain nitroglycerin, nitrobenzene, &c., or not. Of guncotton I have said what is important. Dynamite is, as you know, nitroglycerin absorbed in kieselguhr, a pure silicious earth. Blasting gelatine is, as mentioned already, a solution of soluble guncotton in nitroglycerin, and gelignite is a similar solution of thinner consistency mixed with an absorbing powder consisting of potassium nitrate and wood pulp. From both dynamite and blasting gelatine the nitroglycerin may exude when it is not sufficiently held by the absorbent. Properly speaking, this is not a chemical, but only a mechanical instability. In the case of dynamite the exudation depends both upon the absorbing capacity of the kieselguhr and upon the influence of temperature to which the dynamite may be subjected during storage. If the temperature is too low, the nitroglycerin freezes in the explosive and contracts nearly one-tenth of its volume. It will thus leave the outer layers of the absorbent, and if the explosive is thawed up again, it may not distribute itself uniformly through the porous absorbent as before. If the temperature is too great,

then the nitroglycerin expands, and, should the guhr in the explosive have been originally slightly supersaturated, the nitroglycerin will ooze out. There is also the influence of moisture on dynamite, water by osmotic action displacing the nitroglycerin and going in its place. In the case of blasting gelatine, the quality of the soluble guncotton employed is of great importance, because it is well known now that neither the percentage of nitrogen nor the complete solubility of the guncotton in the nitroglycerin is a reliable criterion for the suitability of guncotton to safely retain nitroglycerin.

The possibility of dynamite or blasting gelatine becoming influenced by heat increases with the number of constituents that enter into its composition. Although it may be thought that in dynamite the nitroglycerin only has to be taken into consideration, yet it was found some 12 years ago that with perfectly good nitroglycerin and what was apparently excellent kieselguhr a good dynamite could not be made. On examination it was shown that the kieselguhr contained, besides traces of iron and charred organic matter from calcining, comparatively large amounts of aluminium sulphate. Even a small quantity of this proved to have a decomposing action on the nitroglycerin, with the consequent development of nitric peroxide.

Several years ago great difficulty was found in various factories to ship gelignite to Australia that on arrival would pass the heat test, and some cargoes were condemned and destroyed on that account. Of course, if such explosives travel by a sailing boat in tightly closed hatches without ventilation, exposed to the burning sun on crossing the equator, and arrive in the summer in India or Australia, the manufacturers will have to be careful to allow a sufficient margin for the heat test, and to prevent improper stowing on board ship. Nevertheless, most careful treatment and manufacture, and examination of gelignite before shipment and after a year of storage, revealed the fact that in some cases the gelignite stood all the heat tests in England, whilst in Australia it was condemned. On investigating the matter thoroughly I came to the conclusion that the wood pulp was at the bottom of the trouble. It is of importance that as little moisture as possible should be in the explosive, and therefore the wood pulp is subjected to a process of drying, which in some factories is carried so far that the wood pulp assumes a light chocolate colour; in other factories it is simply submitted to a temperature of about 120° C., so as to drive off all moisture. Generally the wood pulp is so dried in iron drums, with or without a stirring arrangement, that are exposed to a slow fire. If the wood pulp is slightly charred, it is of course evident that partial distillation of the wood and consequently development of acetic acid is going on; but even with comparatively low temperatures there may be accumulation of heat locally, and small nuclei of charring formed, which may spread rapidly in extent. Little notice was usually taken of these particles of charcoal. Acetic acid has a marked reaction with potassium iodide, and the following table shows from actual experiments that acetic acid, formed during the drying of the wood pulp, will influence the heat test very considerably:—

Name of Material.	With the Addition of	Heat Test in Minutes.		
		Before the Addition.	After the Addition.	Loss.
Gelatine for gelignite	Wood-pulp and salt-petre.	31	29	11
"	Wood-pulp.....	33	20	13
"	" .....	34	29	21
"	Salt-petre .....	31	32	2
Nitroglycerin .....	3 drops acetic acid.	39	3	27

Side by side with the development of acetic acid some methylic alcohol is also formed, and if the gelignite contains an alkali, like sodium carbonate, the presence of alcohol will make the alkali decompose the nitro-compounds more rapidly.

On the other hand, I do not think that the presence of acetic acid in gelignite that does not contain an alkali has

any detrimental effect on the stability against heat, or that it would decompose the nitro-compounds, and I have, therefore, little doubt that gelignite may be condemned on account of low heat test when the nitro-compounds, and, in fact, the whole explosive is perfectly stable. The gelignite may be capable of standing heat for a very long time without any nitric peroxide being developed, and yet a reaction on the iodide paper caused through the presence of the harmless acetic acid.

We now come to a class of explosives that has developed so enormously within the last nine years as to revolutionise one branch of the industry, namely, the smokeless powders. It cannot be said that the last word as to their manufacture has been spoken, nor that the ideal powder has as yet been found; every year sees the invention of some new powder, and the old ones are being constantly improved. It is, therefore, not surprising that more attention has so far been directed to their good and safe manufacture than it was possible to bestow on their keeping qualities, since, whatever laboratory tests would be applied, the real test for the stability of a powder under the varying circumstances of its use can only be made by years of experience in practice.

You are now all familiar with the fact that modern smokeless powders are made either from guncotton alone or from mixtures of nitrocellulose and nitroglycerin, nitrobenzene, &c., with or without nitrates and similar substances. In trying to apply the iodide heat test to smokeless powders, I can well imagine the Home Office authorities must have had considerable difficulties, because, as will be apparent later on, these powders sometimes behave in a very erratic way as far as the regulation heat test is concerned. However, the difficulty was seemingly overcome by prescribing that in the case of Schultze and E.C. powder, &c., the powder should be dried in an oven at 120° F., then exposed for two hours to the air before the usual heat test was applied; whilst cordite and similar smokeless powders have to be ground in a mill, sieved through a set of three sieves, and only the powder retained by the second sieve used for the heat test.

It was in September 1895 that my friend Mr. Hermann Güttler, of Reichenstein, the well-known gunpowder manufacturer, pointed out to me the strange fact that, whilst he could get a heat-test reaction with iodide paper from his own powder, the so-called Plastomenite, he could get no reaction from Walsrode powder, or only after hours of heating; and that, moreover, if he put a paper that had the brown mark of the heat-test reaction into a test tube with Walsrode powder, the brown line disappeared almost immediately. The fact was so strange that it demanded investigation, and on my return, in October, I had an opportunity of going fully into the matter in connection with some other questions. It was apparent to me at once that there must be something contained in the Walsrode powder that would act upon the iodine liberated on the starch paper. However, I also found, as will be intelligible to everybody, that on putting a coloured iodide paper into an empty test tube and heating the tube to 180° F., the paper became white again in about five minutes through the evaporation of the iodine. The German zinc iodide paper proved to be more sensitive than the English paper, because I could get reactions with it in a third less time and make the iodine disappear in about half the time. Although this phenomenon threw me off the scent for a few days, yet I soon found that the time for the discoloration of the iodide paper was much too long to have such marked influence as shown in the case of Walsrode powder. I then found that old Walsrode powder gave a much quicker heat-test reaction than recently prepared one, and without going into the details of the many hundreds of experiments that I have made in order to ascertain positively all the circumstances connected with this disappearance of iodine, I had better give you the final rather startling conclusions that I arrived at.

You know that there are a large number of bodies that will either absorb iodine, such as fats and oils, or such that will combine with iodine under certain circumstances, or such that will dissolve it. I have been able to prove that a large variety of ingredients can be and are contained in

different smokeless powders that will stultify the iodide heat test. Perhaps foremost amongst them are acetic ether, acetone, and oils; but also vaseline, aniline, and various others. The greater the density the more difficult it is to drive off the solvent used in the manufacture of the powder, such as acetone, acetic ether, &c. Some powders will have retained as much as 1 per cent. of the solvent, some only a small fraction of a per cent. Although the latter may not show the presence of the solvent by the smell, yet, when such a powder is ground up and heated in the test tube, it will be found that a certain amount of the solvent has always been retained in the interior of the grains of the powder. This solvent or other suitable ingredient, if it acts upon the iodine, will prevent the formation of the brown line on the test paper, because, as the iodine is developed by the nitric peroxide, so the particular solvent or ingredient will make it disappear. This is what I call "hiding" the heat test, and the result will be that a powder may be fully in a state of decomposition, yet the solvent, like acetone or acetic ether, that is in the test tube will for some time prevent the formation of the brown line until either the development of nitric peroxide has become too great, or part of the solvent is driven out through leakages round the stopper and glass rod.

You will not be astonished now to hear that, with a powder made according to Mr. Hiram S. Maxim's patent, consisting of 88 parts of gun cotton, 10 parts of nitroglycerin, and 2 parts of castor oil, using acetone as a solvent, I have sometimes not been able to get a heat-test reaction after even two hours of exposure to 90° C. The same thing, although in a lesser degree, happened with Walsrode powder and with cordite. In the case of cordite, iodide test papers made by two different chemists behaved differently, paper A showing the heat-test reaction after double time than paper B; yet when the same papers were tested on another kind of powder the order was reversed, and it was paper B that showed the reaction twice as late as paper A; but this was not due to a difference of sensitiveness of the test papers.

Considering the high temperatures to which oils can be submitted without apparently boiling or giving off visible vapours, it looked improbable that in the case of a powder containing it, it should be the oil that was hiding the heat test, and I was inclined to attribute it to the acetone only, but I soon found that, for instance, castor oil gave off volatile parts comparatively readily at somewhat low temperatures. I exposed castor oil in a beaker in a layer 1 in. deep to a temperature of 180° F. for 30 minutes, which is good average time and temperature for the Government heat test, and it was found that it lost 0.245 per cent., which, of course, is a far greater percentage than would be required to absorb the small amount of iodine on the test paper. I had also 20 grms. of castor oil exposed in a flat glass basin to a temperature of 38° C. for 72 consecutive hours, and the loss was 0.656 per cent.

It did not seem at all likely that vaseline would affect the heat-test reaction, and for a time it did not occur to me to try its influence, but some erratic behaviour of cordite caused me to approach the question from a different point of view by dissolving both castor oil and vaseline in hot ether and preparing three samples of the same batch of gun cotton, one sprinkled with 5 c.c. of ether only, the other with three drops of castor oil dissolved in 5 c.c. of ether, and the third with three drops of molten vaseline in the same quantity of ether. I then submitted the three samples to a temperature of 40° C. in a drying oven to drive off the ether, and applied the iodide heat test. The times were as follows:—

	Minutes.
Gun cotton alone .....	9
Gun cotton and 3 drops of castor oil .....	19
Gun cotton and 5 drops of Chesebrough vaseline .....	44

There seemed to me a possibility that, during the drying process of the finished explosives containing castor oil or vaseline, some volatile matter may go off that would influence the heat test, and therefore mineral jelly was also submitted for 72 consecutive hours to a temperature of 38° C., when the loss was found to be 0.061 per cent. Three drops of the residue of this exposed vaseline and

castor oil were then dissolved in ether, as before, using a fresh batch of gun cotton of good quality. I may say here already that all my comparative heat tests were made on 1.500 grms. of explosive at a temperature of 80° C., this being the nearest approach in the metric system to 25 grains at 180° F. The results were as follows:—

	Minutes.
Gun cotton alone, sprinkled with ether .....	16
Gun cotton with dried castor oil in ether .....	32
Gun cotton with dried mineral jelly in ether .....	22
Gun cotton with undried mineral jelly in ether .....	22

I had now the undoubted proof that there existed a number of ingredients of smokeless powders that would hide the heat-test reaction, and why some powders behaved in the iodide heat test in such erratic way. A powder that was ground in the evening and tested at once showed much longer heat test than when it was only tested next morning. Coarsely ground powders gave worse heat test than finely ground ones. Sometimes a powder that was exposed for many months gave a better heat test than a freshly prepared one. All this is due to the state of division of the powder when the heat test is made, and to the greater or smaller quantity of acetone or other ingredients retained that could be evaporated in the given time of the heat test. Moreover, the mill as used for grinding smokeless powder is one that does not grind but chips the powder, and although only those grains that are retained on a certain sieve are used for the test, yet there are great differences in size, whereby different quantities of solvent may be given off. All these experiments proved to me conclusively that the iodide heat test, as at present prescribed, is absolutely inapplicable for most of the modern smokeless powders and also some blasting explosives, since the iodine that is supposed to be liberated is acted upon by some ingredients contained in them. If you consider that the heat test is one of the chief criterions for the suitability of a powder for prolonged storage, and that every country in the world has a similar regulation test, you will understand the great importance of my discovery. A manufacturer, or even Government factories, cannot afford to have their deliveries rejected and suffering sometimes great pecuniary losses through an unsuitable method of testing.

It seemed to me that, before abandoning an old trusted friend, I had to get another, and I therefore set about to find a test that could not be hidden by some ingredients of the explosive, that is, one that would only be acted upon by the nitric peroxide developed through heat, and that would as much as possible be capable of application in a similar manner as the iodide heat test.

I have looked up all the various reagents that have been proposed during the last 40 years for the detection of small quantities of nitric peroxide. A number of them I could discard at once, because they would either require a complicated preparation or a treatment of the explosive by chemical operations, or they would act upon the explosive itself. I also did not wish to have a reagent in which the explosive would have to be dissolved or with which it would have to be mixed, because accurate time results could not be expected. Reagents for nitric peroxide have been proposed by Griess (a mixture of sulphanilic acid and naphthylamine in acetic acid), by Plugge (mercuric nitrate and carbolic acid), Jorissen (fuchsin dissolved in glacial acetic acid), Vogel (Rosaniline), Meldola (para-amidobenzoazodimethylamine), Curtman (antipyrine), Kopp (diphenylamine), Frankland (sulphanilic acid and phenol), and Griess (*m*-phenylenediaminehydrochloride).

My chief aim was to get such a reagent that could be applied in a similar manner as the iodide heat test, namely, by placing a drop of the reagent on a piece of filter paper, which can be suspended on a hooked glass rod in a test tube, this way of testing having now become so universally adopted and giving such easy manipulation that it was desirable that any new test should be capable of being done in the same manner. Besides, such a test would not come into contact with the explosive itself, and no chemical combination between the explosive and the reagent could therefore be anticipated. Of the various methods, the antipyrine, metaphenylenediamine, fuchsin, and diphenylamine reactions recommended themselves most. Antipyrine

I had to disregard very soon, because it only gives a very slight emerald-green colour, which is not sufficiently distinguishable. *m*-Phenylenediamine gives a yellow reaction, but proved to be uncertain in effect, and is not well visible in artificial light. For fuchsine, Jorissen's and Vogel's description was that 0.01 grm. should be dissolved in 100 c.c. of glacial acetic acid. This was found too strong for my purpose, and I therefore diluted the glacial acetic acid with water. A drop of this fuchsine solution put on a test paper gives a most beautiful reaction with nitric peroxide: its colour changes from a light purple-red into violet, then gradually into sky-blue, then green, then yellow, and finally disappears altogether. A drawback to it is that free mineral acid turns it yellow at once. I had some hopes of being able to use this test, but after numerous experiments with different explosives I found that the change from red to blue, which I considered to be the safe sign of development of nitric peroxide, was not by any means regular. Sometimes the violet colour appeared immediately before the blue one, but at other times the red changed at once into violet, and it took a very long time before a blue reaction could be got at all. I therefore concentrated all my efforts to the diphenylamine reaction, which, as is well known, is a very sensitive and good one. However, the usual way—as, for instance, applied in the examination of water, namely, dissolving the diphenylamine in strong sulphuric acid and adding a drop of it to the water—could not be resorted to, because the strong sulphuric acid would not be without effect on the test paper, whilst at the same time the reaction would not be sufficiently sensitive unless this solution could be diluted. Diphenylamine dissolves readily enough in strong sulphuric acid, but if this solution is diluted with water, the diphenylamine is precipitated. I used various devices, such as putting the diphenylamine solution on a ground glass plate, then on a milk glass plate, then dipping vegetable parchment paper into it, but in all these cases I got a drop of the solution hanging down, which required a large quantity of nitric peroxide to show coloration, whilst in my case only very slight traces of it were to be detected. I then found that on putting a few drops of water into a flask with the concentrated sulphuric acid, the heat generated would dissolve the diphenylamine, and if further quantities of water were gradually added, still more heat was generated, and a clear solution of diphenylamine in the ratio of 1 to 500 obtained. In order to prevent the too rapid evaporation of the water on the test paper, I mixed equal quantities of this solution and Price's glycerin, and a few drops of this liquid put on the filter paper proved to be an excellent reagent for nitric peroxide. Nevertheless, after keeping this solution for several months, some pink flocculent matter was thrown down, evidently a product of reaction between the strong sulphuric acid and the diphenylamine; and after some trouble I found that the following method of preparation and the following way of carrying out the test answered all purposes, and that diphenylamine solution so prepared could be kept for a very long time:—

Take 0.100 grm. of diphenylamine crystals, put them in a wide-necked flask with a ground stopper, add 50 c.c. of dilute sulphuric acid (10 c.c. of concentrated sulphuric acid to 40 c.c. of water); and put the flask in a water-bath at between 50° and 55° C. At this temperature the diphenylamine will melt, and at once dissolve in the sulphuric acid, when the flask should be taken out, well shaken, and allowed to cool. After cooling, add 50 c.c. of Price's double-distilled glycerin, shake well, and keep the solution in a dark place. The test has to be applied in the following way:—The explosives that have to be tested are to be finely subdivided, gun-cotton, nitroglycerin, dynamite, blasting gelatine, &c. in the same way as at present directed by the Home Office regulations. Smokeless powders are all to be ground in a bell-shaped coffee mill as finely as possible, and sifted as hitherto. 1.500 grms. of the explosive (from the second sieve in case of smokeless powder) are to be weighed off and put into a test tube as hitherto used. Strips of well-washed filter paper, or strips of any good chemical filter paper, 25 mm. long, 10 mm. wide, are to be hung on a hooked glass rod as usual. A drop of the diphenylamine solution is taken up by means

of a clean glass rod, and the upper corners of the filter paper are touched with it, so that when the two drops run together about a quarter of the filter paper is moist. This is then put into the test tube, and this again into the water-bath, which has been heated to 70° C. The heat-test reaction should not show in a shorter time than 15 minutes. It will begin by the moist part of the paper acquiring a greenish-yellow colour, and from this moment the paper should be carefully watched. After one or two minutes a dark blue mark will suddenly appear on the dividing line between the wet and the dry part of the filter paper, and this is the point that should be taken.

I believe this test will recommend itself as very simple and effective to everybody, and I hope it may be adopted as a standard. I may be therefore permitted to give some explanations for the reasons why certain details have been worked out in the way indicated.

Instead of having to re-crystallise potassium iodide from alcohol, to carefully wash filter paper, to dip it, after drying, into the potassium iodide solution, to dry this again in a dark room, to cut off the edges, divide it into strips, and yet have test papers that will only keep for a short time,—this new test of mine allows to use any good chemical filter paper, such as it is supplied in circular sheets of great purity, and a solution of diphenylamine, which, when once prepared, is practically unaltered, or at least, within my experience, not during six months, and can be made within a few minutes. The diphenylamine solution has a strength of about 1 in 1,000 by volume. The subdivision of the explosive requires some remarks. In all these tests it is essential that the explosive should contain as little moisture as possible, otherwise the test paper will soon be thoroughly dampened, and no test could be made. It is, however, not advisable to dry explosives at higher temperatures, because my experiments have shown that nitric peroxide in minute traces is developed already between 45° and 50° C., and if explosives were dried at this temperature the heat test would not be accurate. The present Home Office regulation of drying gun-cotton in an open water-oven at 120° F. is satisfactory, although it might be advisable to dry one hour instead of a quarter of an hour, but at 40° C. only. The mixing of blasting gelatine and the like with French chalk is a very good way of subdividing the tough mass. Smokeless powders should, as a rule, not be dried, because many of them contain ingredients that are volatile to some extent even at 40° C., and because they do not, as a rule, contain moisture to an appreciable extent. On the other hand, they should be ground and sifted. The reason for the desirability of subdivision is twofold. Firstly, in a very dense and tough explosive the nitric peroxide developed would have to loosen the structure of the grain before it could escape, whereby the reaction would be retarded. On the other hand, although the test tube has a small diameter and the height of the explosive in the test tube is small, yet the coefficient of transmission of heat cannot at all be neglected. If the powder is in the shape of dust, the emission of nitric peroxide through the layer of powder into the empty space in the test tube takes some time. If the explosive be too coarsely grained, a lesser quantity of nitric peroxide may be set free in a given time. Were a smokeless powder not ground at all, the hard surface resulting from black-leading, as it is sometimes done, would delay the development of nitric peroxide. It is therefore desirable to have the powder in a fairly uniform state of subdivision, so as to get with the same explosive an equal constant, due to the delay in transmission of heat and start of the decomposition.

I have said just now, that the coefficient of transmission of heat cannot at all be neglected, and direct experiments to prove this gave remarkable results. In a water-bath, heated to 70° C., the temperature of the room being 12° C., it takes 8½ minutes to reach a temperature of 69½° C. in a test tube filled with ground cordite or ground ballistite, but 11 minutes if the ballistite is not ground. The temperature rises to 60° C. in about 3 minutes, but the last 10 degrees take so long, and it makes little difference whether the test tube is of thick or thin glass, the time for heating the

interior to 70° C. differing only by the fraction of a minute in favour of the thicker tube.

I was inclined to attribute this delay in heating the interior of the test tube to the fact that half the length is exposed to the cooling action of the ambient air. I had, therefore, a test tube made by Messrs. Müller and Co., of High Holborn, the upper half of which was jacketed, and the jacket completely evacuated; but there was quite a negligible difference in the time. On filling the test tube with mercury, the time for heating to 70° C. is 2 minutes, and, the delay through the thermometer having been found to be 30 seconds, the loss of time by the transmission through the glass is 1½ minutes. The reason for the additional delay of 6½ minutes is to be found in the fact that air is a bad conductor of heat, and it is the air enclosed in the test tube that requires this additional time.

I now tried to find whether the fact of the air expanding through heating, and an increased pressure being set up for the unity of volume, had any influence on the time for heating. For this purpose I tried two empty tubes, first with the india-rubber stopper tightly fixed in, and afterwards with it laid loosely on the top so as to allow for expansion. The following table shows the result, the water-bath being kept at 70°:—

Minutes.	Ordinary Test Tube.		Vacuum-jacketed Test Tube.	
	Tight Stopper.	Loose Stopper.	Tight Stopper.	Loose Stopper.
0	14	14	14	14
1	31½	36	32	37
2	44½	52	45½	53
3	53½	60½	54½	62
4	59½	65	60½	66
5	63½	67½	63½	67½
6	66½	68½	66	68½
7	67½	69	67½	69
8	68½	69½	68	69½
9	69	69½	68½	69½
10	69½	..	69½	..
11	69½	..	69½	..

It appears, therefore, that if the stopper of the test tube or the glass rod in the stopper fit loosely, the duration of the heat test can be reduced by about two minutes.

The temperature for the heat test I have, after very careful consideration, put down at 70° C. A general test like the heat test ought to be the same in every country,

so as to be able to compare results; and as we are gradually giving up the use of grains and Fahrenheit temperature scale, it was best to resort to the metric system. The temperature was originally put down by the Home Office at 150° F. for gun-cotton, Schultze powder, E.C. powder, &c., and was gradually raised to 170° F. for gun-cotton and to 180° F. for all other explosives. A careful comparison of a large number of explosives at present in the market, both with the iodide and my diphenylamine test, has shown that the temperature of 180° F. is too high to allow of a sufficient margin for observation and errors. I believe this high temperature was resorted to because with the former temperature of 170° F. some smokeless powders that bide the heat test seemed to give such extraordinarily good tests as to necessitate waiting for hours for a reaction, and it was thought to expedite matters by raising the temperature. I have shown by my diphenylamine test that the reaction actually takes place in a very short time at lower temperatures, and even some good powders in the market would, if exposed at 180° F., scarcely stand 10 minutes. It will not be doubted that the temperature of 70° C. is one that is not likely to occur under ordinary circumstances of storage and use.

The sensibility of my reaction is a very marked one; the blue mark on the test paper appears within a few seconds, whilst with iodide paper it takes sometimes two minutes to have a brown line well defined, and I know how even careful operators have often disputes as to whether there was a brown line already or not. At night the blue mark is not so well visible as at daytime, but still sufficiently clear, so that it cannot be missed. It is best to look at the paper with the light shining on to it, and not to look through the paper. In cases of doubt a screen of filter paper behind the test tube will make the blue more visible. The best light for such observations is the incandescent gas light, for reasons that will be readily understood; with electric or ordinary gas light a screen of thin light blue paper will prove to be of advantage.

I now append here a long series of heat tests made at 80° C. with almost every smokeless powder that I could get hold of. I wish to state distinctly that this table is not made for advertising a particular explosive, nor can an inference to the general keeping qualities of an explosive be drawn from such isolated experiments. My tests simply show the behaviour to the heat test of a particular sample of powder that I obtained in the open market, and were chiefly done with a view to compare the relative value of the iodide heat test and my diphenylamine test.

#### HEAT TESTS OF VARIOUS SMOKELESS POWDERS.

Temperature, 80° C. (176° F.); Quantity of Powder, 1·500 grms.

I = Iodide paper; G = Guttman's diphenylamine paper.

Name of Powder.	Remarks.	Composition.	Time in Minutes.	
			I.	G.
Gun-cotton .....	From Waltham Abbey .....		9	8½
Schultze .....	Small white grains .....	Wood-nitrocellulose, and saltpetre .....	16	14

It will be seen clearly from the above table that the addition of castor oil, acetic ether, acetone, camphor, vaseline, &c. make the iodide heat test quite impossible, whereas perfectly reliable results are obtained with my diphenylamine test. I have repeatedly made a number of diphenylamine tests with the same batch of powder at very carefully regulated temperatures, and always found the test to coincide very well. This led me to investigate whether a relation could be found between the temperature to which a sample is exposed in the heat test and the time within which the diphenylamine reaction shows itself. I used for my experiments to this effect guncotton from Waltham

Abbey, since in this no other constituent could influence the heat test, and checked them by several smokeless powders. The following diagram has been made from actual well coinciding experiments, and you will see from the curves that the relation between the temperature and the time is one that can be expressed for differences of minutes in steps of degrees centigrade in a geometric progression of the value:—

$$k + m, k + 2m, k + 4m, k + 8m, k + 16m, \dots$$

$k$  being a constant due to the delay in transmitting the heat through the explosive and in starting the decomposition.

I believe this geometric progression to hold good for all nitro-compound explosives, and at some future time intend to lay before you diagrams of a large number of explosives.

Meanwhile I think it will be useful to those wishing to construct similar curves, if I give them simple formulae by which they can do so. The formulae are the result of

careful calculations, and I do not think it necessary to state at length how they were arrived at, as their correctness can be easily checked.

Let—

$a, b$  be the times in minutes found by experiment.

$\frac{z}{a}$  the relation between any two real times in the geometrical progression,

$d = b - a$  = difference between the times found by experiment.

$m_1, m_2, m_3, \dots, m_n$  the real times for each degree without the constant.

$k$  a constant for the transmission of heat and starting the decomposition.

$n$  the number of degrees centigrade between one determination and the other.

$f$  the factor of the geometrical progression;

then we have—

$$f = \sqrt[n-1]{\frac{z}{a}} = 1.1487$$

$$m_1 = \frac{d}{f^n - 1}$$

$$a - m_1 = k$$

$$a - k = m_1$$

$$m_1 f = m_2$$

$$m_1 f^2 = m_3$$

$$m_1 f^3 = m_4$$

$$m_1 f^4 = m_5$$

and so forth;

$$m_1 f^{n-1} = m_n$$

The powers of  $f$  can be found for the practical variations of temperature from the following table:—

$f = 1.1487$	$f^{15} = 8.00$	$f^{29} = 55.72$
$f^2 = 1.32$	$f^{16} = 9.19$	$f^{30} = 64.00$
$f^3 = 1.52$	$f^{17} = 10.56$	$f^{31} = 73.52$
$f^4 = 1.74$	$f^{18} = 12.13$	$f^{32} = 84.45$
$f^5 = 2.00$	$f^{19} = 13.93$	$f^{33} = 97.01$
$f^6 = 2.30$	$f^{20} = 16.00$	$f^{34} = 111.43$
$f^7 = 2.64$	$f^{21} = 18.38$	$f^{35} = 128.00$
$f^8 = 3.03$	$f^{22} = 21.11$	$f^{36} = 147.03$
$f^9 = 3.48$	$f^{23} = 24.25$	$f^{37} = 168.90$
$f^{10} = 4.00$	$f^{24} = 27.86$	$f^{38} = 194.01$
$f^{11} = 4.59$	$f^{25} = 32.00$	$f^{39} = 222.86$
$f^{12} = 5.28$	$f^{26} = 36.76$	$f^{40} = 256.00$
$f^{13} = 6.06$	$f^{27} = 42.22$	
$f^{14} = 6.96$	$f^{28} = 48.50$	

Take as an example the guncotton curve. Let us say we found by experiment for  $80^\circ 9$  min., and for  $70^\circ 21$  min. We have then—

$$m_1 = \frac{21 - 9}{1.1487^{10} - 1} = \frac{12}{4 - 1} = 4.$$

$$k = 9 - 4 = 5.$$

Temperatures.	Duration in Minutes.	
	Real.	Apparent.
$80^\circ = \frac{12}{4-1}$		4.00 9.00
$79.4 \times 1.1487 = 4 \times 1.15$	4.60	9.60
$78.8 \times 1.1487^2 = 4 \times 1.32$	5.28	10.28
$77.4 \times 1.1487^3 = 4 \times 1.52$	6.08	11.08
$76.4 \times 1.1487^4 = 4 \times 1.74$	6.96	11.96
$75.0 \times 1.1487^5 = 4 \times 2.00$	8.00	13.00
$74.4 \times 1.1487^6 = 4 \times 2.30$	9.20	14.20
$73.0 \times 1.1487^7 = 4 \times 2.64$	10.56	15.56
$72.0 \times 1.1487^8 = 4 \times 3.03$	12.12	17.12
$71.4 \times 1.1487^9 = 4 \times 3.48$	13.92	18.92
$70.4 \times 1.1487^{10} = 4 \times 4.00$	16.00	21.00

If we compare the curves on the diagram, we find that guncotton has a low constant and a high factor of progression, whilst sporting ball-tite has a high constant and a very low factor. A high constant means that it takes a long time to start decomposition, a high factor that the explosive decomposes very slowly. The best explosive will, of course, be one that has both a high constant and a high factor.

It seems to me that it will scarcely be sufficient to say that an explosive must stand a certain number of minutes at a particular temperature in order to pronounce it as one that possesses reasonable safety. I can quite conceive a case where an explosive has a constant approaching 0, and yet the decomposition in increased temperatures may take wide intervals of time. On the other hand, you may have to wait rather a long time to start decomposition, but once started it may develop rapidly.

Considering that, as shown before, it takes  $8\frac{1}{2}$  minutes to heat the contents of a test tube to  $70^\circ$  C., it may surprise that the constant of some powders on the diagram is 5 minutes, and that of guncotton 3 minutes only, but this is due to the fact that with them decomposition starts at a lower temperature than  $80^\circ$  C. The heat test value of an explosive will, therefore, be the inferior the more its constant is below the time required for obtaining equilibrium between the outer and inner temperature of the test tube, and it will be advisable to fix a minimum limit for the constant, say 5 minutes.

I do not think that with my diphenylamine test all the objections are overcome which have been raised from time to time against the value of the heat test as such. Those well acquainted with such tests know that widely different results are sometimes obtained under the same conditions; that frequently no reaction at all is shown on the test paper, or one that does not give the required depth of tint even after hours of heating. The same will occur with my diphenylamine test; and the reasons for these vagaries of the heat test are difficult to find. I believe they are partly due to the physical state of the explosive, but in a good many cases the treatment of the explosive during manufacture will account for very large differences. The heat test will always be an empirical one to a certain extent, but the beneficial effect obtained by it so far has proved that it is a necessity.

#### DISCUSSION.

Mr. W. F. REID considered the paper of even greater importance than it might appear at first sight, since the test which it dealt with was one which, as a condition of the license under which they work, affected all the manufacturers of explosives in this country. There could be no doubt that the present heat test of explosives was most erratic in its behaviour, and had in consequence engaged the attention of experts for many years past. Mr. Guttman had therefore rendered great service in discovering the reasons of its unreliability. It would, he thought, have been better, in discussing the ingredients which gave rise to the irregularities complained of, to classify them into volatile and non-volatile bodies, seeing they possessed properties of very different character. While he agreed with the author's remarks as to the irregularities of the heat test, he could not quite accept his explanation of the causes. In making experiments on the flashing points of explosives he had devised an apparatus which consisted of a bath of mercury in a porcelain vessel, and capable of being completely covered in. Using this, he found that the flashing point of explosives rose considerably, especially that of guncotton; a sample of soluble guncotton heated in the air-bath in the ordinary way flashed at  $125^\circ$  C., but in the mercury bath at  $212^\circ$  C. Another sample, when mixed with castor oil partially nitrated flashed in the air-bath at  $145^\circ$  C., but in his apparatus at  $205^\circ$  C. Further experiment revealed that the castor oil was itself nitrated by nitrogen peroxide and nitrous acid. He therefore concluded that in all cases where castor oil, or other drying oil of similar composition, was mixed with the explosive, it would absorb nitric peroxide, but in the case of acetone there might be a different action. With regard to the presence of a solvent in a powder, his own experience corroborated Mr. Guttman's. He had found solvent present in E.C. powder 15 years old. With regard to the volatilisation of the castor oil, he thought that was accounted for by the presence of water, from which the oil was never entirely free. Glycerin would also sometimes contain oxidation products of linseed oil, if the two bodies had been at any time in contact. He hoped that Mr. Guttman's new test would be of general utility.

Mr. BERTHAM BLOUNT, referring to the statement that alkalis have a direct tendency to decompose nitric compounds, said he would like to see the equation showing how that came about. He heartily congratulated the author on the prescience which had led to the discovery that particles of lead sulphate in the washing apparatus carried up so much nitrous matter as to impair the quality of the nitroglycerin. He would also be glad to be informed—as the author inferred that neither the chemical composition nor the physical condition of the nitrocellulose was an index to it—how one could discern the best quality of nitrocellulose to be used. Could this knowledge be gained only by direct experiment, or could the author give them any further information as to the cause of the phenomenon referred to? Another interesting point arose out of the author's statement that "acetic acid has a marked reaction of potassium iodide." Save that it might tend to liberate hydriodic acid, he thought that acetic acid would be unlikely to affect potassium iodide; certainly he should not expect it to liberate iodine. If this was so, he did not see how the test could be more sensitive when acetic acid was there. He quite agreed with Mr. Reid's opinion that the loss of weight observed in the case of castor oil was in all probability due to the expulsion of water, and not to any loss of oily matter. Further, supposing that Mr. Guttmann's test were adopted, was it not a fact that the higher oxides of nitrogen were absorbed by oils both of the drying and non-drying classes, and would it not therefore follow that any oxide of nitrogen evolved would not only have its action on the paper smothered, but would be stopped at the very source by the oil present in the explosive? Considering what happened in the claudin reaction, it was at least possible that the higher oxides of nitrogen might never get away at all. The new test appeared to him to be a very happy idea, and if it led to the substitution of a method depending on something other than the liberation of iodine, the author's action was amply justified.

Mr. P. G. SANFORD observed that his own experience with one of the powders shown on the board did not agree with the author's, who gave 13 minutes as the time for the test reaction, both when using the old iodine test and with his own heat test. It was well known that this powder was gelatinised with acetone; he would like to ask Mr. Guttmann how he explained this.

Mr. G. TRENCH bore witness to the generally satisfactory results obtained by the heat test. The failures of cargoes sent to Australia to pass the test there were due rather to the dirty condition of the holds of the ships employed than to the character of the explosives themselves. He also hoped that some arrangement might be made whereby manufacturers could be supplied with test papers from the Home Office, so that they might work with the same papers as those with which the official test was to be made. At present manufacturers were making their own, and he had found some considerable time-differences between papers, all of which he was assured were recently made. If they were supplied with a new set of test papers at the beginning of each month, it would be a most satisfactory arrangement, and for his part he would be most willing to pay for the convenience.

Mr. W. MACNAB, while admitting that the results of the heat tests were sometimes erratic was surprised that the author had made out so bad a case against iodide of starch paper, especially with respect to the testing of Maxim powder. So far as his experience with castor oil and other "suitable oils" had gone the difficulty had not been to get a reaction but that the reaction was got only too readily. As a rule, however, the failures were due to the unsatisfactory character of the nitro-cottons and the nitro-glycerin used. He knew, however, that with castor oil a good powder could be made which would easily stand the heat test for from 15 to 30 minutes. These facts proved that oil could not always have the tremendous masking effect ascribed to it by Mr. Guttmann. He considered the diphenylamine test well worth further study, though the old test was by no means so unsatisfactory as the author considered it.

Mr. R. W. S. GRIFFITH, as a manufacturer, had a deep interest in the question before the meeting. He had used the heat test for 25 years, and quite agreed with the

author's statement that it was sometimes apparently erratic. At the same time, those who used it daily, became accustomed to its behaviour, as was the case in his own laboratory, and having that knowledge were able to so use the test as to obtain perfectly reliable results. He quite agreed with the views expressed by Mr. Guttmann, as to the necessity for insisting on great care and purity in the materials used in the manufacture of nitro compounds. In his own manufacture he had been compelled to bar the employment of alkalis and lead. The use of the latter body had been the cause of a serious accident at his own works 18 years ago. Experience also showed that in the preparation of wood pulp, it was essential to avoid any charring during the drying process. He mentioned these facts in confirmation of the statements made by the author. With regard to the shipments to Australia, he agreed with Mr. Trench that the failures were due rather to the condition while in the ships than to the climate, for he had known powder to be sent out and to be brought back again without being landed, and received back the worse for the journey. He regarded the proposed test as a valuable auxiliary to be used in conjunction with the older method. There were some points in the subject extremely difficult to understand; for example, looking through the figures given by the author, and knowing the composition of the powders concerned, he could not see that the law laid down by Mr. Guttmann as to the presence of "hiding" materials producing differences of time was in force throughout the whole of the tests. In considering this question, the physical condition of the material at the time the test was applied should be carefully borne in mind, and that was a point which he hoped the authorities would deal with in a more satisfactory manner than at present.

Dr. A. DUPRE, F.R.S., said that, as Chemical Adviser to the Explosives Department of the Home Office, and responsible for the application of the heat test to all explosives manufactured in or imported into this country, it would be understood that he could not criticise the paper fully at that moment, as any remarks from him might hamper future action by the authorities. He could assure the author, however, that he would give the proposed process his best consideration, and if he found it an improvement on the old test would be happy to recommend it to the Home Office, the authorities at which were always ready to receive and fully consider complaints or suggestions in the most courteous manner. Having said this he would make a few general remarks. He could not admit that the iodine test was as bad as Mr. Guttmann made out, but, naturally, an inventor was enamoured of his own process and could hardly be expected to be thoroughly impartial. Many complaints had been made about the heat test and he had often investigated them, but they generally turned out to be due not to the test itself but to the method of applying it. To take the case of maxinite and cordite, was it not possible that the difference in those cases was due to the fact that the powders contained nitroglycerin, which was volatilised and decomposed by the sulphuric acid on the test paper? He had never known cordite to stand 120 minutes, rarely for much more than 30 minutes, but there were many points which might account for the difference, for instance, with a leaky stopper the test might be protracted for hours. Again, if the sample was too moist the margin between the dry and the moist part of the paper would shift downwards and there would be no test got at all. The explosive must be of the proper degree of dryness so that the dividing line did not move perceptibly. As regards the time necessary to heat the sample in the test tube, he thought that Mr. Guttmann had over-estimated its influence, the time of the test being governed not so much by the total quantity of explosive used as by the amount of the surface exposed to heating. One might go as low as three grains of gun-cotton, and if it were properly disposed might get the test as fast as with 20 grains. The quantity was given mainly to give sufficient heating surface. If vaseline had the influence attributed to it by the author one would imagine cordite, which had been heated for some time in an open vessel, would give the heat test more readily than cordite heated in a closed vessel, but the reverse was the case. He thought the author was mistaken, too, as regards the action of acetic acid. If that

body were added to good guncotton it would affect it but slightly at first, but if kept for some weeks at 100 the test would be materially lowered. With regard to the shipments to Australia, to which many references had been made, he would point out that the cargoes condemned were as often blasting gelatin as gelatin dynamite, the latter only containing wood meal. He had found some years ago, and mentioned the fact in his annual report, that gelatin dynamite, Nos. 1 and 2 (gelignite was not an officially recognised name) stood the heat test worse than blasting gelatin, and he then thought this due to the wood meal; now, however, it was just the reverse and the latter stood the test worse. This might be due to the fact that the one could be made at an ordinary temperature, while the other required a slightly elevated temperature, therefore it was probably not the wood meal which did the chief damage. Another point not referred to was the very general opinion held among manufacturers and chemists that it was the acid which caused bad heat tests. That he considered a great mistake, as a rule acidity could be readily washed out. It was some compound or compounds which decomposed at a lower temperature than the explosive proper, which were mainly of volatile character, and difficult to get rid of by washing, which caused the difficulty. The difficulty in the case of nitroglycerin was to get the happy medium. If one used too much air the mixture was churned up too much and separated with difficulty, but with sufficient aeration nitroglycerin could be made to stand any reasonable test. All explosives were the better for aeration, and it was of no use to try to get rid of the acid only. No one was more sensible of the shortcomings of the heat test than himself; nevertheless, he was sure that, if carefully applied, it did no injustice. In the process of manufacture the explosive could be followed step by step, and as it was more washed or aerated the test would rise. An explosive which would stand the heat test well was sure to be a stable body in our climate at least, though not, perhaps, in tropical climates; but it did not follow that if it did not stand the heat test that it was necessarily a bad one, but there being no difficulty in getting an explosive which would stand the heat test it was well to insist upon it. Undoubtedly the test was, in a great measure, influenced by the physical condition of the bodies tested, and it was therefore extremely difficult to arrange tests which, while safeguarding the public, would not unduly hamper the manufacturers. This they had endeavoured to do by laying down rules as to the degree of sub-division and using different temperatures. They had also carefully regulated the amount of test tube which should be above the water, and the distance at which the margin between the dry and the wet paper should be above the heated surface. That was an important point; for if the paper were put into too warm a part of the tube the test was necessarily prolonged. It should be near enough to be readily affected, but not too near. In the early days personal equation often influenced the test, or again, it was a question of light, as on a dull day the action would not be defined with sufficient sharpness. To overcome that difficulty they had instituted a standard tint line. The standard paper was placed in a tube side by side with the tube containing the sample to be tested, and the operator had then before him a paper without the line and one with the brown line. That method eliminated the personal equation and enabled the test to be made in any light sufficient for seeing the standard line. Lastly, most of the difficulties of the test arose when dealing with good explosives giving a heat test of, say, 20 minutes and upwards, whereas when dealing with bad explosives difficulties were rarely experienced and different observers generally agreed. The former was of but little importance, for whether a powder stood for half an hour or an hour was, from his point of view, immaterial, but it was of importance that bad explosives should be discovered.

Mr. OTTO HELMER observed that possibly the two tests were not on the same footing. The iodide test was used generally to detect nitrous compounds, the diphenylamine test to detect nitrites or nitrates, the latter of which would not be detected at all by the iodide test. It was obvious, therefore, that in many cases the tests could not give the same results, because they did not apply to the same thing.

Dr. S. RIDEAL thought that the alleged absorption of nitrous compounds by lead sulphate might have some importance in connection with accumulator work, for if nitrous compounds were so absorbed it would influence the behaviour of accumulator plates afterwards. He agreed with Mr. Helmer's remarks as to a *nitrate* test giving different results to one for *nitrites*; and it also seemed to him that the test effected a narrowing of the variations, whereas what was wanted was a test which increased the differences. He feared, therefore, that diphenylamine was too delicate a reagent for use in this connection, as it had been found in the case of milk examination. It would be recollected that its use was suggested for detecting the adulteration of milk by water, but it was afterwards found that milk to which no water had been added would, under some conditions, give the diphenylamine reaction.

Mr. F. W. JONES writes as follows:—Does acetone "hide" the heat test? Mr. Guttman's experiments say decidedly "No." Many of the explosives of which he gave comparative results, contain acetone, some even as much as 2 or 3 per cent. In some of those I have in mind there was an actual increase of time with the diphenylamine paper, whereas Cooppl's which could not contain more than the merest trace of its hardening solvent (I question if it is acetone), showed a very great difference in the two tests. The diphenylamine paper gave generally tests of shorter duration, and one would naturally expect where the iodide paper gave the longest time the difference would be the greatest, which explains many of the results.

The heat test, we must all admit, is an empirical one; furthermore, it is a washing test, and while it is sufficiently reliable for nitrocellulose and nitroglycerin in the raw condition, it is quite unreliable for them when made up into their various forms. Mr. Guttman explains this in the case of gunpowders by the action of one of the minor ingredients in these explosives. I maintain, on the other hand, that in the main this difference is accounted for by the change in the physical nature of the base, and what Mr. Guttman has told us has not changed my views. I believe that until these products are brought to practically the same condition as the base, and that the same test is applied, reliable and comparable results will never be obtained and injustice may be done, and remember we only want to find if the ingredients of these products were properly washed. The Home Office heat tests for nitrocellulose and nitroglycerin are well known, the materials are in certain physical conditions and any alteration which increases or decreases the exposed surfaces affect in an inverse ratio the time they stand any prescribed test. Thus, if the 20 grains of nitrocellulose were gelatinised and formed into 1 grain the time would be the longest, and between this and impalpable dust the time decreases step by step. It is therefore obvious that one particular heat test will never apply to all gunpowders. The grinding, until they pass a fairly large meshed sieve, is not sufficient, because the "chips" from grains of 0.100 in. thickness will be very different from "chips" stopped by the same sieve from grains of 0.010 in. thickness.

I have proposed that gelatinised guncotton preparations be ground in a mill, and only the dust that passes a sieve of 60 meshes to the inch be accepted for the test and that the test be exactly the same as that applied to guncotton. I have satisfied myself by innumerable experiments that such finely divided gelatinised nitrocellulose stands the heat test practically the same as the nitrocellulose from which the powder was made. I believe also for those gelatinised preparations that contain fairly large percentages of nitroglycerin but which are not plastic, the above test would be quite sufficient, but for gunpowders, like cordite, which when rubbed through a 60 mesh sieve are quite plastic this treatment increases the time, because, as a matter of fact, the exposed surfaces are reduced owing to the oily nature of the mass, and here, possibly, the blasting gelatin heat test would be the correct one. Except in the case of cordite it is entirely contrary to my experience with gelatinised compositions to find as Mr. Guttman states that the coarsely-ground powders give worse tests than the finer. Furthermore, it is contrary to my experience to find that dry heat lessens the heat test; I have always found the opposite to be the case. From time to time we

have had occasion to keep loaded cartridges at temperatures varying from 120° F. to 170° F., and although the powder is practically in a hermetically closed case, yet the heat test improves as the time of heating is prolonged. In one instance cartridges were kept at 160° F. for 72 hours without intermission; and whereas the powder stood 26 and 23 minutes before heating, it stood 63 and 120 minutes after heating; many experiments of the same nature gave similar results. The difference is more rapid and more pronounced if the powder so heated is exposed to the air during heating. Although Mr. Guttman's test does not seem so different from the official test as to necessitate any change, yet as a corroborative one it will be of great service to explosive manufacturers.

Allow me to correct one statement in the paper as to the composition of the various rifleites, and S.S., S.R., and S.V., which are said to be composed of nitrocellulose and nitrobenzene. As the manufacturer of these products I may state that nitrobenzene does not enter into the composition of any of these explosives.

Mr. O. GUTTMANN, in reply, said he had fully expected that his paper would draw upon himself and the proposed test some hostile criticism. Such matters were so controversial in their nature, and required so many experiments to appreciate their value, that he could not expect any other treatment. He did not claim that the proposed test was a perfect one, and could quite imagine that a better one would be found; but, so far, diphenylamine had proved itself superior to all others. Although Dr. Dupré suggested that his opinion was due to the natural enthusiasm of a discoverer, Dr. Dupré knew well that nobody was more critical than himself, and he was not likely, therefore, to be over-enthusiastic. Mr. Reid had asked that the bodies concerned should be divided into volatile and non-volatile constituents, and he, in common with another speaker, stated that castor oil and other oils would absorb nitric peroxide and not show it. He could only say that if those gentlemen would take any pure explosive, say gun-cotton or nitroglycerin, and sprinkle finely-divided castor oil upon it, they would find the heat test to go up. He was convinced that that fact was not due to the absorption through the oil itself. Mr. Blount had called attention to the elaidine reaction, and thought this showed conclusively that nitrogen peroxide was absorbed by the oil itself. He could only say that he had made many experiments, and did not get the elaidine reaction sufficiently quickly to prove that that was the case. To produce such a reaction took hours, and therefore the oil could not be the cause of the disappearance of iodine. Mr. Reid and Mr. Blount also held that the loss in weight of the castor oil was due to the volatilisation of water. In reply, he would point to the tests given in his paper, in which the castor oil was exposed for 72 hours, by which time the gun-cotton and the oil as well had lost all the water; yet after all that drying, the castor oil would hide the heat test, and, in fact, would do so at any time. Mr. Blount asked for an explanation why alkalis decomposed nitro compounds. He would be happy to give that information, though, probably Mr. Blount was well aware that Colonel Hess, in 1871, showed that with caustic alkalis reaction took place most violently. He also asked why the percentage of nitrogen and the degree of solubility were not sufficient to show the suitability of collodion cotton for making blasting gelatin. The reason was that the physical state of the jelly had to be considered, and the capacity of the collodion cotton for retaining the nitroglycerin in the form of a jelly. Mr. Sutford said he had found that cannonite stood the test for two or three hours, and could not understand how he (the author) had got only 13 minutes. A similar opinion was given by Dr. Dupré. He would point out, however, that it followed from his paper that the age of the powder and the state of division were important factors: with an old powder in a fine state of division and very dry it would be found that the solvent had gone, and so there was nothing to show a difference. Mr. Trench and others had spoken about explosives going to Australia. Seeing that cargoes worth thousands of pounds were destroyed every year because they failed to pass this test in Australia, it was obvious that the matter was a very serious one. All he could say was that a blasting gelatin that did not contain wood pulp would stand the heat test better than gelignite, which did contain it. It must

be remembered that blasting gelatin is a tough substance from which nothing can come out of the interior; any decomposition would, therefore, show itself on the outer surface only in the first instance. It was different with dynamite No. 2, some of which was perfectly gelatinous, some very porous. He was not speaking only of explosives manufactured in England; such products were made everywhere; but the same tests were used for explosives wherever and however made; therefore, when he spoke of gelatin dynamite being not in a perfect jelly, he was not necessarily speaking only of explosives made in this country. Nitric peroxide was developed at low temperatures—at 45° C. already,—and if the dynamite were left for some days it would be found that at 50° C. it was gone—it would openly decompose. When, therefore, it was shipped to Australia in badly ventilated vessels, the heat would rise. Moreover, it had been found that explosives stored in hot places, such as Aden, blew up voluntarily, so that it was not only the filthy condition of ships that was to blame. Mr. Maenab stated that he got the reaction too soon. He thought the differences between the tests must be due to the imperfect character of the nitro-cotton. He knew Mr. Maenab's reputation for great accuracy, and therefore accepted his statement, but it did not agree with his own experience. Where erratic behaviour was the order of the day, experiments must differ in the hands of different men. He was glad that such an experienced man as Mr. Griffith could confirm, from his own knowledge, most of the statements he (the author) had put forth. And now he came to the most important contribution to the discussion, viz., Dr. Dupré's remarks. It was difficult for him to reply to Dr. Dupré, because there was no man of greater experience than he on this subject. Ever since he had had to do with explosives—for nearly 25 years—he had been a disciple of Dr. Dupré, and he could quite understand that, as the father of the iodide heat test, he was loth to give way to a newer method. Still he was sure that Dr. Dupré would be the first to put aside a bad test if he was dissatisfied, and his object was to convince him that the iodide heat test was really not reliable. Dr. Dupré said he had never come across a complaint due to the heat test itself. That might be the case, but he must certainly have had many well-founded complaints which were based on it. Both Dr. Dupré and Mr. Blount remarked about the action of acetic acid. No doubt acetic acid does not combine with iodine, but it also cannot be said to affect nitro compounds. The fact is not yet quite cleared up, but it exists; and the acetic acid does not require days to show itself, but, shows immediately, as proved in his paper. Let anyone take nitroglycerin of undoubted excellence, and add to it one drop of acetic acid, and down would go the heat test. Then Dr. Dupré said that he had never seen cordite or Maxim powder stand for 120 minutes. He could only reply that he had, and for longer; and the gentleman who had made the test with him was in the room. It was clear, therefore, that the test was absolutely erratic, and the differences in the tests were due to nothing but the fact that one powder was older and more finely ground than another. He was confident that Dr. Dupré would find that he was right, and that the iodide heat test was unreliable. With regard to Mr. Jones's remarks, he was surprised that Mr. Jones did not take the trouble to make a simple experiment, which would have satisfied him, in less time than it took to write his question, that acetone did hide the heat test very much indeed. Both he and Mr. Blount referred to certain powders in the table made with acetone, and which yet gave equal results with the two tests. He could only say that he had had these powders in his possession for 18 months, and they were probably quite that age when he got them, so there might have been no acetone left in them. At the same time it would be interesting to know how Mr. Jones determined the percentage of acetone, as there might be an error in this. The physical state of the explosive had not nearly so great an influence as Mr. Jones attributed to it. That powder in cartridges should give better heat tests after prolonged heating was contrary to experience. He knew that the powders made by Mr. Jones did not contain nitrobenzene, but, in view of an action pending in the courts, he thought it was near enough.

### SESSION 1896-97.

Meeting held on Friday, March 5th, 1897.

MR. GEORGE E. DAVIS IN THE CHAIR.

## ON PARANITRANILINE RED.

BY A. LIEBMANN, PH.D.

PREVIOUS publications have always been directed to the following points, viz., purity of the paranitraniline, the manner of its diazotation, and the preservation from decomposition of the  $\beta$ -naphthol on the fibre. I now propose to show what influence the presence of  $\alpha$ -naphthol in the  $\beta$ -compound has on the brightness of the red, and to prove experimentally the limits within which  $\alpha$ -naphthol may be present in  $\beta$ -naphthol if at all.

The important problem which confronted me at first in regard to the  $\beta$ -naphthols was as to whether and in what way a pure compound could be obtained from the article of commerce. Perhaps it will be best now to shortly state the results of my experiments, and to show by what line of investigations they have been obtained. In the first instance, I have prepared, as far as I know, by a new method, chemically pure  $\beta$ -naphthol from the commercial product. Secondly, I found new analytical tests, qualitative and quantitative, to prove the presence of  $\alpha$ -naphthol in  $\beta$ -naphthol, even if present only to the extent of 0.01 per cent. Thirdly, I examined a series of commercial  $\beta$ -naphthols for this impurity. Fourthly, I studied the injurious influence of  $\alpha$ -compound if present in the  $\beta$ -naphthol on the final colour; and, finally, I made some experiments to determine by which analytical methods the presence of meta- and orthonitraniline could be detected in paranitraniline. I have not finished my experiments with orthonitraniline, and I will leave this matter to further examination.

The preparation of pure  $\beta$ -naphthol was based on the following observations:—

I had studied the solubility of commercial  $\beta$ - and  $\alpha$ -naphthol in toluene. On dissolving a weighed quantity of  $\beta$ -naphthol in a weighed quantity of toluene, and on cooling the solution thus obtained to about 7° to 8° C. for two hours, the whole of the liquid appeared to solidify to one mass of fine crystals, which were separated by filtration from the toluene. The filtered solution was then evaporated on the water-bath, and the solubility at this temperature of  $\beta$ -naphthol in toluene was found to be 1 per cent. A corresponding experiment, carried out with  $\alpha$ -naphthol, proved its solubility to be 3.55 per cent.; but no notice is taken in this experiment of a certain loss of naphthol which is always sustained from evaporation of its toluene solution. A further difference between the two compounds as to their solubility in toluene, is that on addition of petroleum ether to the toluene solution,  $\beta$ -naphthol seems to be completely precipitated whilst the  $\alpha$ -naphthol remains in solution on the addition of the petroleum ether to the toluene solution.

The purification of the commercial  $\beta$ -naphthol was now an easy matter—50 grms. of commercial  $\beta$ -naphthol were dissolved in 500 c.c. of toluene; the solution was allowed to cool; the precipitate was separated by means of a suction filter, washed with 100 c.c. of a mixture of equal quantities of toluene and petroleum ether; and finally washed with 50 c.c. of petroleum ether—40 grms. of  $\beta$ -naphthol were obtained, melting at 122° to 124° C. With this quantity of  $\beta$ -naphthol, the operation was repeated as before described, and the melting point of the repeatedly purified product was found to be now at from 122° to 123° C. A sample of this naphthol was recrystallised several times from hot water, with the addition of animal charcoal, but the melting point did not alter but remained at 122° to 123° C. This seemed to me not to indicate yet a completely chemically pure product, and another purification was resorted to; 5 grms. of the  $\beta$ -naphthol, which was obtained in the before described manner by purification with toluene and petroleum ether, were suspended in 50 c.c. of water, and were then distilled with steam. From the distillate it crystallised in beautiful, white glittering flakes, which were filtered, dried, and, repeatedly recrystallised from boiling water. Its melting

point was now  $122^{\circ}$  to  $122.5^{\circ}$  C. All the melting points were taken with a normal thermometer tested by the Imperial Physical Institute at Berlin.

To test the purity of the product thus obtained, I was thrown on my own resources, or rather I really arrived at the subject for which this investigation was undertaken. There is in literature no test described to prove the presence of  $\alpha$ -naphthol in  $\beta$ -naphthol. I owe, however, to the kindness of Mr. Levinstein a description of the test now in vogue amongst industrial concerns interested in this product. It is as follows:—Dissolve, in a dry 200-c.c. flask, 2 grms. of  $\beta$ -naphthol in 10 c.c. alcohol, and add 5 c.c. iron perchloride solution (50 grms. iron perchloride to 1 litre). After two minutes standing, add 40 c.c. water, when a precipitate is formed, shake this well up. If the sample is free from  $\alpha$ -naphthol, the precipitate is white (with a greenish shade in the beginning) and must remain white. If the sample contains  $\alpha$ -naphthol, the precipitate is at first slightly coloured, and, on standing, turns violet, till blue, according to the quantity of  $\alpha$ -naphthol present. By this test the presence of 0.05  $\alpha$ -naphthol can easily be detected if the sample to be tested is allowed to stand a few hours. If the  $\beta$ -naphthol contain more than about 0.2 per cent. of  $\alpha$ -, the precipitate formed is at once coloured violet, which on standing becomes deeper in shade. The depth of the violet colour produced when  $\alpha$ -naphthol is present, if worked under exactly the same conditions, is proportionate to the quantity of  $\alpha$ -naphthol present in the sample, and the method can therefore be used for quantitative tests, viz., by making mixtures of pure  $\beta$ -naphthol with known quantities of  $\alpha$ -naphthol, and by comparing the shades produced with the sample to be tested.

Good as this test undoubtedly is, yet I venture to say that the new method which I am going to discuss is superior to it in every way, indicating even the presence of 0.01 per cent. of  $\alpha$ -naphthol in  $\beta$ -naphthol, and being easily adapted for quick and reliable analysis. This test is based on the property of  $\alpha$ -naphthol to combine readily and in presence of  $\beta$ -naphthol in preference to this compound with diazo-solutions, and to produce combinations with alkalis forming coloured solutions, whilst the corresponding bodies of  $\beta$ -naphthol are insoluble or nearly insoluble in alkalis. Amongst the diazo-compounds applied in this way diazo-benzene was not very successful, as the solution of the oxy-azo compounds in alkalis is not sufficiently pronounced.

A number of experiments have been carried out with this amine, but, as I said before, I soon threw diazo-benzene overboard, and turned to other diazo-compounds to achieve my purpose. Strange to say, the very compound for the benefit of which this research had been undertaken was the one which finally led me to overcome the difficulty, and yielded the most perfect results, viz., the diazo-compound of paranitraniline; and I will now at once give a description of the test, as I at last settled it, to determine the presence of  $\alpha$ -naphthol in its isomeric compound.

Weigh 0.144 gm. of the  $\beta$ -naphthol to be tested, dissolve in a graduated test-tube in 5 c.c. pure alcohol, and make up to 15 c.c. with pure toluene. Dissolve 0.14 of paranitraniline in 9 c.c. of dilute hydrochloric acid, cool outside with ice, preferably mixed with common salt and diazotise with 1 c.c. of normal nitrite of soda solution. Now allow 1 c.c. of this diazo-compound, which equals 0.014 of diazotised paranitraniline, to run into the graduated test-tube containing the naphthol solution; shake well, add some water, and separate the two layers which form by means of a small separating funnel. Shake the toluene solution with 5 c.c. of normal caustic soda, and compare the colour of the alkaline solution with the alkaline solution obtained in exactly the same manner from a  $\beta$ -naphthol containing a known quantity of  $\alpha$ -naphthol. By comparing two such solutions, the amount of  $\alpha$ -naphthol in  $\beta$ -naphthol is readily determined.

My first idea was to prepare a scale of such coloured solutions, ranging from 0.01 per cent. up to 1 per cent.; but I found that the very dilute solutions containing from 0.01—0.1 of  $\alpha$ -naphthol will decompose on being kept for some time, and therefore it is always advisable to make new tests side by side.

Of course, a great number of experiments had to be made before I determined on the method which I have before described, and I do not think that anything can be learnt from the more imperfect tests which resulted from these experiments. I should, however, like to mention one experiment which was rather surprising. I was under the impression (and I believe it is a general impression in literature) that  $\beta$ -naphthol does not combine with diazo-paranitrobenzene in a hydrochloric acid solution. I have, however, observed that if a hydrochloric acid solution of paranitrodiazobenzene be added to an alcoholic solution of pure  $\beta$ -naphthol, a yellowish-orange precipitate is at once formed. This yellowish-orange precipitate changed as soon as I attempted a purification or even on standing a few seconds or on attempted filtration, into the well-known and beautiful red paranitrobenzene-azo- $\beta$ -naphthol. This compound could only be either a hydrochloride of the latter body or a paranitrodiazohydroxynaphthalene, and I incline very strongly to take the latter view. Of such bodies there are only very few instances known, if any at all. I am informed by Prof. Meldola that he has described or made one of this class of compounds by acting with paranitrodiazobenzene or orthobromo- $\beta$ -naphthol.

I have examined about half-a-dozen different products, and I find that, with the exception of one of them, they all contained more or less  $\alpha$ -naphthol. The results are as follows:—One of the samples contained 0.3 per cent., another 0.1, the third 0.09, and the fourth 0.7 per cent. of it. One sample I found to be practically free from  $\alpha$ -naphthol, containing only  $\frac{1}{100}$  per cent. of it.

This investigation would not be complete unless I proved also the influence which these quantities of  $\alpha$ -naphthol in  $\beta$ -naphthol have on the final paranitraniline red. The red was produced in the manner described by A. G. Green at one of the meetings of the Society of Dyers and Colourists in Manchester with the exception that I elected to take a stronger solution of  $\beta$ -naphthol, which means that I used a solution containing about 2 per cent. of  $\beta$ -naphthol. The result showed plainly that the presence of 0.25 of  $\alpha$ -naphthol in  $\beta$ -naphthol distinctly exercises an injurious influence on the colour, and probably to an experienced eye even the quantity of 0.1 per cent. would be plainly visible.

I produced a series of dyed materials using pure  $\beta$ -naphthol and  $\beta$ -naphthols containing 0.1 per cent., 0.25, 0.5, 1, 2, 3, 4, and 5 per cent. of  $\alpha$ -naphthol. In using  $\beta$ -naphthol containing less than 0.1 per cent. of  $\alpha$ -naphthol the result was such that I could not detect any difference between the colours resulting from pure  $\beta$ -naphthol and such a product. If, however, the quantities are 1, 10 and more of  $\alpha$ -naphthol in  $\beta$ -naphthol, as I said before, the experienced eye will be able to detect the difference from the result obtained from the pure product. My attention was then directed to an examination of the commercial paranitranilines and I will here at once say that I found the commercial paranitranilines very pure products. I however succeeded in devising a method for estimating the meta-amidonitraniline in paranitraniline if 0.1 per cent. or more is contained in it. The reaction is based on the well-known fact that metanitraniline after reduction, produces metaphenylene-diamine, which, on treatment with nitrous acid, yields Bismarck brown, the dyestuff perhaps better known as Manchester brown.

As there are certain precautions to be observed in carrying out this experiment I will give a detailed description of it:—

0.25 part of paranitraniline are covered with water in a flask which is provided with a cork fitted with a glass tube and a piece of india-rubber with a slit closed at the end with a glass rod which allows gas to escape but not to enter. Some hydrochloric acid is added and some zinc dust and the flask is shaken, preferably with exclusion of light, until a colourless solution is obtained; it is then quickly filtered, and the solution is made up to 250 c.c. 0.025 parts of metanitraniline are reduced in exactly the same manner and also diluted to 250 c.c. If 10 c.c. paranitraniline solution are diluted to 50 and one or two drops of a weak solution of sodium nitrite are added, only a very slight change to a light yellow can be observed. If, however,

10 c.c. of the reduced paranitraniline solution are mixed with 0.1 c.c. of the reduced metanitraniline solution and made up into 50 c.c., a light brown coloration will be produced on the addition of one or two drops of dilute sodium nitrite solution and this coloration will be all the more intense in proportion to the quantity of reduced metanitraniline present.

I intended to devise an analytical method for estimating the presence of orthonitraniline in the commercial paranitraniline by means of the property of the orthodiamido-compounds to form combinations with phenanthrene-quinone, but unfortunately I was, whilst in the middle of these experiments, called away from Manchester and was therefore unable to finish them in a satisfactory way, but I hope on some future occasion to lay before the Society satisfactory results in respect of such compounds also.

Now to recapitulate shortly the results of my investigations: I have discovered that the presence of  $\alpha$ -naphthol in  $\beta$ -naphthol is deleterious to the production of a good paranitraniline red: I have further discovered a method which can be easily carried out for the estimation of  $\alpha$ -naphthol in  $\beta$ -naphthol, and finally, a method for the estimation of metanitraniline in paranitraniline, for which latter method however, I found that there was unfortunately no necessity as commercial paranitranilines are practically chemically pure products.

I have to mention that I have been very ably assisted, in carrying out these experiments, by Dr. Albert Liebmam, to whom I am very much obliged for the careful and assiduous attention he has devoted thereto.

## THE CAUSE OF LUMINOSITY OF HYDROCARBON FLAMES.

BY WILFRED IRWIN.

ABOUT 12 months ago I read a paper before this Section entitled "The Effect of Heat on the Illuminating Power of Coal-Gas and its relation to the Theory of Flame," in which I raised what appeared to me to be vital objections to Prof. V. B. Lewes's acetylene theory of luminosity (this Journal, 1896, 80). To this Prof. Lewes replies in a paper entitled "The Development of Light from Gas Flames," read at the late Gas Exhibition in New York, and published in the "Gas World" of Feb. 6th.

During the present century several theories relating to the luminosity of gas and hydrocarbon flames have been put forward.

I. The earliest assumed that when a hydrocarbon was burnt the oxygen of the air united with the hydrogen of the hydrocarbon, leaving solid particles of carbon at a temperature sufficiently high to account for the luminosity. This assumption was shown to be erroneous, from the fact that when hydrocarbons are exploded with oxygen, the latter always combines with the carbon first, and if there be an insufficiency of oxygen, free hydrogen always is left.

II. The theory of Frankland that luminosity is due to dense but transparent hydrocarbon vapours radiating light at a high temperature. The experiments mentioned in my last and to be alluded to presently tell against this theory.

III. That luminosity is due to the decomposition of dense hydrocarbon vapours, the carbon separating out in a solid form for an instant, and owing to the high temperature reemitting light. This theory, as stated, fails to account for the whole of the light; as I have shown that hydrogen and smoke raised to a temperature higher than that of the hydrocarbon flame emits very little light.

IV. Prof. Lewes's acetylene theory, according to which the hydrocarbons in the flame are decomposed, or in the case of  $\text{CH}_4$  condensed, to form acetylene  $\text{C}_2\text{H}_2$ , which, in its turn decomposes into C and H, the heat of decomposition raising the C liberated to a high temperature, acetylene being an endothermic body. Prof. Lewes has shown that acetylene will, when pure, decompose with evolution of light at  $800^\circ\text{C}$ , the temperature being thereby raised to  $1,000^\circ\text{C}$ ; also that when mixed with hydrogen a similar decomposition occurs, though at a higher temperature.

He has found that the gas at the top of the non-luminous part of the flame contains far more  $\text{C}_2\text{H}_2$  than

when it leaves the burner, owing to the decomposition of benzene  $\text{C}_6\text{H}_6$  and other hydrocarbons in the gas.

When Prof. Lewes first laid this theory before the chemical world I must say that it appeared to me the most rational explanation of the cause of luminosity; for all experiments which I have made point to the fact—Frankland's opinion notwithstanding—that solid particles of carbon are necessary to the production of a bright luminous hydrocarbon flame. But I have shown that smoke and hydrogen heated to  $1,400^\circ\text{C}$ , a temperature above that at which luminosity commences, emits very little light compared with that from a gas flame.

I have also shown that in a 20-candle gas flame burning for 1 hour, not more than 2.4 grms. of carbon has been actually engaged in emitting light during the whole time. Certainly at any given period not more than 0.0001 grm. of carbon is so employed.

Now this extraordinary brilliancy is altogether out of comparison with anything obtainable from mere heated smoke, and the acetylene theory has the merit of offering another explanation for it. But there are several objections to it alluded to in my last paper which Prof. Lewes does not answer to my satisfaction.

I. I have shown that—

Benzene,  $\text{C}_6\text{H}_6$ , is a better enricher than acetylene,  $\text{C}_2\text{H}_2$ .

Xylene,  $\text{C}_6\text{H}_4(\text{CH}_3)_2$ , is a better enricher than benzene,  $\text{C}_6\text{H}_6$ .

Naphthalene,  $\text{C}_{10}\text{H}_8$ , is a better enricher than Xylene,  $\text{C}_6\text{H}_4(\text{CH}_3)_2$ .

Given that the acetylene theory is the correct one, one would naturally suppose that the above comparisons would be reversed, but Prof. Lewes says that the reason benzene is a better enricher than acetylene is because less of it is unchanged on its way up the flame, and that decomposition takes place just before the resultant acetylene is required for splitting up into its elements with the emission of light. On the other hand, he says acetylene polymerises to benzene, &c., but he does not show what harm that can do when such bodies are so easily split up again into acetylene just at the point they are required to do so.

Were it not that he assumes that benzene has changed definitely into acetylene to such an extent as to be estimated by analysis, before the decomposition of the latter, I should suppose, assuming his theory to be correct, its greater enriching power to be due to its power of yielding 3 mols. of acetylene, all close to one another, and therefore more concentrated and consequently able to decompose at a lower temperature than would otherwise have been the case.

If acetylene polymerises so readily, as Prof. Lewes assumes, and does not return to its original form, how does he know that it is really acetylene that he is dealing with when he sees it decompose in glass tubes heated to  $800^\circ\text{C}$ ?

You may remember where I showed that in passing gas through a heated tube, the illuminating power disappeared when the temperature reached  $850^\circ\text{C}$  to  $900^\circ\text{C}$ , but without production of smoke, and that as the temperature increased to  $1,400^\circ\text{C}$ , smoke was formed. But that, on looking down the tube, neither at  $850^\circ\text{C}$  nor at the higher temperature of more complete decomposition of the gas, was any glow visible.

This last observation, Prof. Lewes, in his summary of my paper, omits altogether, and charges me with misunderstanding his theory, because I make no reference to what is going on inside the tube. Prof. Lewes says that decomposition with production of luminosity is going on inside the heated tube, but this is what I could never discover; and this leads me to my second objection to his theory.

II. How is it that when passed through a heated tube, coal-gas loses its luminosity without any luminous glow in the tube being produced?

III. My third objection to his theory is that in a feebly-luminous flame, formed by burning acetylene and hydrogen, stratification occurs, as in other feebly-luminous hydrocarbon flames, showing, I think, that at least two different reactions occurring at different temperatures are taking place.

Prof. Lewes answers this by assuming that reactions take place which are very unlikely to occur, and which stultify other conclusions which he has arrived at in his experiments on the action of heat on mixtures of  $C_2H_2$  and  $H_2$ .

The following experiment, which I have lately made, will be of interest in demonstrating my own latest ideas on luminosity.

A horizontal iron tube, 1 in. in width and 4 ft. long, corked at either end, was provided. By a small pipe just passing through one of the corks, a stream of coal-gas was admitted, whilst the temperature of the middle of the tube was gradually raised, by means of a furnace, until the gas issuing from a pipe through the other cork had lost its illuminating power. This latter cork was then withdrawn, and the interior of the tube examined from that end whilst the gas was passing. All that could be seen was that the pipe was red-hot where it had been heated, and neither smoke nor glow of any kind could be detected. The temperature was now raised almost to the melting point of wrought iron, still no glow was discernible, though smoke began to form, owing to complete decomposition of the hydrocarbons.

Next, by means of a small pipe reaching the heated part of the iron tube, a jet of air was introduced, when immediately a very bright glow made its appearance round the end of the jet, which attained its greatest degree of brightness when smoke ceased to be emitted from the open end.

This experiment shows that the presence not only of heat but of air is necessary to the formation of a luminous flame, firstly, in order to decompose the molecules of benzene, &c. before they can be all changed into acetylene; secondly, to combine with the freshly-liberated carbon, to form  $CO$ , with production of light.

My theory of the cause of luminosity, then, is as follows:—

The hydrocarbons are first condensed, to form bodies such as benzene, containing in their molecules carbon atoms in combination with very few H atoms.

That in this form they are attacked by oxygen in the lower part of the luminous band of the flame, and split up, yielding  $CO$ , free C, and  $C_2H_2$ , which latter passes to above what is the non-luminous band in feebly-luminous flames, where the heat is sufficient to again condense it as aforesaid.

That the free carbon, on being liberated, combines with more oxygen, to form  $CO$ , and in this reaction emits the intense light which is characteristic of the flame.

I have shown that the carbon, to possess this light-giving power, must have been recently precipitated in the flame; and if any material time elapses between the precipitation and combination with oxygen, very little luminosity is produced.

*Meeting held on Friday, April 2nd, 1897.*

MR. GEORGE F. DAVIS IN THE CHAIR.

## ON THE ADULTERATION OF SILK BY WEIGHING.

BY SIR THOMAS WARDLE, F.C.S., F.G.S., ETC., AND J. CARTER BELL, A.R.S.M., ETC.

The history and present practice of weighting silk presents some very interesting features, both from industrial and scientific aspects. I propose to speak of the industrial weighting of silk by chemical means, as well as of the chemistry of the subject, whilst to my friend Mr. Carter Bell (who with me, since he was appointed to the honorary office of chemist to the Silk Association, has given considerable attention to it) I shall leave the analytical part, promising you that his investigations will possess much interest, both in subject-matter and methods. I have to speak of deception the most refined; unspeakable fraudulent intent;

the application of chemical science (from the modern rage for cheapness) to the opposite of economical purchasing; and a procedure and practice of adulteration now so universal in all continental silk centres as admittedly to threaten the industry with destruction, if much longer continued in its present excessive state.

If this paper can help forward the laudable effort now being made on the continent by the best manufacturers and dyers to expose the chicanery and sophistication of the excessively weighted and spurious fabrics mis-called silk, and mendaciously sold as such, its object will be attained. The treatment of my paper may be thus epitomised. 1. The history and development of silk adulteration. 2. The nature of silk and its adulterants. 3. The present state of silk weighting. 4. The simple detection of the presence of this sophistication. 5. And Mr. Carter Bell's more abstract treatment of the chemistry and analyses of silk so weighted.

### THE FIRST SINNER.

If we must begin at the beginning, we have to select what was doubtless an object-lesson to the industry in the silkworm itself, as being the first silk loader, for amongst the countless millions of silkworms hatched into the world, not one of them has appeared without the power of weighting, or as the French say "charging" its silken fibre with at least 25 per cent. of weighting matter, and this in the shape of a substance, called in England, gum, and in France, grès, the composition and nature of which I will describe farther on.

This gummy substance, called in chemistry, sericine, is seriposited on the fibre at the moment the fibre itself is seriposited, from what are erroneously termed, the spinnarets of the silkworm, in the act of forming its cocoon. As is well known, the silk is never seen in its natural beauty and lustre, until this weighting matter or sericine has been removed by boiling soap baths or by the vapour of steam.

The instinctive object of the silkworm is apparent enough, namely, by a coating of varnish to protect the delicate fibre or bave which it eriposits, from climatic and other dangers, from and during the time it passes from the larval and pupal state, and until it emerges from its cocoon envelope as an imago or moth, then to begin to perpetuate its race.

Now if we can fix upon the silkworm as the first sinner in the idea of weighting silk, it is not surprising that this example should have been followed by those intent on gain. I mean, that the silkworm itself was the first to reveal the fact of a possible attachment of a substance to the fibre, foreign to the nature and properties of the fibre itself. It is true that this gummy attachment is almost, if not entirely, mechanical and not chemical; but it was in this way that the earliest dyers began to add weight, I won't say to the fibre of silk, because that is scarcely correct. I have just said that before the beauty of the silk is revealed and before its lustre can be manifested in fabrics or in the skein, this gum must be dissolved from the fibre; but a textile fabric consists of two parts, warp and weft. The weft being generally concealed between the warp threads, or so woven as to be seen only on the back of the fabric, need not have this gum removed, that is, need not be lustrous. I think the practice of weighting was wholly of European origin, for I have never been able to find any ancient silken stuffs of China, Japan, India, Persia, or even the egypt grave-cloths of the early Egyptian Christians, which were not bright both ways, or both warp and weft "boiled-off" as we dyers say, that is, the gum first discharged from the fibre.

I think the ancient dyer, no doubt, first began to weight the weft and in the gum. I don't know how ancient the practice was, history does not tell us, but it probably commenced in France through competition with the broad weaving in Italy.

Here are some specimens of Italian and French brocades of the century, when the silk designing and colouring and dyeing of the renaissance had reached almost the highest pitch of artistic excellence and of the artistic periods of Louis quatorze, quinze, and seize. Also a specimen of the period of the Empire when artistic decline had set in. All these silks are made of pure boiled-off silk, both warp and shute.

### The specimens are—

Italian brocade of the 15th, 16th, and 17th centuries.

French brocade of Louis 14th, 15th, and 16th.

French brocade of the Empire about 1800.

The weft, better known, as shute, when handed to the dyer by the manufacturer to be dyed, was accompanied by instruction from him to dye the warp with the gum removed, and the weft or shute with the gum left on the fibre. In this latter state it is generally termed, *souple*, or hard, and instead of the dyer returning it 12 ozs. per lb., as in the case of the warp, he returns the weft if unweighted, 15 to 16 ozs. to the lb., *i.e.*, close upon its original weight, thus having dyed both the gum and the silk.

Developments gradually crept in. It was found that by immersing the silk, whether boiled off or in the gum, in vegetable extracts containing tannic acid, an affinity of one towards the other was set up; a chemical union took place between the warp and the tannic acid, bringing up the silk to nearly its original weight before it was boiled off, or replacing nearly the 25 per cent. of gum it had lost in that process.

The case of the non-boiled-off shute or weft was different. The tannic acid had two missions, one to unite with the fibre, and the other to the gum, forming both a chemical and mechanical attachment; but its weight in this operation increased in proportion to the amount of tannin and the nature of the process generally, say, from 2 to 3 ozs. per lb. on the original undischarged weight. But something else occurred, and it is this which constitutes the chief reason for the adoption and recent developments in the processes for charging or weighting silk. Silk fabrics are not sold by weight, but by the yard, therefore it is obviously of but little use to weight the silk when sold by measure, merely for the purpose of increasing its specific gravity, unless in those cases where silk is sold by weight.

What does take place is that the silken fibre, in absorbing the tannic acid, expands, as a dry sponge does with water; the fibre thus becomes thickened, and generally in proportion to its amount of absorption. This rule has, however, exceptions, which need not be discussed here. This expansion of the fibre therefore renders it unnecessary to use as much silk as would be required if the silk were woven in the gum-discharged state.

The economy or cheapening by this property in silk, of increasing its bulk by absorption of chemical substances, lies in the fact that these substances and their application are all much less costly than silk, and, so long as the natural beauty of the silk can be preserved, modern demands for cheapening prove insatiable, as I shall presently show. The cheating, or cheapening, if you like, of the manufacturers of the latter half of the 17th century is innocent as compared with the relentless demand of the wholesale merchant of to-day, who is not content unless the fabric is cheapened to its utmost limit, and, consequently, adulterated to maxima truly alarming.

### EARLY WEIGHTING.

Originally, in fact, down probably to the 18th century, the weighting of silk was confined to the weft and upon the gum; but other chemicals, being found to possess affinities for silk, gradually came to be applied also to the warp, chiefly metallic salts having basic properties. First, alum, which always adds a little weight to silk, although only used as a mordant, then salts of iron, lead, and, lastly, tin, for which silk has a most surprising affinity. There are few subjects in modern chemistry which have occupied the attention and close study of chemists to a greater degree, in conjunction with dyers, than the creation of affinities in the processes of weighting silk: so much so now, that no dyehouse is complete without its laboratory, and no dyer's education is complete without a large command of the domain of both organic and inorganic chemistry, not so much for tinctorial purposes, but for swelling the fibre of silk by chemical means. Unhappily, the better chemist the dyer is, the more he is sought after by the manufacturer and his customer, the wholesale dealer, whose cry ever is cheaper, cheaper, and cheaper still, until at

last silk is now manufactured into dress and other materials, the average maximum of adulteration of which is but little below 100 per cent., and often to a much higher degree.

As to maxima of weighting silk in the gum and boiled-off conditions, I will expose a few sophistications as examples:—

A piece of black ribbon, the warp of which is 24 ozs. per lb. on boiled-off silk, and the weft 76 ozs. per lb. on silk in the gum, or containing, respectively, 50 per cent. and 375 per cent. of adulteration.

Samples of coloured silk in the hank, weighted before dyeing in the boiled-off state respectively to 50 per cent., or 24 ozs. per lb.; also others weighted as heavily as 40 oz. per lb., or 150 per cent.; that is, each 12 oz. of silk containing 12 oz. and 18 oz. of weighting matter.

Samples of black silk in the skein, weighted on the undischarged silk to 100 per cent., or 32 oz., and 40 oz. per lb.

A sample of spun silk, that is, silk spun in short fibres or drafts from silk waste. It was termed *cordonnet*, and has been sold largely for fringe and tassel purposes. It was given to me by a Lyons dyer, who had weighted it to the incredible extent of 920 per cent., or 160 oz. per lb., or 144 oz. of weighting matter added to each 16 oz. of silk. It is sold at about 2s. 6d. per lb. in its present state, whereas the yarn in the grey cost 8s. per lb.

A sample, such as is used in the elastic web trade, in which the weighting has been carried on a boiled-off silk to 30 oz. per lb. Weighting in this branch of trade has had two unfortunate results, a greatly diminished use of elastic webs for boots, and the substitution of wool for silk, which wears better than silk when so heavily weighted.

Also a skein of black *souple* tram, weighted to 400 per cent., or 80 oz. per lb.; and samples of old Admiralty handkerchief silk, weighted before the reform, of which I shall speak presently, the warp 26 oz. dye on boiled-off silk, the shute 50 oz. *souple*.

### THE CAUSE OF DECLINE OF ENGLISH SILK INDUSTRY.

The excessive weighting of silk is one of the causes of the decline of the English silk industry, because it is to Continental chemistry that the adoption and practice of weighting methods are due. Large fortunes have been made by Continental dyers or, as I ought more properly to say, weighters and by manufacturers by their skill in silk sophistication, and never so much as at the present moment is the weighting of silk a Continental industry.

English manufacturers have been obliged to send their silk abroad—not indeed to be dyed, for that is unnecessary, but to be weighted. English manufacturers and dyers, with a few exceptions, have been slow, as well as unwilling, to adopt the pernicious practice. It is sad to have to state that if the British industry is to be brought back it must be by British dyers and manufacturers weighting the silk exactly to the same extent as it is practised on the Continent, unless (which is more desirable) the large wholesale distributors of silk return to a purer state of trade. This, in the absence of a public demand for pure silk, does not, I am grieved to say, appear likely. As a case in point, one of the most important modistes in London, on my pointing out to her that the Paris silks she was making up were heavily weighted with tin, replied, Well, we must have the cheapest silks; why don't the English manufacturers put tin in theirs?

I do not find any mention of silk weighting in books on silk dyeing up to the middle of the 18th century, that is, before the time of such chemists as Macquer, Berthollet, Pileur d'Apligny, and Hellot. I have an Italian book of processes of the early part of the 16th century. Weighting does not there appear to have been dreamt of. Neither Pileur d'Apligny, who wrote in 1776, but on cotton dyeing, nor Hellot on wool dyeing in 1750, make any mention of substances used for weighting. But Macquer, who brought to a focus the state of silk dyeing in France of his time, in 1763 wrote his comprehensive and interesting contribution to those magnificent volumes issued by the French Academy, at the instance of the Government in that century, known as "*Les Arts et Metiers*." He entitled his work, "*Art de la Teinture en Soie*."

In the process of dyeing black on silk, Macquer describes the use of nutgalls and sumac, also antimony, litharge, plumbago, orpiment, corrosive sublimate, arsenic, sal ammoniac, copperas, and sugar, all needlessly confused together in the same operation for dyeing black, accompanied by this remark: "For the black dye the silk is boiled as usual, having been washed and beetled according to custom: you then give the gall liquor for heavy blacks twice, but for light blacks only once. These two blacks are alike in beauty and shade, differing only in the weight of the silk; the light black has, however, rather more lustre"; and with regard to black souple or "black in the raw" (*crud*), he says, "the silk should be galled in a cold liquor of fresh galls."

These methods indicate a weighting on soft and souple, but of not more than 3 to 4 oz. per lb., which, although termed heavy blacks ("noirs pesants" as distinguished from "noir léger"), were innocent as compared with the present state of things.

#### SILK WEIGHTING IN CHARLES I.'S TIME.

The advance of the silk industry in England under beneficial restrictions appears from a proclamation issued by King Charles I. about 1630; this proves that a quantity of raw silk was worked in this kingdom, sufficient to cause the issue of a proclamation, which stated as follows:—"Deceptions in the dyeing of silk have been discovered consisting of an addition to the dyeing mixture, by means of which it is intended to increase the weight of the silk, and owing to this fraudulent combination not only is the dye inferior, but the silk itself also becomes tender. We therefore most strictly command that henceforth no silk dyer shall make use of, in the dyeing of silk, such injurious additions as, for instance, alder-bark, iron-filings, or other fraudulent substances, and not only for black but for coloured silk; further, that no silk be dyed with other than 'Spanish black,' and the use of the so-called 'London black,' or what is called 'light weight,' is to be entirely avoided. Also, before the raw silk is dyed the gum must previously be altogether extracted by boiling."

Some years later the King partly withdrew the prohibition contained in his proclamation by allowing some silk to be dyed in the gum—that which is generally called "hand silk," intended for rough taffeta, patterned Atlas, fine thin ribbons, and both black and coloured Floret or Ferret ribbons." The King, with commendable straightforwardness, gave as his reason for this retreat from his first pronouncement that he had since become better acquainted with the subject.

I have already stated that the older methods of weighting were upon silk with its gum not discharged. In this case the weighting matter added had the effect of combining with the gum, which surrounded the silk fibre as a thin bark does a branch. By weighting, this bark becomes swollen in proportion to the weight added. I will show you on the screen the actual appearance upon Italian silk several black souples, weighted from 16 oz. to 96 oz. per lb. You see the silk fibre remains of its original size, whilst the gum has been increased to a considerable thickness, and where it is broken off, because of its brittleness, it resembles bobbins on a thin rod, at intervals from each other, or a branch of a cork tree with its thick bark removed at intervals.

Now let me show you the difference on a fibre of silk weighted after the gum has been removed. This is an original fibre weighted to 150 per cent.; or 40 oz. per lb., and afterwards dyed. The first or gum-weighted silk is to some extent mechanical, and is easily rubbed off, whilst the second is a chemical incorporation of metallic salts with the fibroin of which silk is composed. The following formulae of silk and gum will be of interest:—

The composition of raw silk or fibroin is—

<i>Fibroin, Cramer.</i>	
Carbon .....	48.60
Hydrogen .....	6.40
Nitrogen .....	18.80
Oxygen .....	26.11
	<hr/> 100.00

giving the formula  $C_{15}H_{23}N_3O_6$ .

As to the composition of the sericin or gum, no two chemists agree in their analyses. Silk has been examined by Cramer, Mulder, Bolley, Schutzenberger, Board, Rosa, Vogel, Staedeler, Bourgeois, Persoz. Bolley shows the following as its composition:—

#### *Sericin or Silk Gum.*

Carbon .....	44.72
Hydrogen .....	6.48
Nitrogen .....	18.50
Oxygen .....	31.20
	<hr/> 100.00

giving the formula  $C_{15}H_{25}N_3O_8$ .

It approaches in composition very closely to albumen and fish-glue, as the following tables show:—

	Egg Albumen.	Fish-Glue.
Carbon .....	53.40	50.10
Hydrogen .....	7.00	6.60
Nitrogen .....	15.50	18.50
Sulphur .....	0.10	
Oxygen .....	23.50	25.00
	<hr/> 100.00	<hr/> 100.00

I may here remark, in passing, the curious and unique property possessed by this insect-fibroin for uniting with inorganic salts, which materially add weight to it. It is not possessed by the fibre of cotton (which, as we know, is cellulose), by linen, or any other vegetable fibre, nor do animal fibres partake of the affinities possessed by fibroin. It is true wool unites with alum, chromic and other salts, as cotton with tannin and other mordants, but not in a weight-taking capacity. It is said it is possible to weight wool, but I have not met in commerce any wool so weighted. It may be safely said that woollen manufacturers are fortunately free practically from chemical weighting. If woollen fabrics require to be cheapened, recourse is had to mixing cotton with them; or, if cotton has to be weighted, mechanical sizing is used. How strange then that it is reserved for a product of the insect world to have a monopoly of combining in this way with inorganic salts and tannin.

The silk of spiders I have proved to possess the same property. I have found on the silk of a species of Indian spider as much as 50 per cent. of gum, which, after being discharged, I have dyed and weighted like the silk of Bombyx Mori. Here are several samples of spider silk, both raw and woven, from Madagascar, India, and other countries.

#### GRADUAL INROAD OF WEIGHTING SILKS.

The gradual development of weighting silk, "in gum," as it is termed, by the employment at first simply of the tannic acid extracted from such vegetable matters as sumach, valonia, galls, catechu, the cutch plant, &c., and afterwards in the dyeing of blacks, a gradual increase of weighting by double mordanting with iron salts, notably persulphate of iron, and ferrocyanide of potassium, which, combining with the iron on the silk, formed a base of Prussian blue, helping the formation of the tone of black, and enabling the tannin afterwards employed to combine in larger proportions with the silk, and so increase its weight, until the weighting, at first only amounting to an increase of 2 oz. per lb., has gradually risen in practice to 100 per cent., or 80 oz. per lb., on souples for textile goods, or even more, and 40 to 50 oz. on boiled-off silk.

Here is a German dyed sample of silk weighted to 400 per cent. You will notice that the silk possesses no lustre, but, as it would be covered by a warp which has lustre, that does not signify. This excessive weighting swells up the silk, or rather the gum, and pads the fabric like stuffing a cushion, giving it fictitious feel, appearance, and substance.

An excellent example of this occurred about 10 years ago in the black silk neckerchiefs supplied to the sailors by the Admiralty. Jack is privileged to have a new black neckerchief annually, but for which, however, he has to pay.

The Admiralty, ordering the goods by tender, generally accepted the lowest, and, not knowing the nefarious ways of contractors, and not being patriotic, gradually became their victims, until the weighting of the silk of which the neckerchiefs were made became so abnormal that even Jack rebelled; for after a day's wear in summer he came home to his wife with a neck as black as his kerchief.

Several years ago the Director of Admiralty Contracts consulted me on the subject; he said things had got to such a pass that Jack threatened to refuse to wear his neckerchief. I said, "The fault is yours for accepting the lowest tender and encouraging foreign competition," either the goods having been made in Germany, or the English manufacturers having no resource but to order their silks, warp and weft, to be weighted, but generally sending their silk in the skein to Germany to be so weighted and dyed. There are specimens, the warp a 26-oz. boiled-off black, *i.e.*, 12 oz. of silk weighted to 26 oz., or 14 oz. of increase on 12 oz., and the weft weighted on the gum to 50 oz., or 300 per cent.; no wonder the black weighting matter rubbed into Jack's neck. I at once suggested unweighted silk, but the Director of Contracts, in fear of too great an increase in the annual estimates, not daring to accept my recommendation not to weight the silk at all, I recommended a 16-oz. dye for the warp and a 20-oz. dye for the weft. These dyes were adopted, and the following words were at once inserted in the Admiralty specifications:—"The dye of the warp to be of a sound, permanent black on boiled-off silk, and not to exceed 16 to 17 oz. per lb.; and that of the shute to be a boiled-off black, not to exceed 20 oz. per lb. An inspecting officer shall be permitted to see both the spinning of the yarn and the manufacture of the handkerchiefs to be supplied."

There was then no chance of escape, for I gave, by request, to the Admiralty chemist methods for analysing the weighting of both warp and shute, and the standard has been observed by the manufacturer down to the present time, with two distinct and surprising results: first, that a handkerchief after a year's wear is now looked forward to by Jack's wife as none the worse, whereas under the old régime they were worn out often before the year had passed; second (and this is singular and interesting), that the handkerchiefs since the reform have been all made in England—pointing to this, that silk can be made as cheaply here as abroad, providing the weighting is forbidden, or where equal conditions are observed.

#### THE HISTORY OF THE WEIGHTING OF BOILED-OFF SILKS.

In course of time, and competitive trade—which, I take it, meant money-making for its own sake, versus the making of artistic goods for the sake of the pleasure thereof and reputation—the weighing of boiled-off silk began, as I have said, with tannic acid to the extent of 15 to 20 per cent. its limit by this method; then sugar weighting (a purely mechanical operation) came in the latter part of the last century, and stayed until more chemical methods were discovered.

A syrupy solution of sugar can be added as a coating to silk fibre to nearly the extent of tannic acid, sometimes employed on the top of tannin-weighted silk in the case of souches where lustre is not the desideratum. But sugar, being deliquescent, subjects the silk to several fatal objections: destruction of silky feel; substituting for the natural silky touch, a clammy feel; silk so weighted is also liable to mildew and other fungoid growths; also it is easily detected when present by its sweet taste. Its use is now practically abandoned on the Continent and almost so in England. It is at best a clammy artifice. I need not mention the many chemicals which have been from time to time experimented with, like barium salt for example, which from its high specific gravity, was once thought to be a great find, but like several others only introduced to be abandoned.

I will at once come to the modern methods of adulteration, the subject of Tin weighting, stannous chloride,  $\text{SnCl}_2$ , also known as tinsalt, tin crystals, muriate of tin. This salt has for a long time been used in the dyehouse as a mordant for colouring matters, chiefly for scarlets and crimsons from cochineal, and for violets and reds from dye-

woods, notably logwood and Brazil woods. Various forms of solution of tin were employed, according to the ideas of both dyer and manufacturing chemist, but they may be classed, for the purpose of this paper, under the generic term of tinsalt or muriate of tin.

About 40 years ago, a blue called Napoleon blue was for several years the prevailing fashionable blue, being less cold in tone than indigo. It was dyed in the following way, being, in fact, a modified form of Prussian blue. In one bath was a solution of tinsalt and ferrieyanide of potassium, and in another a solution of muriate of iron. The silk was worked in these baths alternately, and a rich blue was the result, the tinsalt being used for mordanting with no intention of silk weighting, although a little weighting resulted. The reason I mention this is to show how tinsalt began to be employed in the dyeing of black silks for weighting purposes. It was a discovery of a lamentable nature and purely accidental. It has formed the groundwork of all the subsequent discoveries, not accidental, of inordinate and abnormal silk weighting.

A well-known dyer at Crefeld about 40 years ago, whom I knew personally, was occupied chiefly in dyeing Napoleon blue and ordinary 16-oz. blacks on boiled-off silks. One day one of the men working in the blue-dyeing department, larking with another close at hand in the black department, threw at him a large hank of silk which he had just been wringing out of the tinsalt bath. The silk missed its mark and fell into a bath of catechu ready for being used to weight some silk for black. It was of course ruined for blue, turning at once green; and the men, to conceal knowledge of the lark, allowed the hank to pass along with the parcel for black. When the silk was dried at the end of its processes, a hank was found in the parcel more bulky and heavier than the rest, and considerably brighter and bluer in shade. This was enquired into and found to be the one missing from the blue parcel. A small parcel of silk was then put to the test of experiment, being mordanted with the tinsalt as for Napoleon blue, and it was found to result in an improved colour and increase of from 12 oz. of boiled-off silk to 18 oz., or a return of 18 oz. per lb. This accidental discovery caused a great sensation in the silk-dyeing world, and I remember going over to Crefeld to consult my friend Mr. Adolf Kottgen, a silk dyer there, since dead, on the subject. He told me the story I have stated, and when I visited him, he was dyeing large quantities of silk black in this weighted way.

Shortly after, the French dyers took up the process, and by their cleverness and ability in dyeing soon increased the weighting to much heavier degrees. The way was led, at first, singularly enough, by a French dyer in London, named Drevon, who, finding not much room for his genius in this direction in England, the English manufacturers being adverse to the introduction of such sophistication, went to Lyons, and in a short time became one of the largest dyers there. His increment of addition did not exceed 26 to 30 oz. per lb. on boiled-off silk; but since his time, now 20 years ago, the Lyons, Swiss, and German dyers have discovered methods to enable them to carry into very extensive practice the weighting of black silk to at least 40 oz. per lb.; that is, 12 oz. pure silk made to return in black 40 oz. without in any way impairing the lustre of the silk or its solidity of colour. Here is an example. In fact, we have the curious phenomenon of weighted black silks being more permanent in colour than unweighted ones, mainly from the tinsalt forming both mordant and weighting media. With time and chemical development, another important change was introduced. Unavailing were the efforts to give weight to silk by immersion in tinsalt solution alone, without the intervention of tannic acid or catechu tannin. Stannous chloride, although an excellent mordant, has in itself little or no practical weight-giving property. It combines with fibroin very much as alum does, but, unlike alum, in the presence of tannin, especially the Catechu tannin obtained from Catechu, affinities between the fibroin, tinsalt, and tannin become quickened, with a result of a considerable expansion of fibre and increase of weight. These affinities are increased by the previous treatment of the silk with persulphate of iron and ferrieyanide of potassium, without which good

blacks or sufficiently weighted could not be obtained. Of course, these processes were inapplicable to the weighting of silk intended to be dyed into colours, because of the groundwork of first the iron salt, then the ferrocyanide of potassium, which gave a dark blue, and afterwards the tin and tannin, which left the silk so dark in shade and so dirty a green, that to dye it into colours was of course out of the question.

The difficulty of giving abnormal weight to fibroin was at length solved by the discovery that a strong solution of Pinksalt gave the desired result without imparting any colour to the silk, and made it equally applicable to silk in the gum or boiled-off. Here was the commencement, more than 10 years ago, of a new era in silk weighting by the introduction of pinksalt, which, as you know, is a double chloride of tin and ammonia, having the formula  $\text{SnCl}_2 \cdot 2\text{NH}_4\text{Cl}$ . By passing the silk before being dyed into a solution of pinksalt, and then into a soap bath, the silk increased in bulk and weight, according to the number of repetitions of these processes, but not equally. I find the bulk does not increase so much after the silk has increased to 100 per cent., or 12 oz. of boiled-off silk to 24 oz. After these operations the silk can be dyed any colour, or white, without much difficulty. This process was found to be too costly, and other developments caused a cheapening.

The price charged at first was 6d. per ounce for each ounce of increase of weight. At the present time the German dyers are engaged in a fierce price-competition, and the cost has been reduced one half. The methods by which this has been accomplished are very interesting, and show the importance of a profound acquisition of chemical science in any dyer intending to maintain his position in his trade.

After the silk had received its tin it was soaped. The effect of this was to precipitate the tin into the fibre, probably as an oleate of tin. Many chemicals were searched for and tried as substitutes for soap, and at length phosphate of soda was introduced and found to do its work better. But this change did not sufficiently lessen the cost, and at length the Germans introduced silicate of soda as an additional process after the phosphate of soda. This caused the tin to combine with the fibroin with leaps and bounds, until now, as the latest achievement, 167 per cent. in colours, or 53 oz. per lb., has been reached, as you see here, in the samples recently sent me by one of the largest Crefeld dyers. To the unassisted eye, or to the touch and taste, it is scarcely possible for even an expert to tell that the silk is weighted at all. The weighting matter (unlike sugar) is in direct chemical union with the fibroin, and is part and parcel of its substance, becoming a new and another product. The defect inherent to this method of weighting is, that by exposure to light, especially in sunlight, decomposition sets in, and the fabric soon becomes rotten, and what at first seems a cheap dress is soon useless.

Although I have described the *rational* of this method of causing tin to combine with the silk, it is only right for me to say that I have only stated the broad lines on which the methods are based; developments occurring as each month succeeds another, having for their results lessened cost, the modification of former defects, and the discovery and use of other salts which quicken the affinities of the metals with the fibre, none of which, however, are yet, and it is hoped never may be stable. (See page 326.)

I will now show you the comparative results of burning pure and adulterated silk after the manner of the incandescence light, making a similarly shaped mantle. There would be much incandescence with the weighted silk if the heat were great enough. The tin glows like lanthania and other rare earths, but it will be seen how indestructible the weighted mantle is and how immediately the pure silk is consumed.

#### REASONS FOR WEIGHTING SILK.

A few words on the reasons for weighting silk. Two causes only, in my opinion, have led to this disastrous state of things: the insatiable pressure of the merchant's buyer for cheapness, and the baneful and degenerate spirit of commercial competition amongst the manufacturers themselves, which

in too many cases has degraded itself into mere underselling without due regard to, or, in too many instances, knowledge of the differential and integral totality which constitutes the cost of production and the necessary margin of profit.

With regard to the first of these two causes, I may illustrate the truth of what I state by what I was told by one of the most important of the Lyons manufacturers—one of my colleagues at the Paris Exhibition of 1889. He said the English buyers who periodically came to Lyons had become very pressing in the matter of price. He said they went to Crefeld and got quotations, with which they squeezed the Zurich manufacturers, and then came down to Lyons saying, we can buy these goods at such and such prices at Crefeld and Zurich, and unless you are prepared to compete we cannot place our orders with you. So much so was this the case that my informant told me there were several English buyers whom they preferred never to call on them. No wonder, then, that under this severe pressure hidden means are taken to cheapen the fibre artificially by extending it by chemical methods and so economising the employment of silk.

To such an extent is this now practised at each of the three great silk centres I have mentioned, that the very existence of their staple industry is most seriously threatened, and great alarm occasioned amongst the manufacturers and dyers themselves, the latter being the first to be roused by the danger.

At a meeting held in Crefeld of the dyers of that town, a memorial was drawn up asking the Chamber of Commerce to make an enquiry into the excessive adulteration they were compelled to apply to the silk sent them to be dyed and weighted by the manufacturers, requesting them to call a conference of manufacturers and dyers with a view to fix a maximum limit to this scourge; and further giving notice in this memorial that they, the dyers, would not be responsible for the decomposition and rotteness of the fabrics so adulterated, and would refuse to weight the silk to a higher degree than 50 per cent., or 24 oz. to the lb., which on boiled-off silk means 12 oz. of pure silk weighted to 24 ozs. Their report, addressed to the Crefeld Chamber of Commerce, runs as follows:—

"The undersigned dyers beg to bring the following report conjointly with the meeting of silk merchants, makers of silk stuffs, and silk dyers, held by them on the 22nd December 1896, to the knowledge of the Chamber of Commerce, and to all those whose interests are bound up or closely connected with the successes of the silk trade."

"On account of the disappointing results which the silk industry has had to witness during the past year concerning the solidity of dyed and very heavily filled stuffs, a speedy change is urgently required, if the general desire is not to endanger the existence of the whole market. The absolute necessity for a remedy to produce a better state of things, has caused the undersigned dyers to call the general attention to the following points:—

"Until the introduction of the phosphate silicate method all makers used the so-called 'charge mixte,' and that to a very limited extent only as regards its strength. Makers did not go beyond 40 per cent. to 50 per cent. The apparent insufficiency of this mixture was, for a long time, passed over by the buyers. The effect of this insufficiency was observable when dyeing light and dark shades causing the self-same quality of cloth, taken for both shades to have the appearance of two different qualities; further, that this so-called mixture in a greater strength did not produce the strong and desirable grip or feel in the goods; and, still further, that when dyeing repeat shipping orders, very often a great difference appeared as regards this grip, and this without the least fault on the part of the dyers. It is also a fact that the solidity of light tints remains far behind in comparison with that of dark tints. To overcome this want of grip and feel, the phosphate-silicate method is used. This method has been condemned as producing unresisting dyes, but this is not justified.

"The unresisting nature of dyes showed itself simply on account of the overcharge of mixture used; and the following comparisons are instructive. It is a fact that, by applying the phosphate-silicate method the silk thread swells enormously, and it can be taken for granted that by

using, for instance, mixtures 40 to 50 per cent. above par, the thread gets stronger and more grippy than when using 20 to 30 per cent. of the phosphate-silicate charge.

"However, we do not pretend to say that when using the phosphate-silicate method the swelling is doubled; that when applying the 'charge mixte,' the fact remains that it comes very near that proportion. This shows that when applying this 'charge mixte' to all those stuffs for which, up till the present day, 80 per cent. of the Ph. S. method is still used; and it is here apparent that, in proportion, such an addition is too great. On account of this overstepping of limits lies the danger and the chief cause of the brittleness shown by dyed stuffs; it is necessary to remember that as soon as the quantity added of the 'C.M.' is out of proportion to the silk weight, the consequence must be the destruction and breaking of threads. The dyer cannot fix these proportions, because it is of great importance for him to know where the raw silk came from and how it has to be woven. It has been shown, for instance, that of one lot of web, part was used for weaving 'surah' (or rather long reeded-stuff), which proved sufficiently strong as to wear and tear, whereas the other part of that same lot, used for weaving a so-called 'rustling taffeta,' came up in a brittle and broken state. Further, it has been proved that even heavier weighting used for weaving surahs brought them out sufficiently strong, whereas less weighting showed them to come up brittle—a proof, this, that the manufacturer must step in here and try to succeed in fixing the proportion of weighting necessary to employ for each article. A great factor in the effect is light. The metallic powders contained in the threads follow physical laws when they are extended or contracted. The thread itself has, of course, to follow these changes. If too much metallic matter is contained in a thin thread, it will be forced to break without any chemical process going on besides. For this reason, the maker should be asked to use only a limited amount of weighting for certain tissues.

"But this is not so easily done, on account of the different processes adopted, and the maker must try to find out what is the right thing to do in all these different cases. Should the manufacturers content themselves in future, not to insist in getting better results than formerly obtained with the adding of 40 per cent. to 50 per cent. of 'C.M.,' then it would be preferable to go on with the 'Ph. S. method,' and not to introduce again the 'C.M.' for reasons above mentioned. It would also have to be taken in account that the 'C.M.' is, firstly, a dear process; and, secondly, it would have to be used in larger quantities, which, of itself, would in consequence cause an increase of cost. For the establishment of a healthy market generally, the use of heavy threads from good spinners combined with lighter weighting would have to be the rule.

"The undersigned dyers therefore have decided not to execute any orders in future where the weighting material is asked to exceed 50 to 60 per cent.

"The makers will, on the other hand, receive the thanks of the various trades if they, as mentioned above, use more of the better and stronger silks, and less of sizing material.

"As, firstly, dyers cannot lay down a hard-and-fast rule in that direction; and, secondly, it being a fact that ready-made goods suffered by being heavily sized, against which the dyers had no remedy, although the silk used was originally of good quality; and as, thirdly, the buying parties are generally inclined to ask for a certain guarantee from the manufacturers, and these demands being, in the end, thrown upon the dyer, who, naturally, is not in a position to give such guarantee—then the consequence must be that the undersigned dyers must feel themselves compelled to decline giving such guarantee for goods when manufactured.

"Leaving aside the pecuniary guarantee, it must be clear that the dyers are not in a position to give a moral one; but they are persuaded that, by the introduction of the above-mentioned methods, general confidence will return within a short period as regards the position of the silk market.

"The annexed treaty is recommended to the Swiss dyers for their special consideration. The meetings of the Swiss dyers have already had the effect of bringing forward

special recommendations, as regards weighting systems, but these as yet have not gone deep enough into the subject, to our thinking, as there is especially a want of comparative methods used for producing strong and effective results for putting weight into goods, such as 'C.M.,' and for heavy black weighting.

"According to natural laws, any methods to produce heaviness in silkstuffs by artificial means must injure and reduce the strength and durability of the silk thread. The question only is, how far one can go, and which method can be proved to be the right one. Up till now, only a deteriorating effect on all points has shown itself.

"It is a well-known fact that silk goods well covered up, or kept in well-closed boxes, have shown their faults in the same degree as freshly-made goods for robes, which proves clearly that this result is not only caused by the influence of light rays, but is also caused by other still unknown influences which play a part in the deterioration of silk-stuffs. To find within a short period an unfailing remedy to produce a harmless and useful weighting method would form a highly important theme for a scientific treatise. As the manufacturers and the buyers must have the same interests at heart as the dyer, the undersigned believe that it is the duty of the Chamber of Commerce to cause such scientific treatise to be written and distributed. Finally, requesting the calling of an early meeting for an exhaustive exchange of opinion on this matter, we remain," &c.

[Here follow the signatures.]

The Zürich manufacturers and dyers, taking fright, met; and it appears, from a proclamation which appeared in the papers a fortnight ago, they have signed a convention, with heavy penalties for infringement, the clauses of which are as follows:—

#### PROCEEDINGS TOWARDS THE ATTAINMENT OF UNIFORMITY BETWEEN SILK MANUFACTURERS AND DYERS REGARDING THE WEIGHTING OF BOILED-OFF COLOURS ON SILK.

A convention has been appointed for the purpose, in the interest of the trade. The terms agreed upon are as follows:—

"1. The undersigned firms of dyers bind themselves from the 1st April 1897 not to weight boiled-off colours under any circumstances, and for whomever it may concern, more than 60 to 80 per cent. for tram, 20 to 30 per cent. for orgazine, excepting seal-brown for lining stuffs.

"2. These maximum weightings shall undergo a further reduction to 50—60 per cent. for tram, *viz.*, (a) for white, (b) for colours, in case the tram is intended for taffetas.

"3. The undersigned silk manufacturers on their part bind themselves not to have any heavier weightings produced, not even by local or foreign dyers, whether members of the conference or not.

"4. It shall be declared with every order the uses of the coloured silk, whether the silk is intended for taffetas or other textures, and, in case of a dispute, the manufacturer has to prove that the silk in question has in reality been used for the indicated purpose.

"For every disposition of colours, the dyer has to be supplied with the correct titres and particulars.

"5. There will be a committee chosen whose task it will be to watch that the agreement will be rigidly carried out by both parties. This committee will consist of three confidential persons, the first of whom to be elected by the manufacturers, the second by the dyers; the director of the Silk Conditioning House for the time being is to be the third member. In cases where preventive measures have to be adopted, two additional members are named, one a manufacturer and one a dyer. The director of the Silk Conditioning House will be salaried with 500 to 1,000 francs per annum, according to the claims upon his time. The committee is pledged to the utmost discretion.

"6. Each of the undersigned dyers pledges himself to a security, the amount of which will be fixed in each separate case by the committee. The securities will be deposited by

the committee in the archives of the valuable writings of the Swiss Institute of Credit. For the withdrawal of them, all the three signatures will be required. The security will be wholly or partly forfeited when the majority of the committee find that the present agreement has been broken by the dyer in question. The disposal of the amount will be in favour of the Institute of the Silk Industry School of weaving, and textile drawing school; and will be decided upon by the majority of committeemen.

"7. Manufacturers acting in contravention to this agreement are subject to a fine of ten times the amount of the cost of dyeing.

"8. The circulars of the dyers issued January 18th and February 10th, as well as that of the silk manufacturers dated February 1st of this year, are withdrawn, concerning the responsibility for their method of dyeing, and matters remain as before. In disputed cases the committee shall decide.

"9. Exhaustive investigations are to be at once undertaken, based on scientific and practical foundations, as well as with regard to the different methods of weighting, and their effect on the silk, as concerning the thickness, strength, durability, &c. of the textures. The expenses incurred thereby are to be borne in equal shares by the dyers and manufacturers, as well as the other expenses of the committee.

"10. This agreement to be in force for the term of one year, *viz.*, until March 31, 1898, and, in case there shall be no notice given to the contrary by January 1st at the least by either side, it will continue to be valid for another year."

Notwithstanding this bane of weighting silk, there are several English houses which, on principle, offer to the public only pure and unadulterated silks. It is not a little singular and encouraging that these houses are doing, not only the best trade, but export to France to customers who are content to pay an extra price for a pure article. Of the great majority of British manufacturers, I know that they have their silks weighted only to the most moderate degree that foreign competition permits, and in so doing act unwillingly.

### SILK ADULTERATION.

BY J. CARTER BELL, A.R.S.M., ETC., COUNTY ANALYST.

During the last few years I have worked with Sir Thomas Wardle on this question: "The Adulteration of Silk," and perhaps it will not be out of place if I give a short account of the analysis of the various samples. The question is to ascertain the real amount of silk in these heavily weighted samples; to attempt to estimate all the weighting materials would be to court failure, therefore it is better to use various solvents which will not act upon the silk. If we analyse the raw silk we shall find that it contains about 25 per cent. of a gummy substance, which must be removed before dyeing operations can take place. This, I may say, is not always the case, for just within the last few days I have analysed a sample of Japan silk, which had evidently been dyed in the raw state, that is, with the gummy matter left in the silk, for on estimating the moisture and the amount soluble in water there was a loss of over 25 per cent., the ash being as low as 0.464. The ash of a pure white silk was 0.349. While a Chinese salmon-coloured silk only contained 0.246 of ash. Therefore it is plainly seen that the Chinese and the Japanese have not yet learnt the fraudulent art of selling mineral matter for silk; it has been left to the French, Germans, and Swiss to carry this to perfection, and the heaviest weighted silk I have as yet examined is where 100 pounds of silk were sent to the dyer with a request that it should be made into 1,000 pounds; this particular silk gave 43 per cent of ash, there was 9 per cent. of moisture, and the amount of nitrogen was under 2 per cent.; this would give less than 10 per cent. of silk in the sample. The only advantage I can see in such a compound (for it is a misnomer to call it silk) is to make an incombustible dress for a lady, for it would be an impossibility for her to be burnt to death in

such a dress. When such a compound is raised to a high temperature it does not flare up but simply smoulders away and leaves the original form intact, and in many cases with a beautiful silky lustre. This compound is not a true weighted silk.

In the analyses of these weighted compounds it is better to take the moisture from using 5 grains of silk, then to extract with ether, alcohol, and water weighing between each solvent. This will give the quantities of soap, oil, sugar, and such like compounds added for weighting purposes. Half of the sample may now be treated with hydrochloric acid diluted with one or two volumes of water; the silk is then dried at about 230° F. It can then be reduced to powder, which can be mixed with the soda lime and the combustion for nitrogen carried out in the usual way. One of the metals which is largely used for weighting silks is tin; this can be detected by heating the silk with strong hydrochloric acid, added in quantity to effect solution, then diluted with water and a current of  $H_2S$  passed; the tin is precipitated, and may be recognised by the usual tests.

As I have already said, silk weighted to 800 and 900 per cent. is not easy to burn; but certain black silks which have been weighted up to 300 or 400 per cent. have been known to take fire spontaneously, and for dyeing blacks the substances usually employed are catechu, gall nuts, and certain salts, specially sulphates of iron, basic and non-basic. A silk of this dyeing was found to contain over 20 per cent. of moisture and from 12 to 15 per cent. of mineral matter. When dried at about 230° F. it took fire spontaneously as soon as air got free access to it. This may be owing to the rapid absorption of moisture, during which oxidation occurs. It is not so many years since that a fire broke out in the warehouse of a large silk mercer in Paris. The fire was soon discovered, and this gave rise to the discovery that it originated inside a large parcel of black dyed silk which had been returned from the dye-house only 24 hours previously. I believe that it is a well-known fact that black silk, under certain conditions, is liable to spontaneous combustion, but the real explanation of the cause is yet to be discovered. It is very advisable not to keep large quantities of black dyed silk together, and also to prevent it getting very dry, and above all, care should be taken to prevent it being exposed to any great degree of heat. In 1871 a fire occurred in a silk-dyeing establishment in America, and was traced to the heavily weighted goods, and it is considered unsafe to pack them in deep boxes for transportation.

Astringent matter like tannin, which is used for blacks and greys, and catechu which is used for brown, in combination with sulphate of iron, take up oxygen very readily, and it only needs a little oily matter with heat to have the whole mass smouldering to ashes. I have never myself been able to obtain actual flame from these experimental spontaneous combustions, but the mass, as a rule, smoulders away to ashes.

Some think that silk waste and silk rags are as dangerous in regard to spontaneous combustion as cotton waste. This question of heavily weighted silks is worth the attention of the insurance companies.

The ash of a genuine silk may vary according to the district in which it is produced, but I think one may take as an average 0.5 per cent.; in the raw state the ash varies very much. Some years since a new silk was introduced into Europe from China, a native worm feeding on oak leaves instead of mulberry, it was called the "Tussur silk," it was found to contain over 8 per cent. of ash; while good Italian silk only contains about 1 per cent. But when this Tussur silk is first treated with some alcohol, next with dilute  $H_2SO_4$  and then washed in a soap bath, the quantity of ash is brought down to about 0.5 per cent. I believe one of the reasons why this silk is not more widely known is, that it has a less affinity for mordants than the ordinary Italian silk.

In estimating the real amount of silk in a sample I prefer to estimate the nitrogen, either by soda lime or Kjeldahl's process, and I prefer the latter with certain modifications of Mr. Stock.

The following are a few analyses of weighted and un-weighted silks:—

	Moisture.	Ash.	Silk.
	Per Cent.	Per Cent.	Per Cent.
1. White silk.....	5.1	0.349	100
2. Salmon-coloured Shanghai.....	5.5	0.246	100
3. Black.....	7.9	1.87	25
4. White.....	8.9	50.0	25
5. Shot silk.....	0.2	34.7	39
6. ".....	10.2	33.7	32
7. Pink silk.....	8.5	43.2	54
8. ".....	8.1	52.4	43
9. ".....	8.1	49.5	46
10. Blue.....	0.5	35.4	60
11. Gold colour.....	5.8	41.7	52
12. Cream colour.....	9.1	45.7	45
13. Pink and green.....	8.6	34.2	50
14. Pink.....	8.6	28.2	60
15. Cream.....	9.3	8.9	87
16. Yellow.....	8.6	9.1	88
17. Black.....	8.5	42.9	12
18. Sky Blue.....	9.1	48.9	37
19. ".....	8.1	45.9	36

The standard for silk, which I have taken in these analyses, is what is called pure boiled-off silk and dried at the ordinary temperature; such silk as this will contain about 18 per cent. of nitrogen.

Tussah silk, which one may say is a child of Sir Thomas Wardle's, as he has done so much work to introduce it into this country, differs a little in composition from the ordinary silk. Tussah silk may be easily distinguished from mulberry silk by the action of zinc chloride. Tussah does not dissolve so readily as mulberry silk, which dissolves at 45° B., while for tussah it has to be at least 60° B. In case of a mixture of the two silks, zinc chloride at 45° B. will dissolve the mulberry silk after boiling for a minute, leaving the tussah silk unattacked.

I think one may venture to say that the original cause for weighting was a desire to make up the original weight of the raw silk, the loss being occasioned by the boiling off, which amounts to about 25 per cent., that is, a lb. of 16 oz. is reduced to 12 oz. In 1875 it was stated that weighting was then carried on to the extent of 100, 200, and 300 per cent., but through fierce competition these numbers are now left far behind, for, as you will see from the analyses, it has reached 900 and 1,000 per cent. until it is no longer silk, but a mere conglomeration of mineral matter.

### SESSION 1896-97.

*Meeting held in the Chemical Theatre, Durham College of Science, on Thursday, March 25th, 1897.*

MR. W. W. PROCTOR IN THE CHAIR.

## THE SAMPLING AND ANALYSIS OF COKE, AND VALUATION OF COAL FOR COKING PURPOSES.

BY W. F. KEATING STOCK, F.I.C.

*Introduction.*—I have ventured to bring the laboratory aspects of the coke trade before this Section for several reasons, chief among which is my desire to draw the attention of members to a growing necessity for greater uniformity of method in dealing with matters which are now inseparable from this very important branch of commerce. Another circumstance which has guided me in the choice of my subject is the scattered and fragmentary nature of its literature. It would be difficult to say where, outside of private reports and laboratory note books, one could find detailed information regarding such points as the proper method of sampling coke, its chemical analysis, its suitability for special purposes, or the improvement of coal from inferior seams, to fit it for coking. All these are matters which can be decided in the laboratory, probably to the satisfaction of the individual analyst, but it is a lamentable fact that occasionally upon one or more of these issues serious discrepancies arise; and it seemed to me that it would not be out of place to introduce the whole question as a subject for discussion before an influential society of industrial chemists, sitting in the very metropolis of the coal and coke trade. It would be too much to expect one's own ideas to meet with universal favour. I should be very well satisfied if they eventuated in the adoption of methods of working of established accuracy.

*Sampling of Coke.*—I think it will be generally conceded by analysts that, when dealing with material which, in the nature of things, is variable in composition, there is no more fertile source of discrepancies in analyses than insufficient and inefficient sampling. No matter how perfect the analytical methods may be, no matter how scrupulously they may be carried out, a faulty sample renders them of no avail, and I have found by long experience that the taking of a sample of coke from bulk is the rock upon which analysts most often split. I have abundant evidence that the time has come when vendor and purchaser alike would welcome any plan which would place this matter upon a fair and systematic footing. I have elsewhere pointed out, as a matter of actual observation (Iron and Coal Trades Review, 1887) that a sample of coke may be taken in at least six different ways. (1.) A few small pieces of coke may be broken off as many different columns. (2.) The whole of a column may be taken. (3.) The top or bottom "lift" of a column may be taken. (4.) The sampler may proceed to break small pieces of coke off a few columns, holding the latter, as he strikes them with his hammer, over the pail or other utensil in which he intends to carry the sample. All these methods are improper, the latter extremely so. Of the first three, it may be said that not in one case in a hundred would a representative sample be obtained, and of the fourth, that all the fine particles of shale, which are non-adherent to the column, would be started, out of the interstices of the coke, and would cause the ash to mount up quite abnormally. A fifth method, which is fairly reliable, and which is a convenient "works" method, consists in the sampler going over the surface of a train of coke, and breaking at least 10 columns on each truck, from each of which he takes a few pieces as they lie and transfers them by hand to his pail or bag and so proceeds until he has collected at least 20 lb. weight, the further treatment of which will be described later. The sixth method, which I do not hesitate to say is the one which should always be followed in case of dispute, is carried out in this way:—If the coke is in trucks at the ironworks, the trucks are run up on to the gantry over the storage bunks and two doors on one side of each truck are let down. This allows half the load to be seen from top to bottom, and enables the sampler to judge of the relative proportions of "large," "small," and "breeze." Portions of the coke are taken at bottom, middle, and top, and this is repeated for, say, 10 trucks, resulting in a bulk sample of from 3 cwt. to 5 cwt. If the coke is at the ovens, the sampling is simplified, as a barrow can be taken along the draw-bench, and filled

according to the judgment of the sampler. The bulk sample so obtained is then knocked down on clean iron plates (which are always available at an ironworks or coke ovens), until it is reduced to about macadam size. It is then thrown up into a heap and thoroughly mixed, after which it is spread out into a good sized square, and divided by running a shovel through it twice at right angles thus:

The corners A and D are now thrown out and all the small and dust belonging to them is swept away. The whole process is now repeated on the portions B and C, alternately pounding, mixing, squaring, and dividing until the sample will pass a  $\frac{1}{2}$ -in. sieve. The sample is well mixed at this stage, and about 20 lb. is taken for further reduction. This and the 20 lb. sample obtained by method No. 5 may now be treated alike. The sample in either case is taken down on a bucking plate until it will pass a  $\frac{1}{2}$ -in. sieve. The whole of it must pass through the sieve. It is again mixed, and 100 grms. are weighed off for moisture. A further portion of 500 grms. is put through a 20-mesh sieve, and after again thoroughly mixing, 20 grms. are taken and dried for analysis, after which this 20 grms. are finely triturated in about 2 gm. lots in a hard Wedgwood mortar. Finally, the whole of the fine powder is returned to the mortar and thoroughly mixed with the pestle. It is of vital importance that this final detail be not neglected. I attribute to its non-observance, several cases of serious discrepancy, which have been from time to time referred to me for settlement. It may be thought that such elaboration is uncalled for, but when I mention that differences of 3 or 4 per cent. in the ash, and of 3 or 4 tenths per cent. in the sulphur are not uncommon in samples of coke taken by different samplers from the same bulk, it seems clear that some standard mode of sampling is much wanted.

**Chemical Analysis of Coke.**—Coming now to the chemical analysis of coke, it will be necessary to revert for a moment to the 100 grms. of coke, which was taken for moisture when the sampling had reached the  $\frac{1}{2}$ -in. stage. This portion is dried for three hours at a temperature not exceeding  $105^{\circ}\text{C}$ . I myself prefer the heat of a water-oven in test cases. It is quite sufficient to weigh on a balance sensitive to one centigram. The loss is recorded as moisture. For the ash, 1 or 2 grms. of the finely-powdered coke are ignited in a platinum capsule at a bright red heat, until no further loss of weight is observed. A muffle furnace is indispensable where a large number of analyses are carried out simultaneously. The ash determination is always done in duplicate, and the greatest allowable difference between the duplicates is 2 mgrms., such a difference is rare where care is exercised. For the estimation of sulphur in coke, many methods have been proposed. I have used one method exclusively since 1874, in which year it was devised and published ("Chem. News," 1874, page 211) by myself. I mean what is known as the "lime method." It has undergone some important modifications in my hands, and as I often meet with singular "sports" from this method, I take the opportunity of describing it as now used in my laboratory. One gm. of coke in fine powder is mixed in a round bottomed platinum capsule with approximately 1 gm. of half hydrated caustic lime (see foot-note), moistened with 1 c.c. of water, rapidly dried, and heated in a muffle at bright redness, till all carbon has disappeared. The assay is then cooled, transferred to a 6-oz. conical beaker, 20 c.c. of cold distilled water added, and then 5 c.c. saturated bromine water. Solution is then effected by the addition of  $7\frac{1}{2}$  c.c. pure strong HCl, and boiling for five minutes. The solution is filtered through a 9 c.m. Swedish filter paper. The filtrate must be bright. If not, it is passed a second time through the filter. The empty beaker and the filter are then washed three times respectively, the beaker washings being passed through the filter before the latter receives its three washes.

The filtered solution is boiled, and whilst boiling, 10 c.c. of 5 per cent. barium chloride solution are run in from a pipette, in such a way that the boiling is not sensibly checked. The boiling is continued for half an hour, and the beaker is then kept on the hot plate, so that its contents are nearly at boil for at least three hours. Finally, the resulting precipitate of  $\text{BaSO}_4$  is filtered off, washed very thoroughly with hot water, the filter and its contents is loosely folded whilst wet, and put into a platinum capsule. The filter is then slowly charred, the  $\text{BaSO}_4$  is heated to redness for five minutes, weighed, and calculated to sulphur. It must be noted here that the sulphur assays are never, on any account, to be fired in the same muffle simultaneously with ash assays. The latter give rise to free  $\text{SO}_2$ , which is absorbed by the lime of the sulphur assays and converted into  $\text{SO}_3$ .

The carbon is taken by difference, and the analysis is stated thus:—

	Per Cent.
Carbon .....	..
Ash .....	..
Sulphur .....	..
Moisture .....	..
	<hr/> 100.00 <hr/>

Since the introduction of the manufacture of hematite iron into the Cleveland district, a good deal of attention has naturally been attracted to the question of phosphorus in coke. According to my experience, the proportion of this element in different coke varies from 0.005 per cent. to 0.017 per cent., and it is a point which ironmasters cannot afford to neglect if they are to undertake to guarantee low phosphorus irons for any acidic method of steel making. I have found the following method of determining phosphorus in coke to be convenient, and to yield check results on duplicate assays of any given sample:—Ten grms. of the coke to be assayed are spread out on flat trays of platinum and heated in a muffle until burnt to an ash. This is finely ground in an agate mortar, transferred to an ordinary 8-oz. beaker, and treated with 20 c.c. of brominated HCl. The mixture is digested at near boiling for one hour, the beaker being covered with a watch glass to prevent too rapid evaporation of the HCl. The watch glass is then drawn aside, and the greater part of the HCl is evaporated as quickly as is safely possible. The solution is now diluted with 20 c.c. of water. It is filtered into a conical flask, and the residue and filter are washed with distilled water. Filtrate and washings should not exceed a bulk of 45 c.c. Fifteen c.c. of strong ammonia are now added to the contents of the flask, and this is neutralised by cautious addition of nitric acid from a small pipette. When resolution takes place, dilute ammonia is dropped in till a faint opalescence appears, and this is taken up with a few drops of nitric acid. All these operations are carried out at near boiling. The faintly acid solution now receives a further addition of  $2\frac{1}{2}$  to 3 c.c. of strong nitric acid, and then 5 c.c. of a 10 per cent. solution of ammonium molybdate is suddenly added from a measure (not a pipette), whilst the contents of the flask are being briskly agitated. The solution should remain quite clear for a second or two, and then the yellow ammonia-phosphomolybdate makes its appearance in a granular form which rapidly settles out. When this takes place as described, the experiment is almost certain to succeed. The flask is heated to about  $90^{\circ}\text{C}$ . with constant shaking for five minutes, and then the precipitate is filtered off on a hardened filter paper, washed three times with 1 to 50 nitric acid, dried in the water-oven for  $\frac{1}{2}$  to  $\frac{3}{4}$  hour, brushed off the filter into the balance scoop and weighed. The weight in parts of a gm. multiplied by 0.163 gives the percentage of phosphorus in the coke.

**Mechanical and Chemical Analysis connected with Coal Washing for Coking Purposes.**—I have already alluded to

NOTE.—The half hydrated lime is made by calcining marble, and dividing the calcic oxide so obtained into two equal portions. One of these has added to it exactly the weight of water to form  $\text{Ca}(\text{HO})_2$ , and is then mixed with the other half. This leaves a mixture to which more water may be added without fear of loss by spattering.

the utilisation of inferior seams of coal for coking. It will be unnecessary to remind members of this Section of this Society of Chemical Industry that for at least a quarter of a century efforts have been made to improve the condition of certain qualities of coal by various washing processes, differing in elaboration from the ordinary long wood trough with its screens and settling ponds, to the wonderfully complete system of the Lubrig Company of most recent introduction. As the construction of washing plant varies, so does the cost, which may be from 250*l.* to 10,000*l.* or more, but, whatever the system employed, it has recently become the practice for coal owners to enquire to what extent the coal they propose to wash will benefit from the treatment. Coals differ very greatly in their amenability to washing processes, especially those processes depending upon gravity. A coal containing a hard stony waste is readily cleaned, whereas coals containing light carbonaceous shales, whose ash runs to 18 or 20 per cent., whilst their gravity is only a few points above that of the clean coal, will resist all ordinary treatment.

Again, the question may be one in which the sulphur only is involved. There are certain coals with a low ash and a very high sulphur, and it is often a matter for enquiry whether the proportion of sulphur can be reduced by washing. These questions are seldom directed to the whole produce of a mine. In the majority of cases it is what is known as "rough small," that is, the coal which remains when the screens have separated the more valuable descriptions, which is subject to washing. This is not a paper on coal-washing but in many cases it is imperative that coal should be washed before coking, and I have introduced the subject in order to indicate how it may be shown in the laboratory to what extent a given coal may be improved for coking purposes by a given method of washing. I can best illustrate the lines on which the procedure runs by giving one or two actual examples:—

A sample of "rough small" coal sent for analysis will probably be divisible into five different portions, viz.:—"Nuts," "Peas and Pearl," "Pearl and Duff," "Washer Waste" and "Coal lost in Washer Waste." In order to separate quantitatively these different portions, two sieves are required, a  $\frac{1}{2}$ -in. mesh and a  $\frac{3}{4}$ -in. mesh, a good supply of calcium chloride solution of about 1.35 specific gravity, and a tall glass cylinder which will hold 3 litres. For the analysis, 500 to 1,000 grms. of the air-dried sample are taken according to the proportion of "small" it contains. This is thrown on to the  $\frac{1}{2}$ -in. sieve. The "nuts" are left on the sieve and are weighed. The portion passing the  $\frac{1}{2}$ -in. mesh is then put on to the  $\frac{3}{4}$ -in. sieve. "Peas and pearl" remain on the sieve and are weighed. These two portions are now carefully examined for shale and stone, which are picked out, the weight deducted in each case and the combined weight is added to that of the washer waste. The portion passing the  $\frac{3}{4}$ -in. sieve is now treated with the calcium chloride solution in the glass cylinder. This must be done by half filling the cylinder with the solution, and then carefully shooting in the coal from a smooth scoop. The mixture is then very thoroughly stirred with a smooth wooden rod. It is absolutely necessary that every particle of the solid should be wetted. The cylinder is now filled up to within about 2 ins. of the top and the mixture stirred repeatedly during two or three hours; it may then be allowed to stand at rest for 18 or 24 hours. At the end of this time the glass jar is examined and the clean coal is found at the top, a clear portion in the middle, and all the separable earthy impurities at the bottom. A large porcelain basin is now filled over two-thirds with clean water and the cylinder is tilted about it, when, with a little careful management the whole of the coal can be made to fall into the water. The rest of the manipulation is only a matter of thorough washing with the aid of fine cloth filters for the smaller particles of coal. When the washed coal is dried and weighed, it stands as "pearl and duff." It only remains now to wash, dry, and weigh the waste, and the mechanical analysis is complete. What has been done so far shows the amount of waste the coal will give on washing. But the cleaned and washed coal is then analysed for ash and sulphur, and the complete analysis stands as follows in the example selected:—

*Composition of the Air-Dried Sample:—*

	Per Cent.
"Nuts," from 1 in. down to $\frac{1}{2}$ in. ....	34.40
"Peas and pearl," from $\frac{1}{2}$ in. down to $\frac{3}{4}$ in. ....	9.15
"Pearl and duff," below $\frac{3}{4}$ in. ....	47.00
"Washer waste" .....	6.52
"Coal lost in washing" .....	2.93
	100.00

*The washed coal yields:—*

Coke .....	65.95
Volatile matter .....	34.05
	100.00
Ash in washed coal .....	4.67
Sulphur in washed coal .....	1.62

Assuming that the coal contains  $\frac{1}{10}$ ths of the sulphur contained in the coal, the composition of the dry coke would be—

Carbon .....	91.54
Ash .....	7.06
Sulphur .....	1.40
	100.00

It now only needs comparison with the analysis of coke from the same coal untreated, to show what the gain in quality (if any) is.

Before leaving this part of my subject I will ask permission to quote another example where the problem is much more complicated than in the one just given. A sample of "peas and duff" had been washed, and it was required to know how it differed from the unwashed article, and what proportion of stony waste it retains, also what proportion of coal was passing off with the stony waste. Upon my answer to these questions depended largely the erection of a very expensive plant. I asked to be supplied with samples of the original "peas and duff," the same washed by the process in use, and a sample of the stony waste. In this case the sieves were not used as the samples were too fine. The calcium chloride method was adopted, and the following results were obtained:—

	"Original."	"Washed."	"Washer Waste."
Mechanical analysis:—	Per Cent.	Per Cent.	Per Cent.
Good coal down to "pearl," .....	67.40	89.29	4.90
"Fine duff" .....	1.80	2.90	3.55
"Stony waste" .....	27.80	7.90	92.45
	100.00	100.00	100.00
Chemical analysis:—			
Fixed carbon .....	48.90	60.64	Omitted.
Volatile hydrocarbons .....	29.50	31.97	
Ash .....	18.30	5.00	
Sulphur .....	1.47	0.97	
Moisture .....	1.83	1.42	
	100.00	100.00	
Yield of coke .....	67.20	65.65	
Ash in coke .....	27.30	7.60	
Sulphur in coke .....	1.00	0.73	
Fixed ash in coal .....	2.75	2.22	
Free ash in coal .....	15.55	2.78	

Shortly summarised, the foregoing analyses prove that the washing process in use is capable of removing 82.23 per cent. of the free ash from the coal along with 33.03 per cent. of the sulphur, resulting in a diminution of 19.70 per cent. of ash in the coke, and 0.36 per cent. of sulphur, whilst in effecting this improvement, there has been a loss of 7.55 per cent. of coal with the "washer waste." It is, however, necessary to carry the enquiry a step further in order to ascertain what would be the gain in quality, and what the ultimate loss of coal when using the most perfect type of washing plant. In order to arrive at this information, the two grades of coal, namely, "pearl" and "fine duff,"

recovered in the foregoing mechanical analyses, were separately subjected to chemical analysis. The following are the results obtained in the examples quoted :—

	"Original."	"Washed."	"Washer Waste."
	Per Cent.	Per Cent.	Per Cent.
Good coal down to "pearl":—	64.65	64.55	67.55
Coke.....	35.35	35.45	32.45
Volatile matter.....	100.00	100.00	100.00
Ash in coal.....	2.60	2.70	14.55
Sulphur in coal.....	1.00	1.02	1.59
Ash in coke.....	4.00	3.25	21.50
Sulphur in coke.....	0.84	0.79	1.11
"Fine duff":—			
Coke.....	67.40	68.10	68.90
Volatile matter.....	32.60	31.90	31.10
	100.00	100.00	100.00
Ash in coal.....	5.00	4.60	16.48
Sulphur in coal.....	1.07	0.95	1.90
Ash in coke.....	7.40	9.70	23.80
Sulphur in coke.....	0.79	0.70	1.38

In order to avoid confusion, the whole of the foregoing analyses are rendered on the air-dried samples.

The general conclusions to be drawn from the example just quoted are:—

1st. That the sample in the original is not fit for coking purposes.

2nd. That by perfect washing it yields 72.20 per cent. of coal, and that the whole of this is well adapted for coking.

3rd. That the sample which is washed at the colliery is of very fair quality for coking purposes, the ash being 7.60 per cent. and the sulphur 0.73 per cent., although the presence of practically 8 per cent. of stony waste shows that it is imperfectly washed. It is shown also that it is susceptible of great improvement by perfect washing, for when perfectly cleaned, the coke it yields contains only 3.50 per cent. of ash and 0.77 per cent. of sulphur.

4th. That with regard to the sulphur the colliery washer brings it down to as low a figure as can be got by perfect washing.

5th. That the total loss of coal resulting at the colliery washer is only 2.00 per cent. That this coal is of very inferior quality. It averages 15.50 per cent. of ash and 1.70 per cent. of sulphur. That if recovered (which could only be done by perfect washing) and spread over the perfectly washed coal, it would raise the ash in the coke from 3.50 per cent. to 5.00 per cent., and the sulphur in the coke from 0.77 per cent. to 0.83 per cent. It was quite clear that in this case the erection of a more perfect washer could not have improved the quality of the coke whilst saving the coal, and that the coal was not worth saving. It is probable that, had the proposed scheme been carried out, it would have entailed an annual loss to the colliery of nearly 500l.

*Discrimination of the Origin of Coke.*—It is sometimes required to know whether two or more cokes have a common origin. The matter is simple enough when the proportions of ash and sulphur in each are widely different. When these are closely in agreement, it is best to resort to complete analysis of the ash of the samples. Here is a case in point:—It was required to know whether three samples of coke were from one and the same seam of coal in the same pit. They were dried and the ash and sulphur were determined in each with the following results:—

	No. 1.	No. 2.	No. 3.
	Per Cent.	Per Cent.	Per Cent.
Ash.....	9.15	8.20	9.60
Sulphur.....	0.87	1.37	0.98

Considering the variations found in these constituents in samples from bulk, I thought it unsafe to rely upon these indications, as the matter was a very important one, and therefore had recourse to the complete analysis of the ash, when the following results were obtained:—

	No. 1.	No. 2.	No. 3.
	Per Cent.	Per Cent.	Per Cent.
SiO <sub>2</sub> .....	47.80	38.32	46.87
Al <sub>2</sub> O <sub>3</sub> .....	33.82	26.52	33.45
Fe <sub>2</sub> O <sub>3</sub> .....	10.15	22.96	11.01
Mn <sub>2</sub> O <sub>3</sub> .....	Trace.	Trace.	Trace.
CaO.....	3.47	6.46	4.43
MgO.....	1.60	2.51	1.40
K <sub>2</sub> O.....	0.56	0.23	0.25
Na <sub>2</sub> O.....	0.56	0.23	0.64
P <sub>2</sub> O.....	Trace.	Trace.	Trace.
SO <sub>2</sub> .....	2.21	2.80	1.92
	99.97	100.06	99.97

On the strength of these analyses, I felt justified in reporting that Nos. 1 and 3 had the same origin, whilst No. 2 had a totally different origin.

*Excess of Moisture in Coke.*—Disputes occasionally arise as to the proportion of water in coke. As coke is drawn from the ovens in an incandescent state, large volumes of water quickly applied are necessary to prevent loss by oxidation, and very considerable judgment has to be exercised to prevent excessive quantities remaining in the coke when slacked. I have known a sample come off the bench with over 11 per cent. of water; but as a rule, samples received for analysis do not exceed 1 per cent., and in the majority of cases 0.70 per cent. is the maximum limit. As to the highest possible proportion of water a sample of coke can contain, I have the following results from a recent experiment. A number of pieces of hard blast-furnace coke, dried at 212 F., weighed 399 grms. After soaking in cold distilled water for 24 hours, and freeing from extraneous water by dabbling with a sponge, they weighed 475.5 grms., giving a gain of 76.5 grms., or 19.17 per cent. I have met with no such proportion in practice. In 1894 I followed 16 trains of coke from various localities to their destination after a heavy rainfall of some hours duration. All these cokes were analysed at the ironworks laboratories by myself, after sampling by the method I have described as No. 6. The lowest moisture was 2.30 per cent., and the highest 12.36 per cent. Average, 5.25 per cent.

*Mechanical Condition of Coke.*—This is a matter upon which the analyst is often asked to report. The most he can fairly say is whether the sample is hard, dense, and of good colour. I have tried to arrive at a standard of mechanical condition by dropping columns of coke of nearly approximate weight from measured heights. I failed to get consistent results from different samples of the same coke from the same delivery; and my opinion is that it is not a laboratory question, save in so far that the analyst is perfectly justified in giving his opinion of the respective value, for example, of "black ends" and "bright coke," when he can base that opinion on chemical analysis and practical knowledge.

In bringing this paper to a close I may refer to some curiosities of coke analysis.

*Coke-Oven Flue Dust.*—The analysis of coal or coke-ash serves to show that its composition is fairly complex. It has often occurred to me that metals capable of volatilisation might reasonably be expected to occur in coal, and that the flue dust of coke-ovens would be a substance which would repay investigation. One would not, for example, expect to find zinc in the ash of either coal or coke, but that it exists in coal in some cases is beyond doubt. I have myself detected zinc oxide in coke-oven flue dust in two

instances. The samples I examined had the following percentage composition:—

	No. 1.	No. 2.
	Per Cent.	Per Cent.
S.O. <sub>2</sub> .....	23.37	34.67
Al <sub>2</sub> O <sub>3</sub> .....	18.96	29.08
Fe <sub>2</sub> O <sub>3</sub> .....	0.57	8.85
Mn <sub>2</sub> O <sub>3</sub> .....	Trace	Trace
PbO .....	Trace	Trace
ZnO .....	13.51	24.04
CaO .....	1.37	1.37
NaO .....	0.99	0.96
KCl .....	0.59	Omitted
NaCl .....	1.11	Omitted
H <sub>2</sub> O .....	3.89	0.15
SO <sub>2</sub> .....	None	None
	99.37	89.12
Metallic zinc .....	34.91	19.29

*State of Existence of Sulphur in Coke.*—The question of the occurrence of sulphur in forms other than that of sulphides of iron has been investigated by quite a number of observers, and it has been sought to prove that such of the sulphur as existed in combination with alkalis or alkaline earths did not combine with iron in the blast furnace. This no doubt is the case; but although it is quite a quarter of a century since this question first attracted attention, blast-furnace managers are as shy as ever of sulphury cokes. I am not at all clear that we possess a reliable method for the separation of oxidised sulphur compounds or soluble sulphides from sulphides of iron when they exist together in coke. I have never been able to find more than very insignificant amounts of sulphur which could be got out of north-country cokes by boiling with sodium carbonate solution. However, this is a debatable point. I have found one compound of sulphur in certain cokes, which is very embarrassing to the analyst unless great precaution is taken in grinding the sample for analysis. This is a magnetic iron sulphide, which may readily be sorted out of a roughish sample with the aid of a magnet. It contains, according to my analysis, as much as 16 per cent. of sulphur and is difficult to reduce in a mortar. It occurs in cokes containing a low and ferruginous ash. A good plan of securing its proper diffusion throughout the sample is to reduce to fine powder, pass this through a 70-mesh brass bolting cloth, and stamp the coarse particles in a steel diamond mortar until all will pass the 70 mesh, when the whole is mixed carefully in the Wedgwood mortar once more.

*Occurrence of Soluble Salts in Coke.*—On treating a considerable weight of powdered coke with distilled water, and agitating frequently for four or five days, varying proportions of matter dissolve out of different samples.

In the case of three varieties of West Durham coke the following results have recently been obtained in my laboratory:—

	No. 1.	No. 2.	No. 3.
Percentage of soluble matter dissolved by the coke.	0.08	0.27	0.124

In all these cases calcium and magnesium were the only metals found in weighable quantity in solution, and the acid radicals were thiosulphuric, sulphurous, and sulphuric. There were no soluble sulphides. It is exceedingly probable that the salts dissolved out of coke by even air-free water, are oxygen derivatives of the calcium and magnesium sulphides, which must exist in the coke before it is slacked. The addition of water to incandescent carbonaceous matter containing an admixture of calcium and magnesium sulphides, would, of necessity, lead to complicated reactions, and, given free access afterwards to air and moisture, it is not surprising that soluble sulphides are no longer to be traced.

## DISCUSSION.

Dr. H. S. PATTINSON had been much interested in Mr. Stock's paper. He agreed with Mr. Stock that the importance of proper sampling could not be over-rated, and he thought that the method adopted by the author of the paper of estimating the whole pieces and the small breeze was a very good one, but a method which could not always be carried out. On Tyneside, where samples had often to be taken as the coke was being loaded into ships, the practice of his firm had been to take long sections of the coke as it was on the spouts, and in that way probably a column from each truck would be secured, the sample being then broken down as described by Mr. Stock. With regard to the breaking down of the sample, if this were done on an iron plate and the crushed sample then ground fine on the same plate the ash of the coke would be very considerably increased, the sharp hard particles of coke causing very appreciable wear of the iron surfaces. Of methods of sulphur testing he (Dr. Pattinson) had not much experience, as he invariably used the method described by Mr. Stock. With regard to phosphorus in coke, that was a constituent they were not often asked to determine, but they usually found the amount of phosphorus in Durham coke to run from 0.01 to 0.03 per cent. The presence of more than 0.03 per cent. would cause an iron maker to seriously consider whether he ought not to change his coke.

Mr. W. W. PROCTOR said he always used Mr. Stock's method of estimating sulphur, and had found it very satisfactory. He would like to ask Mr. Stock whether he had found that the insoluble portion contained phosphorus? Lately in the *Comptes Rendus* a writer had stated that no wet method gave the whole of the phosphorus actually present, and that in all cases the fusion method gave a higher result than the wet processes.

Dr. H. S. PATTINSON said that their experience had been that in some cokes all the phosphorus could be got into solution, but that in some cases where, for instance, titanous acid was present this was not possible. On the whole, their experience led them to believe that there was not very much difference between the two methods.

Dr. BEDSON asked whether the apparent discrepancy between Dr. Grace Calvert's results and those of other analysts with regard to the extraction of sulphur with sodium carbonate solutions, might not be owing to the fact that Calvert worked with Lancashire coke.

Mr. W. F. K. STOCK, in reply to Dr. Pattinson's remarks concerning sampling, agreed that the rubbing fine of the sample on the bucking plate was quite inadmissible. He used a chilled steel bucking plate, but even with that it was quite easy to increase the ash of the coke by 0.2 per cent. owing to the steel particles rubbed off. With regard to Mr. Proctor's question, he (Mr. Stock) thought that the writer in the *Comptes Rendus* was at fault in that he attempted to extract his phosphorus with *aqua regia*, but it was well known that if much phosphorus was present the nitric acid would have little effect upon it until the acid was largely broken up. For his own part, he had never found any difficulty in extracting the phosphorus with strong hydrochloric acid. In fireclays with, perhaps, 3 per cent. of titanous acid it was often very difficult to extract the phosphorus, but this would again depend upon the condition in which the phosphorus was present—if the phosphorus and titanium were in combination, it was very difficult to separate them. There was another point with regard to the fusion method for estimating phosphorus, and that was that he had never met with a sample of sodium carbonate free from phosphorus. In reply to Dr. Bedson's suggestion it seemed probable that Dr. Calvert's results might be due to the cause he mentioned. The whole practice of coke-making had changed in the last 30 years, and one had to deal with varieties of patent oven cokes and others never met with formerly. If Dr. Calvert's experiments were carried out with soft coke, he probably would get out the sulphur by his method, but with modern hard cokes it seemed too intimately held by the carbon. He had never been able to extract more than a trace of sulphur by Dr. Calvert's process.

## SUPPLEMENTARY NOTE. April 17th, 1897.

At the close of the paper the Chairman drew attention to a statement by Louis Campredon (Comptes Rend. 1896, **123**, 1006—1003) to the effect that when very finely powdered coal-ash is heated with concentrated HCl for 15 or 20 hours the whole of the phosphoric acid is not dissolved, and that as much as 10 per cent. or even 25 per cent. of the total phosphorus present may be left in the insoluble residue.

Dr. H. S. Pattinson spoke of the probable presence of titanium in coke-ash, and of its ascertained action in retarding the complete separation of phosphorus. (This Journal, 1895, p. 433.)

I have since analysed several samples of coke for phosphorus, and I have in four cases tested the soluble and insoluble portions for that element. My results, as shown in the subjoined table, substantially confirm those of L. Campredon as to the inability of HCl to dissolve all the phosphorus. But I did not find, as mentioned by him, that the temperature at which the incineration took place had any influence on the result, nor did I find any titanium in these samples.

	High-Phosphorus Coke.		Low-Phosphorus Coke.	
	No. 1.	No. 2.	No. 3.	No. 4.
Percentage of P dissolved in one hour by brominised HCl.	0.064	0.062	0.0047	0.0044
Percentage of P recovered by fusing residue with pure Na <sub>2</sub> CO <sub>3</sub> .	0.006	0.003	0.0006	0.0013
Total percentage of P...	0.070	0.072	0.0053	0.0057
Ratio of soluble to insoluble P.	100—2.37	100—4.34	100—12.76	100—29.54
Percentage of titanium in ash.	None	None	None	None

According to these results, fusion with alkaline carbonate must be resorted to when the total phosphorus is required; but the method given in the body of my paper still remains a rapid means of sorting high- and low-phosphorus cokes.

## MICRO-CHEMICAL EXAMINATION OF ALLOYS.

BY J. E. STEAD.

(This Journal, 1897, 200.)

## DISCUSSION.

Prof. H. Lott wished to draw attention to two points. In the first place, if he had understood Mr. Stead correctly, the latter had stated that the result of Prof. Arnold's work was to show that the gold in the gold-bismuth alloy was not in an allotropic condition. He (Prof. Louis) had attacked the problem some time ago in a totally different way, namely, by making various gold alloys, and then dissolving out the alloying metal, a typical example being the parting of gold cornets. In every case he obtained the gold in a brown, spongy, and sometimes highly voluminous mass, the specific gravity of which was always markedly higher than that of ordinary gold.\* As the gold was thus liberated in an allotropic condition he concluded that it existed in this state in the alloy itself. At the same time he so far agreed with Mr. Stead's view that he did not hold that the brittleness of the alloy was due to an allotropic modification of the gold, because he had obtained similar results in his own experiments, whether the alloy treated were brittle (gold and lead, &c.) or quite malleable (gold and silver, &c.).

With respect to the tin alloys, he had seen something of the arborescent figures produced by etching surfaces of commercially pure tin, just as shown by Mr. Stead; he wished to know whether Mr. Stead had investigated microscopically the structure of tin with just sufficient impurity

in it to destroy the "cry." It was well known that very small amounts of certain metals (antimony, &c.) would prevent tin from giving the characteristic "cry," and he would like to know whether the loss of this property was accompanied by any marked change in the micro-structure of the metal.

Mr. T. W. Hougl said that he was much interested in Mr. Stead's account of the defects in steel rails. In his own experiments on segregated steels he etched the surface of the section of the entire ingot, and in that way the segregated portions could be observed standing out in sharp lines running through the normal structure of the steel. Though he had worked a good deal with etched specimens, he was somewhat sceptical as to the value of the mere examination of the etched surface. Mr. Stead's method of supplementing this examination by a treatment with acid and the extraction in this way of definite compounds was however capable of yielding much information. He had never seen crystals of cyano-nitride of titanium on an etched surface, yet he had shown that something like 2,000,000 crystals of this substance were present in every cubic inch of the alloy examined, and that they could be extracted by suitable treatment with acids.

May 26th (Nottingham).

Meeting held on Wednesday, March 24th, 1897.

MR. F. J. R. CARULLA IN THE CHAIR.

## ON HEHNER'S BROMINE THERMAL TEST FOR OILS.

BY L. ARCHBUTT, F.I.C.

The heat of combination of oils and fats with bromine has been made the basis of a new thermal test by Hehner and Mitchell (Analyst, XX. (1895), 146), the value of which depends upon the fact that there is in the case of most oils and fats, a nearly constant ratio between the bromine thermal value and the Hübl iodine value. The correct determination of the iodine value takes, as is well known, several hours, and involves the use of a special reagent which cannot be prepared for use at short notice; but the bromine thermal value needs no special reagent for its determination, can be ascertained within half an hour or less, and when multiplied by a constant gives a number which, in general, closely approximates to the iodine value. As an auxiliary test it is therefore most useful.

In my experiments I have found no difficulty in following the method of working described by the authors of the process, and I have not seen the necessity for the modifications introduced by Wiley (Jour. Amer. Chem. Soc. XVIII. (1896), 378), which detract from the simplicity which is one

\* Trans. Amer. Inst. Min. Eng., XXII., p. 117; XXIV., pp. 132 and 705.

charm of the process. Wiley does not give any figures showing that the results obtained by his method of working are any more concordant than those obtained by the author's method.

The reagents required are liquid bromine and methylated chloroform. The test is made, preferably, in the vacuum jacketed (Dewar's) tube suggested by the authors, which can be suspended obliquely, by means of a stiff platinum wire loop, as shown in the figure, from the right-hand

VACUUM JACKETED TUBE.

arm of the balance, a counterpoise made from a piece of thick sheet lead being placed in the other pan. By opening the side door of the balance case, the oil or fat can be dropped straight into the tube, and the exact weight required easily and quickly adjusted. The tube is then slipped out of the wire loop and fixed firmly, by means of its short stalk, in a suitable stand, and 10 c.c. of chloroform are introduced from a pipette. The temperature of the bromine is next ascertained to the nearest 0.1 degree, by stirring with a centigrade thermometer divided into fifths of a degree; and the same thermometer, freed from adhering bromine, is then immersed in the chloroform solution of the oil, which is brought to exactly the same temperature as the bromine. In adjusting the temperature, the outer tube may be warmed by the hand or cooled by immersion in cold water; but the warming or cooling of the solution in the inner tube can take place only by radiation, and is the slowest part of the process. Immediately the temperature has been correctly adjusted, 1 c.c. of the bromine is withdrawn from the bottle, by means of a pipette having a short soda-lime tube fixed to the upper end, with a flexible rubber tube for mouthpiece, and is added to the chloroform solution of the oil, which is immediately stirred with the thermometer until the mercury has risen to the highest point and begun to fall again. This takes only about 15 seconds, and the rise of temperature is the "bromine thermal value." The vacuum tube, when emptied, rinsed with chloroform, and wiped with a cloth, is ready for the next test. Five or six tests may thus be made in an hour.

The numerical value of the "constant" for converting the thermal values into iodine values is liable to vary in the hands of different operators, depending upon the heat capacity of the particular tube and thermometer used, and doubtless to some extent upon the exact method of manipulation. Hehner and Mitchell found it to be about 5.5, and the same for most oils; I have found it rather higher, and not quite the same for different kinds of oil. Thus, in experiments with tallow, olive oil, rape oil, and linseed oil, which are the only oils of which I have tested more than single samples, the factor has varied from 5.7 to 6.2; this variation is, however, partly due to the fact that I have found it advisable not to use the same weight of all oils, for reasons explained further on. The results of my experiments with the four descriptions of oil above mentioned are arranged in Tables 1 to 4, and it will be seen that the agreement between the observed and the calculated iodine values is, in general, very satisfactory. Thus, with the seven samples of tallow, the maximum difference is 1.7; in the case of the olive oils it is 2.5; eleven samples of rape oil gave a maximum difference of 1.5; and the agreement in the case of raw linseed oil is nearly as good. The greatest difference observed in testing ten samples of the latter oil was 4.2, but if we omit the first two samples the difference does not exceed 2.5.

In the case of rape oil, a fairly constant ratio exists between the Maumené figure (the rise of temperature with sulphuric acid) and the Iübl value—a fact which has

already been called attention to in the case of some other oils; but although, in my experiments, the Maumené ratio was only one-third as great as the bromine ratio, the agreement between the observed and calculated iodine values was not so close. Thus, in experiments with eight samples of rape oil, the differences between the Iübl values and the numbers calculated from the Maumené figures varied from 0.4 to 2.7, whereas the numbers calculated from the bromine thermal values gave differences varying from 0.1 to only 1.5. The sulphuric acid thermal test has, no doubt, a special value in certain cases, and gives information not afforded by the iodine number; but as a basis for calculating the latter it cannot compare either for accuracy or simplicity with the bromine test.

The use of liquid bromine is not a serious objection to this process, if one has a good fume cupboard: neither is there any real difficulty in measuring the bromine with a pipette, provided the connections between the pipette, soda-lime tube, and flexible tube are perfectly tight. Wiley's plan of forcing the bromine up into the pipette is a good one, but the action of the bromine vapour would soon harden the rubber stopper in the neck of the flask, and the simpler plan of taking the bromine up into the pipette direct from the stoppered bottle in which it is kept seems preferable. An error of 1.5 per cent. in measuring the bromine makes no appreciable difference in the result, and such an error would be a large one with a narrow pipette.

After adding the bromine, the rise of temperature is very rapid, and a sharp eye is needed to read the thermometer, as the mercury, having reached the highest point, quickly begins to fall; yet, in many consecutive experiments with the same oil, the extreme difference I have observed has been 0.3°. Duplicate experiments, if carefully made, usually agree within 0.1°.

Bromine as purchased, the same fully saturated by shaking in a separator with water and drawing off the bromine, and the same dehydrated by shaking with strong sulphuric acid and redistilling, gave practically the same results, as the following figures, obtained with the same sample of rape oil, show:—

Experiment	Thermal Values (Centigrade Degrees).		
	With Bromine as purchased.	With Bromine saturated with Water.	With Anhydrous Bromine.
1	20.4	20.2	20.1
2	20.3	20.4	20.2
3	20.1	..	..
4	20.2	..	..

In my experiments with this process, the only modification I have found it desirable to make has been in regard to the quantity of oil used. Experiments with tallow, which develops comparatively little heat, showed that by working on 2 grms. and dividing the result by two, gave nearly the same result as working on 1 gm. Therefore, for the sake of greater accuracy, I prefer to take 2 grms. of tallow or any other fat consisting mainly of saturated glycerides, dissolve in 10 c.c. of chloroform, add 1 c.c. of bromine, and divide the rise of temperature by two, to obtain the thermal value. The results in Table 1 were so obtained. Of olive, rape, and most oils, 1 gm. is a suitable quantity; but of linseed oil, which reacts very violently with bromine, 0.5 gm. is best taken and the result multiplied by two. As this doubles the error of observation, a single experiment should not be relied upon in the latter case. The results in Table 4 are the means of two or three experiments made in this way.

The results recorded in this paper prove conclusively that the thermal test with bromine is a most valuable auxiliary method for the valuation of oils, and in laboratories where a large number of oils of the same kind have to be examined, a very great saving of time and labour may be effected by it. The test should also prove useful in the examination of single samples, provided that the apparatus used in making the test has been previously standardised by making with it

comparative determinations of the Hübl iodine values and the bromine thermal values of about half a dozen samples of the same description of oil.

My thanks are due to Mr. Hehner for the vacuum-jacketed tube, and to Mr. Rowland Williams for most of the samples of linseed oil used in making these experiments.

# DISCUSSION.

Mr. OTTO HEHNER said that he was pleased that Mr. Archbutt had had the advantage of working with other oils than he himself was accustomed to, and had got such good

results. There was a lowering of temperature when bromine was dissolved in chloroform. If 1 per cent. of bromine was added to 10 c.c. of chloroform there was a falling of temperature, which, under certain circumstances, might influence the result. This had been pointed out by Wiley, who first dissolved his bromine in chloroform, and used the chloroform solution of bromine.

Mr. F. E. LOTT asked whether the purity of the chloroform had any effect on the process, and how far the varying temperature would affect the results.

Prof. F. CLOWES asked how far the process applied to oils generally. He did not know whether it was a general process, available for all oils and fats.

Mr. J. T. WOOD asked whether any experiments had been made with fish oils. Some years ago they tested, by Hübl's process, in his firm's laboratory, a good many samples of fish oil, and found the iodine values varied very much, and gave no information as to the quality of the oils for leather dressing—the purpose for which they used them. If they had been able to use this test, it would have been a great saving of time.

Mr. ARCHBUTT, in reply, thought that it was desirable that a separate factor should be used for each oil. Every chemist who used the test frequently with oils of the same kind would find that he could, by practice, work out a factor with, perhaps, two decimal places, which would give the iodine value very nearly. With regard to the slight change of temperature when bromine was mixed with chloroform, he did not know whether there was such a change when it was mixed with tetrachloride of carbon, and, if not, it might be advisable to use the latter solvent in some cases. The more experience he had of Mr. Hehner's test the more highly he thought of it. In reply to Mr. Lott, he had only used pure methylated chloroform in his experiments, and he had not observed that any difference in the results was caused by the varying initial temperature, which was that of the atmosphere. In reply to Dr. Clowes, Mr. Hehner had tested a large number of oils, and in nearly every case the results came out very well. In a paper recently read before the London Section, blown oils and Japanese wood oil had been shown to be exceptions. Mr. Wood had asked about fish oils. With these he had not made any experiments, but he did not see why the process should not be applicable.

Mr. HEHNER, in reply to a question as to whether all that was necessary was to have excess of bromine, said that this factor was undoubtedly an arbitrary one, and the whole process must be worked out under the same conditions. If the proportions were varied, although the amount of heat produced might be the same, the amount of measurable heat produced was not the same. He had tried pretty well every oil he could lay hands on. He had not had Japanese wood oil, and should like the opportunity of trying it. He had had a few samples of fish oil, and found them come out very well. Neither was that nor any other process capable of saying what the adulterants in fats were. It could only say that if a certain fat gave abnormal values with the test, they indicated some adulteration. Some fats, as was well known, gave a definite reaction. If two fats, neither of which had a definite reaction, came together, one could at most form some vague inference what were there.

*Meeting held at Glasgow on Tuesday, March 30th, 1897.*

DR. JOHN CLARK IN THE CHAIR.

### THE ANALYSIS OF WORTS, BEERS, AND OTHER BREWING MATERIALS: 1. ESTIMATION OF THE SOLID EXTRACT OF WORTS AND BEERS. 2. ESTIMATION OF THE SUGARS.

BY WILLIAM FREW, PH.D. (MUNICH).

THE necessity of adopting certain standard methods for the analysis of the raw materials and of the finished products of any manufacture is being day by day more generally recognised. Unless two distinct methods can give absolutely identical figures, it is useless comparing the results obtained by those methods. In all statements of results, chemists should indicate clearly what methods have been used, as by this means many mis-conceptions would be prevented, and the analyses rendered of much greater value.

In no department of analytical chemistry is this more necessary than in that of worts and beers, and, I regret to say, in no country is a reform in the methods of stating results more urgently required than in Britain. It is often impossible to tell from the reports of brewing chemists how the various determinations have been carried out. The necessity for uniformity in methods and the statement of analytical results has long been recognised on the Continent, so that it is possible in most cases to compare results of various workers.

There is at present one set of standard methods which is generally recognised by the brewing chemists of Austria-Hungary and Germany, and which has also been adopted by the majority of brewing chemists other than those of Great Britain. In regretting that our chemists do not accept this very general standard, I do not for one moment insinuate that the methods they prefer are less accurate; but, in a case of this kind, we are less concerned with *absolute* accuracy as with *comparable* results, i.e., we do not wish to know absolutely how much maltose, for example, there is in a certain wort, but, rather, how the amount found by a given method compares with that in another wort determined in an exactly similar manner.

The standards which I have adopted in my own practice are those proposed by the convention of brewing experts at the International Exhibition of Forestry and Agriculture held at Vienna in 1890. As I have said before, these are adopted by all the brewing chemists in Germany and Austria, and as the results published in those countries so enormously exceed those recorded in this country, it is much more valuable to me to be able to compare my own figures with the former than with the latter.

I do not intend to enter into the details of those standard methods at present. I would only remark, in passing, that both of the following short notes have a certain bearing upon what I propose to communicate in the future.

#### 1. *The Estimation of the Solid Extract of Worts and Beers.*

The great difficulty which has up to the present been experienced by chemists in the direct estimation of the solid extract of such saccharine liquids as wort and beer, is that of rendering the solids left on evaporation anhydrous. It is practically impossible to get rid of the last traces of moisture in the sticky mass obtained by evaporating a wort or beer when one attempts to do this in the ordinary way by heating in a water- or air-bath, and even when one dries *in vacuo* in presence of a dehydrating agent the process is a tedious one.

Owing to this circumstance the indirect method of deducing the dissolved extract from the specific gravity of the liquid in question has been generally adopted, and various factors and tables are in use for converting the specific gravity formed into percentage of solid extract present. In our own country O'Sullivan adopted the divisor 3.85 for the purpose of converting specific gravity into grammes of extract per 100 c.c. Thus water being taken as possessing a gravity of 1.000 at 15.5° C., he assumed that the specific gravity of a solution of starch-conversion products increased 3.85 for every gramme of solid extract per 100 c.c. of the solution. Thus a liquid containing 10 grms. of solid extract in 100 c.c. at 15.5° C. was assumed to have a density of 1.038.5, so that the weight of solid extract present in 100 c.c. of any such solution could be found by dividing its weight above water by 3.85 (C. O'Sullivan, *Trans. Chem. Soc.* 1876, ii., 130).

Brown and Heron (*Trans. Chem. Soc.* 1879, 35, 596) used a constant divisor 3.86 in a similar manner; this was derived from the relation between the density of a cane-sugar solution of sp. gr. 1.055, and the number of grammes of that substance present in 100 c.c. of the solution.

The last-mentioned factor has been, I believe, generally used by British brewing chemists since that time, for the purpose of converting solution density into grammes of extract per 100 c.c. On the Continent a similar method has been generally adopted, and the specific gravity tables of Balling are used to convert solution density into percentage of solid extract present in worts and beers.

Both of those methods are, however, merely arbitrary, as they express the solid extract in terms of cane-sugar—not in terms of actual extract present.

Various tables have been drawn up to show the relationship between the real extract present in worts and beers and the specific gravity. The Schultze-Ostermann tables for the estimation of the solid extract in clear decoction and infusion worts and in de-alcoholised beers were obtained by determinations of the total solids dried at 70°–75° C. under ordinary pressure. The figures thus obtained, however, are too high, as maltose does not part with all its water of crystallisation under such conditions. H. Ellion (*Zeits. f. angew. Chem.* 1890, 291–298 and 321–326) got over this objection by drying the solids left behind on evaporation at 97° C. in a vacuum. Under these circumstances the extract may be rendered anhydrous, although the process of drying is a very lengthy one.

It will be seen from what follows that the last-mentioned tables represent, with a very considerable degree of accuracy, the amount of solid extract present in worts and beers of widely varying origin. My attention was, however, drawn to the *direct* method of estimating solid extract by the extremely interesting and valuable series of papers on the products of the conversion of starch by diastase recently published by Brown, Morris, and Millar (*Trans. Chem. Soc.*, 71, 72). In the first of these papers the authors describe the apparatus used by them for the determination of the solid extract of saccharine fluids. This consisted of "two small flasks united by a tube furnished with a stop-cock and a side tube leading to a good air-pump. The substance to be dried is introduced into one of the flasks, the other being partially filled with phosphoric anhydride. After exhausting the apparatus, the flask containing the substance is immersed in a water, salt-water, or oil bath, according to the final temperature required, and is slowly heated up to a point at which it ceases to lose weight." The authors state that by means of this apparatus crystallised hydrated maltose may be rendered completely anhydrous in a few hours at 105–106°. The dextrins, maltodextrins, and mixed starch-transformation products require much longer drying and temperatures as high as 120°–130° C. before losing the whole of their water.

It struck me that, if one could by a similar process obtain the desired results more quickly, such a method would prove of great value to the commercial analyst in general as well as to the brewing chemist in particular. I have been fortunate enough to devise a very rapid method of estimating the anhydrous extract present in worts, beers, and solutions of starch-transformation products, which also lends itself to the estimation of the dry matter in such substances as glucose syrup and the other preparations of

glucose used by brewers, as well as for the estimation of moisture in samples of cane and other sugars.\*

This process is a modification of that described by Brown, Morris, and Millar, in the paper previously referred to. The drying apparatus consists of two large wide-mouthed bottles, provided with double-bored rubber stoppers, and communicating with one another by a tube. One of these bottles is immersed in a glycerine bath, so that it may be heated up to any desired temperature, and is connected by means of a short length of rubber tube to a wash bottle containing concentrated sulphuric acid. The other bottle contains a small quantity of concentrated sulphuric acid, and is connected with an efficient filter pump. In carrying out an estimation of the solid extract in a wort or beer, the following is the procedure:—

Wide-mouthed stoppered weighing bottles are provided with coils of filter paper, such as are used for the estimation of fat in milk, and are then heated in an air-bath at 110°–120° C. till constant. Into these are then run suitable quantities of the worts or beers, after which they are at once weighed, the increase of weight being the amount of liquid taken. Of course, no more liquid should be taken than can be totally absorbed by the paper coil, the limit being conditioned by the size of the coil. After weighing, the open bottles are placed for an hour in a drying oven at 100° C., after which they are transferred to the drying bottle of the apparatus described above, the temperature of the glycerine bath having been previously raised to about 110°–120° C. The filter pump is now set in action and a slow current of dried air is allowed to pass through the apparatus, its rate being so regulated that a considerable degree of exhaustion is maintained in the apparatus. After an hour the supply of air is cut off and the apparatus is thoroughly exhausted. The rubber tube connecting the apparatus with the filter-pump is now closed by means of a screw-clip, and the whole is allowed to stand for another hour. Dry air is then admitted, the bottles are removed, allowed to cool in a desiccator, and weighed. They are then once more transferred to the drying apparatus which is again exhausted, and the whole is allowed to stand for an additional hour. The bottles are again weighed, and this process is repeated till no further loss of weight occurs.

In the case of glucose syrups, treacle, and golden syrup, and cane sugars, about 20 grms. of the sample are dissolved in distilled water and made up to 100 c.c. Of this solution an aliquot portion is withdrawn and the dry substance determined in the manner described.

I find that by this means one is able to render the solid extract from beers, worts, solutions of Lintner's soluble starch, solutions of glucose syrups, &c., anhydrous after two, or at the most three, hours' heating. There is, even in the case of solutions of soluble starch, practically no further loss of weight after two hours' treatment. The great rapidity with which such substances lose the last traces of moisture in this method, is due to the extremely fine film of extract distributed over the large area of filter-paper.

This method will, I think, prove useful in other ways. Thus, to give one example, it is sometimes necessary to determine the amount of yeast formed during the fermentation of some saccharine liquid, or to determine the percentage of dry matter in a given sample of moist yeast. In the first case this may be done by making the liquid (after fermentation) up to a definite volume, and determining the dry matter in an aliquot portion by the above method. A portion of the liquid is then filtered clear and the dry matter determined in the filtrate, when the difference between the two results will give the weight of dry yeast present. If we know how much yeast we originally added, we can thus determine the amount formed during the fermentation. In the case of moist yeast a weighed portion may be thoroughly mixed with sufficient water in a drying bottle, the paper coil dropped in, and the whole dried as

above at a suitable temperature until of constant weight. Before concluding this note, I should like to give a few determinations of solid extract in worts and beers, to show how closely the figures given in Ellion's tables correspond with the real extract present:—

Description.	Specific Gravity 15°/15°	Extract, per Cent.		
		Ellion.	Brown, Morris, and Millar.	Found.
Stout wort.....	1.08724	20.18	20.29	19.89
All malt wort.....	1.06398	15.08	15.17	14.89
Malt-ice wort.....	1.03526	8.51	8.59	8.42
Light all-malt wort.....	1.01516	3.72	3.72	3.77
Last runnings of all-malt mash.....	1.00578	1.44	1.45	1.22
De-alcoholised beer.....	1.0094	2.32	2.34	2.11

\* These figures were obtained by using the appropriate divisor for a corresponding starch conversion. This, of course, is not strictly correct, as Brown, Morris, and Millar's divisors refer to the products of pure starch conversions; but, as can be seen from this table, they give closely approximating results in the case of hopped malt extracts as well.

To return now for one moment to the indirect method of estimating the solid extract in worts and beers.

As I have already pointed out, both Balling's tables and the use of the 3.86 divisor give, not the real extract, but the weight of cane-sugar present in a solution of that substance of a similar density; of these two methods, the use of Balling's tables is preferable, as they are computed from the amounts of cane-sugar present in solutions of varying gravity, whereas the 3.86 divisor only expresses the relation between what we may call excess gravity (water being taken as = 1,000) and weight of cane-sugar present in a solution of sp. gr. 1.055.

Ellion's tables, on the other hand, express, with a very considerable degree of accuracy, the real dry extract present in a wort—especially when this is an ordinary hopped or unhopped wort which has not been fermented. The most serious discrepancies between my results and the figures obtained by reference to Ellion's tables are in the cases of the last runnings and of the de-alcoholised beer. In both of these, however, the dissolved extract is of an abnormal character, consisting chiefly of dextrins, albumin, and mineral matter.

The low figure obtained in the case of the stout wort is probably due to the volatile matter present in black malt.

## 2. The Estimation of the Sugars.

In no department of analytical chemistry is uniformity of method more to be desired than in the estimation of the sugars by means of Fehling's solution.

Of the two methods of estimating sugars by Fehling's solution, the volumetric cannot be considered so far as scientific accuracy is concerned; if even approximately correct and comparable results are wished, it must be employed under strictly defined conditions, to which I will refer later on. In the same way the results obtained by weighing the precipitated cuprous oxide are only comparable and really accurate when the precipitation is carried out under certain fixed conditions, and the results interpreted by means of tables constructed for this purpose. These two facts were first pointed out by Soxhlet (*Journ. f. prakt. Chemie.* 21, 227), who showed that the reduction factor between copper and sugar is not constant but variable, and is dependent upon (a) the concentration of the two reacting fluids, (b) the amount of copper present. There is, in fact, no stoichiometric regularity in the reaction, and this, of course, condemns any volumetric method where varying quantities of Fehling's solution are added to a sugar solution of varying strength. Soxhlet's results also show the inaccuracy of using a fixed factor for the conversion of precipitated copper into sugar present.

Maereker (*Chem. Centralblatt*, 1878, 584) showed that the alteration in the reduction factors, caused by the relative excess of copper, is quite regular, and so, by allowing

\* Since this paper was read, the author's attention has been drawn to the description by C. N. Rieber (*Zeits. f. d. ges. Braw.* 13, 97) of a similar method. As the latter, however, used a temperature of only 70° C. constancy in weight was only reached after a very prolonged drying, in some cases 66 hours being required.

varying quantities of the sugar in question to act upon equal quantities of Fehling's solution under certain fixed conditions, definite factors might be obtained, from which tables can be constructed allowing the corresponding quantity of sugar to be read off from the weight of copper found.

Such factors have been determined by several Continental chemists for the various sugars, and their results have been collected by Dr. Ernst Wein, of Munich, whose "Tabellen zur quantitativen Bestimmung der Zuckerarten" are almost universally used by brewing chemists in Germany and Austria. The English edition of these tables, published by Spon, represents my small effort in the direction of uniformity of method in this important estimation.\*

The following is a short description of Wein's method:—

The specified quantity of Fehling's solution is heated in a porcelain basin (holding about 250 c.c.) to boiling, when the prescribed volume of the sugar solution is added to the vigorously boiling liquid, and the whole is allowed to boil for the specified time. In no case should the sugar solution exceed 1 per cent. in strength. The Fehling's solution used in most of the determinations contains 34.639 grms. of crystallised copper sulphate, 173 grms. of pure Rochelle salts, and 51.6 grms. of sodium hydrate per litre; no other Fehling's solution than that specified for the sugar in question should be used.

The precipitated cuprous oxide is then filtered off through a previously tared Soxhlet's asbestos filter-tube fitted on to a filter-flask connected with a vacuum-pump. The filtration and washing with hot water are done as quickly as possible, in order to prevent any cuprous oxide redissolving. After washing sufficiently, alcohol and ether are passed through the filter, in order to facilitate drying. The filter-tube (still in connection with the vacuum-pump) is heated in the Bunsen flame until the cuprous oxide is oxidised to cupric, after which the layer of oxide is reduced to metallic copper in a stream of dry and pure hydrogen. The tube is then weighed, and from the weight of copper found its equivalent in sugar may be ascertained by referring to the table constructed for the special sugar.

The filter tubes are prepared by first of all pushing down a plug of glass wool to the bottom for the asbestos layer to rest on. On to this plug finely-divided asbestos, which has been specially prepared by boiling respectively with nitric acid, strong caustic soda solution, and water (in which it is kept suspended for use), is poured until a sufficient layer is formed. This layer is pressed down by means of a glass rod flattened at the end, and is then washed with hot water. Alcohol and ether are passed through to facilitate drying, and the tube is heated for some time in a stream of hydrogen, cooled and weighed. An alternative method of estimating the copper precipitated is to filter off the cuprous oxide through a double filter-paper, wash with boiling water, alcohol and ether as before, and dry. The precipitate is now detached as completely as possible from the filter and shaken on to a piece of glazed paper. The filter papers are then incinerated in a crucible, the ash being reduced to a fine powder by stirring with a platinum wire. After this the cuprous oxide is transferred to the crucible and oxidised to cupric oxide at a low heat, the flame being increased for a few minutes at the close of the operation. It is necessary by means of a few blank experiments, to ascertain how much copper is absorbed by the filter papers—this, for an ordinary "ash-free" filter paper of 9 cm. in diameter, amounts to about 3 mgms. of cupric oxide for 50 c.c. of boiling Fehling's solution passed through. This method gives concordant results with the Soxhlet tube method when carefully carried out, and may prove useful where it is found difficult to obtain suitable asbestos. The Soxhlet method is, however, much more expeditious.

Brown, Morris, and Millar (Jour. Chem. Soc. 1897, p. 105), and Ling and Baker, have found that Wein's maltose table gives results which are about 5 per cent. too low. As the factors from which this table was calculated were determined in 1885, it is quite possible that the

maltose used was not so pure as that prepared by the English workers. It is my intention, when my other work permits of it, to redetermine the factors for the various sugars, taking all possible precautions to obtain pure samples.

It is nevertheless well to remember that this alleged error does not affect the comparison of results in which Wein's tables have been used, and, as I have said before, that is the more important consideration for the analytical chemist. Owing to the method employed in constructing the tables, they are correct within themselves, and if there is an error due to the use of an impure sample of the sugar in question, it will be a constant one throughout the table.

As I said before, the volumetric method as usually carried out is valueless in point of accuracy. There is, however, one mode of working by which approximately accurate results can be obtained.

A solution of the sugar to be determined is made up containing, in the case of dextrose, not more than 0.58 grm. per 100 c.c., in that of maltose not exceeding 0.88 grm.

Into each of a series of small test tubes, 5 c.c. of the solution is run, and to these varying quantities of Fehling's solution are added. The tubes are placed in boiling water for a specified time, after which they are examined to see in which tube all the copper has been reduced. We thus obtain two limits between which we once more arrange a series of tests, until at last we arrive at a point where the difference between two tubes does not exceed 0.01 c.c. From the volume of Fehling's solution used, we can ascertain from the tables what quantity of sugar is present in 5 c.c. of the solution with which we are working.

I have given this short description of a comparatively old method, firstly, because so little seems to be known about it in this country, and, secondly, because it is the standard method recommended by the Vienna Congress in 1890. The gravimetric method as described by Wein, and the tables calculated by him, are used in practically every scientific station for brewing in Germany and Austria, and it is according to them that the maltose figures of any analyses in my future communications will be obtained.

My earnest desire is that British brewing chemists may soon adopt the Vienna standards, so that analyses, so important to the brewing scientist, may be comparable from whatever part of the civilised world they come.

## DISCUSSION.

Mr. BEILBY asked the author how the results obtained by drawing a current of hot air over the residue, spread in a thin layer over filter paper, compared with those obtained by drying *in vacuo*. He remarked that Dr. Frew had supplemented his drying operation in a vacuum, by passing a current of hot air over the residue, and asked whether the author had found that necessary.

Mr. GRAY remarked that he thought the author had placed the volumetric method for estimating the sugar in a somewhat unfavourable light, and asked if Dr. Frew had not found it possible to obtain reliable and comparable results, by carrying out the estimation of the sugar under precisely the same conditions as had been observed in standardising the Fehling's solution. He stated that the fact was well known that varying results were obtained, depending on the concentration of the Fehling's solution, the rate of addition, the time of boiling, and the concentration of the sugar solution; but that the first of these conditions did not require to be considered in practice, as a Fehling's solution of a definite strength was always used, while the only one of the other factors which was of necessity variable was the last named, and that within comparatively narrow limits. He thought that, with strict adherence to rules laid down in connection with the rate of addition and the time of heating between each addition, comparable results might be obtained by different brewing chemists.

Dr. FREW acknowledged that it was possible to get fairly approximate and comparable results under the conditions laid down by Mr. Gray. His objections to the volumetric method employed in this way, however, were, that it was extremely difficult always to add the sugar solution to the

\* "Tables for the Quantitative Estimation of the Sugars," (Wein,) E. and F. N. Spon, London and New York.

Fehling's solution at exactly the same rate, and that it was necessary for each chemist to determine the factors for his own particular method and make up a table therefrom. He regretted that he had not himself compared the relative speed of drying in vacuo, and by passing a stream of hot air over the substance in question, but he believed that Ellison in his paper had stated that by passing a current of dry hot air through his apparatus the desiccation was rendered more rapid. Brown, Morris, and Millar said that by their method of simply evaporating and drying the sticky mass in vacuum a very considerable time was required to expel the last traces of moisture. There was one advantage in using this modification of their method. Several determinations could be made simultaneously by using a drying bottle large enough to contain three or four weighing bottles, whereas in theirs only one could be made at one time. His modification, therefore, made the process as convenient as the ordinary hot-air oven.

## Obituary.

### HUGO KUNHEIM, Ph.D.

COMMERZIENRATH OF THE CITY OF BERLIN, MEMBER OF THE SOCIETY OF CHEMICAL INDUSTRY, &c.

IN the removal by death of Dr. Hugo Kunheim, Germany has lost one of the foremost among those who have made the German chemical industry what it is. About 65 years ago the father of Dr. Kunheim opened a chemical factory, the business of which grew and prospered remarkably. This factory eventually came under the proprietorship of Dr. Kunheim, who succeeded his father, and under his management enormous extensions were made. He was interested in almost every department of chemical industry, and his firm was the first to establish the manufacture of many important chemicals on German soil. Dr. Kunheim was, however, more specially associated with the manufacture of sulphuric acid, ammonia, borax, liquid carbonic acid, oxalic acid, and potassium salts. He was the first German manufacturer of "yellow prussiate of potash" from gas-liquor, and was Chairman of the Convention of Yellow Prussiate Manufacturers. Dr. Kunheim was also the pioneer of the Sicilian citrate of lime industry. In the year 1873 the city of Berlin purchased his factory on the Kreuzberg for six million marks, the site being required for the extension of the city. Dr. Kunheim was a prominent figure in Berlin society, and in Continental chemical circles generally. It is said that he died very wealthy, and he is known to have been financially interested in about a score of large chemical and electrical undertakings on the Continent. Having suffered for a considerable time from a gradual breakdown of the nervous system, the end at last came on the 22nd ult. Dr. Kunheim was about 62 years of age, and he leaves two sons.

## I.—PLANT, APPARATUS, AND MACHINERY.

### PATENTS.

*Filter Presses, Impts. in.* W. E. Heys, Market Street, Manchester. From J. Hundhausen, Hamm, Westphalia, Germany. Eng. Pat. 6873, March 30, 1896.

THE press is built up of a number of frames *h*, mounted on lazy-tongs *p*, and connected at the joints by india-rubber packing. Each frame is provided with perforated metal filter plates *t*, which are formed with projecting arms *e* and are covered with filter cloth, the arms of adjacent frames being arranged to break pitch, as shown.

THE press ram *f* is operated by the pinion *q* mounted on the screwed spindle *g* of the ram. The liquid is admitted through the pipes *d*, *e*, and, after passing through the filter cloth and plates *t*, it flows off through the passages *s* and gutters *l*. The reversing gear of the driving mechanism is controlled automatically by the movement of a safety-valve lever.—R. A.

*Filtering Material, and Process for Making the Same, An Improved.* F. Jurschinn, L. Schnitzer, and F. Hirsch. all of Vienna. Eng. Pat. 6934, March 30, 1896.

THE material consists of ground quartz cemented together by insoluble silicates and silicic acid, so as to leave pores between the granules. The process consists in "wetting" with water-glass a mixture of ground quartz and wood ashes, pouring or pressing the mass into moulds, where it is allowed to harden, drying the moulded hardened bodies, heating them to a temperature of from 1,000° to 1,200° Celsius, and finally boiling them in water.—V. C.

*Mixed Gases, Separating by Refrigeration, Apparatus for; especially applicable to the Separation of Oxygen from Air.* W. Hampson, Mold, North Wales. Eng. Pat. 7559, April 9, 1896.

THE refrigerating apparatus described in this Journal, 1896, 340 (in which compressed gas is allowed to expand and produce cold, which is intensified by interchange of heat between the compressed and expanded gases), is employed in conjunction with additional apparatus, in which the mixed gases, supplied under pressure, are passed through a reducing valve, and are liquefied at the reduced pressure by the cold generated in the apparatus. The liquefied gases are allowed to boil, thereby cooling the chamber in which the liquefaction takes place, so that a further liquefaction occurs, and simultaneously a separation of the gases is obtained by boiling off one of

them from the mixture. The gas boiled off is also employed to reduce the temperature of the incoming gas.

—R. A.

*Producing Cold by Means of Volatile Liquids, Impts. in Apparatus for.* M. Douane, Paris. Eng. Pat. 9127, April 30, 1896.

To prevent leakage of the volatile liquid from the compressing pump, the piston-rod works through a double stuffing-box, within which the rod is surrounded by a liquid enclosed in a chamber, this liquid forming a hydraulic joint with the rod and also serving to lubricate it. "In a single-acting compressing pump having its crank revolving in a closed chamber, a double stuffing-box for the crank shaft," is also claimed. To provide a greater refrigerating surface in the refrigerating vessel in which the liquid is volatilised, the vessel is made of annular form, by means of two concentric tubes. In another arrangement, the vessel consists of a number of horizontal superposed tubes communicating with each other by vertical branches at the ends. "For obtaining ice directly on the surface of the refrigerating vessel without the use of brine, a vertical tubular vessel is employed"; the volatile liquid is introduced through a small tube against the inner surface of the refrigerating vessel, so that it flows down in a thin film over the same and is evaporated before it reaches the bottom. For detaching the ice from the vessel, warm water is introduced into a tank surrounding the coil through which the volatile liquid is delivered, the heat being conveyed by the volatile liquid to the vessel, so as to warm the latter and detach the ice. —R. A.

*Liquids, Impts. in and relating to Apparatus for Heating, Cooling, and Vaporising.* V. C. J. Ortmans, Brussels. Eng. Pat. 10,338, May 14, 1896.

THE liquid to be heated, &c., is passed through a series or cluster of tubular elements, each element consisting of tubes having concentric sides, and constructed so that the heating or cooling medium may circulate around these sides. The orifices connecting the interior surfaces with the exterior may extend nearly the entire length of each element. In one form of element, two tubes are arranged concentrically, the inner tube being connected at its ends with the exterior surface of the outer tube. In another form, the tube is single at its ends, and is bifurcated along the greater part of its length, so as to form a passage between the branches for the circulation of the heating or cooling medium.—R. A.

*Gas Vessels or High-Pressure Gas Reservoirs.* W. C. Tyler, Waterloo Road, London. Eng. Pat. 24,483, Nov. 3, 1896.

THE sides of the vessels or reservoirs are corrugated, to render them capable of withstanding a higher pressure without materially increasing their weight or diminishing their capacity.—R. A.

*Ammonia and other Volatile Liquids [Refrigerating Apparatus], Safety and Regulating Appliance for Apparatus for Compressing Vapours of.* T. B. Lightfoot, 35, Queen Victoria Street, E.C. From The Gesellschaft für Löhde's Eismaschinen, Wiesbaden, Germany. Eng. Pat. 853, Jan. 12, 1897.

THE compressing cylinder is connected to a closed vessel or chamber containing a safety valve, which is covered by a non-volatile liquid, such as oil, so that when the valve is forced open, a quantity of the liquid escapes through it, thereby preventing the escape of the volatile vapour which is being compressed. The liquid which escapes is returned to the chamber by the action of the compressing piston. The "dead space" of the compressor can be eliminated by introducing liquid into the chamber. The connection between the cylinder and chamber is provided with a valve, so that when the chamber is empty, the apparatus can be thrown in or out of work.—R. A.

## II.—FUEL, GAS, AND LIGHT.

*Scrubber Sprinkling.* F. Burgemeister. J. für Gasbeleucht., 40, [6], 85—86.

THE device used by the author for distributing water uniformly over the packing material of gas scrubbers is shown in the accompanying figure. To an opening in the middle of the scrubber top is connected a pipe about 1 m. long and 100 to 150 mm. wide. This supports, by means of two rods, a convex disc about 80 mm. wide. The disc has its

convex side uppermost and is about 250 mm. below the top of the scrubber. The water falls from the usual funnel and siphon pipe on to the disc, and is thereby broken into very fine spray. A scrubber packed for three-fourths of its height with pebbles showed no accumulations of tar after seven years' use under this system of water-distribution. One spraying disc serves for a scrubber 2 metres in diameter.—J. A. B.

*Illuminating Gas, Combustion of, in contact with Cooled Surfaces.* F. Haber and A. Weber. Ber. 29, 3000—3006.

THE combustion of illuminating gas in flames, which neither smoke nor flicker, or against white hot surfaces, as in the Welsbach burner, is complete, i.e. the combustion products either contain no combustible gases, or contain them only in mere traces. On the other hand, Lewes has shown that the combustion products of gas burning against cooled surfaces (as in gas cooking apparatus, water-baths, &c.), contain considerable quantities of combustible gases. The authors are of opinion that Lewes' experiments were not suitably arranged, and they have therefore studied the question afresh. They examined the combustion products obtained from a large Bunsen burner (burner tube 16 mm. wide, modified as described by Teclé) when working with varying proportions of primary air, and with its mouth placed 18 mm. from the bottom of a tin vessel kept cool by flowing water. Around this vessel a metal strip was soldered to form a V-shaped groove, which acted as a constantly refilling gas-reservoir and from which the combustion products could be collected without prejudicing the admission of air to the flame. The gas drawn from this space, after drying by means of sulphuric acid and phosphorus pentoxide, was led through a weighed carbonic acid absorption apparatus. Thence the gas passed through a white-hot capillary tube (Drehschmidt's method), and then into a series of absorption vessels, in which the newly-formed carbonic acid and water were separately retained. The residue of gas was collected and measured.

The results are given in Table I. (Experiments I., II., and III.), from which it is seen that the determinative factor is the primary air content. The latter part of the table gives the corresponding figures obtained with cooking-stoves of various makes. Of these results, those obtained with the Bouehier et Cie.'s hearth are noteworthy. The construction of the latter is such as to prevent the admission of a sufficient supply of secondary air to the flame, and this causes a considerable alteration in the degree of incompleteness of the combustion and the atomic relation of C : H. The conditions here appear to be the same as those under which Lewes obtained his results. This deviation vanished when the distance between the burner and cooling vessel was increased. From an analysis dependent chiefly on fractional combustion, the author finds the composition of the combustible portion of the combustion products, to be—

CO.	H.	C <sub>2</sub> H <sub>2</sub>	CH <sub>4</sub>	Content of Primary Air.
Per Cent.	Per Cent.	Per Cent.	Per Cent.	
0.3	0.04	0.01	0.015	31 to 32 per cent.

Direct estimation of the acetylene in the gases passing away from a cooled Bunsen flame, led to the following values :—

Primary Air.	Combustion Products.	
	CO <sub>2</sub>	C <sub>2</sub> H <sub>2</sub>
Per Cent.	Per Cent.	Per Cent.
33.49	5.8	0.11
30.62	5.8	0.10
19.14	6.2	0.19
20.57	5.0	0.23

The presence of a cooled surface in the Bunsen flame therefore causes the combustion to be incomplete : the cold surface reduces the temperature of certain of the combustible gas molecules to such an extent that oxidation will not occur when these molecules come into contact with the secondary air supply. The smaller and hotter the flame, the less proportionately is the influence of the cooled surface. The combustion zone is small and the motion of the gas-molecules so energetic that after striking the cold surface they rebound into the flame ; the result of this is that the flame boundary is sufficiently hot to allow of complete combustion with the surrounding atmospheric oxygen.

With a decreasing primary air supply and a larger flame, the reactionless zone increases in depth and also spreads horizontally. The gas particles do not rebound so readily into the flame, and the number reaching the flame surface too cold to burn, increases.

Thus, appreciable quantities of combustible constituents appear amongst the products of combustion ; even completely unaltered gas constituents, such as methane, being found under these unfavourable conditions. There is always present, even before cooling below the combustion temperature, sufficient oxygen to convert this hydrocarbon into carbonic oxide and hydrogen ; this agrees with facts as to combustion proceeding by steps, as explained by Smithells and others. The combustible constituents of the flame gases contain much carbonic oxide and little hydrogen ; this is due to the fact that hydrogen burns at a much lower temperature than carbonic oxide, as shown by Mallard and Le Chatelier.

From the practical and hygienic standpoint, the following are the results obtained :—

Flames striking a cold surface give rise to hygienically important quantities of carbonic oxide only when the primary air supply is small ; when this is high, only minute traces are produced. The loss in heating power due to incomplete combustion with small primary air supply is trifling ; even with a high degree of incompleteness of combustion

By the degree of incompleteness (12) is understood the percentage by weight of CO<sub>2</sub> behind the Drehschmidt capillary calculated on the total carbonic acid = 100. The values in the last column are obtained by considering the CO<sub>2</sub> behind the capillary as being formed from CO.

(= 7) (see note to Table II.), in an illuminating gas giving 600 litres of carbonic anhydride and having a heating value of 5,000 cal. per 1 cb. m., the loss due to this cause is under 3 per cent. The poor economic effect of such combustion is due to the lower flame temperature and to the deposition of soot and tar on the cold surface and the consequent decrease of heat-conducting power.

—J. T. C.

#### Gas, Carburetted by means of Benzene. Hoyer.

J. de l'Eclair. au Gaz. 45, [3], 51—53.

CONTINUING the experiments detailed by Pettré (J. de l'Eclair. au Gaz. 1896, 27) in order to determine the cause of the variations in the rate of enrichment obtained by the use of benzene, it was found that the quantities of that substance required to produce a saving in consumption of 1 litre of gas, commencing with a 109-litre gas, were as follow:—

Lighting power.....	109	108	107	106	105	104	103
No. of grms. of benzene required per cb. m. to gain 1 litre.	0.9	0.9	1.0	1.0	1.1	1.1	1.2

Lighting power.....	102	101	100	99	98	97	96
No. of grms. of benzene required per cb. m. to gain 1 litre.	1.3	1.4	1.6	1.7	1.9	2.2	2.7

i.e., to reduce the consumption from 108 to 103 litres, 5.1 grms. of benzene were needed. The reason for the decreased effect recorded below 104 litres, is due to the inability of the Bengel burner, which was made for consuming 105 litres, to develop the true power of the gas under conditions of slower delivery. The results cited cannot be applied for comparison with those obtained in other forms of photometer than the one (that of Dumas and Regnault) employed.—C. S.

#### Coal-Gas, Purification of: The Use of Atmospheric Air with Lime for. S. Carpenter. J. of Gas Lighting, 1897, 69, [1765], 527.

THE author states that:—(1.) Air should not be allowed to pass up the ascension pipes or go into any part of the hydraulic main. (2.) It should not be admitted at the inlet of the condensers. (3.) Nor should it be allowed to get into the lime purifiers, as it interferes with the chemical action of the lime and the gas. The air oxidises the sulphuretted hydrogen and at the same time fixes the sulphur in the lime. If air be admitted into the purifiers to the extent of (say) 1.5 to 2 per cent., the lime is converted into calcium sulphide, which has very little affinity for bisulphide of carbon. The lime should be converted into "hydrogenated" sulphide of calcium (calcium hydrosulphide), which has, in a high degree, the power of absorbing carbon bisulphide from coal-gas. If air, or any furnace gas, or the gas at the end of the charge where anti-dips are used, be admitted into the lime purifiers just before a box is thrown out of action, the impurities which the lime has already extracted from the gas will be evolved and driven forward with the gas which is being made.

If care be taken that no atmospheric air is admitted either directly or indirectly into the lime purifiers, there will be no trouble with them, and the carbon bisulphide in the gas will keep to about 10 to 15 grains per 100 cb. ft.

Atmospheric air, to the extent of 1 to 1.5 per cent., should be admitted at the inlet of the first oxide of iron purifier, and if sulphuretted hydrogen make its appearance at the top of the first oxide purifier, a small quantity of air should be passed in at the inlet of the second purifier. In this manner, the oxide will last in the purifiers for months instead of weeks.—A. S.

#### Calcium Carbide, Manufacture of: A Furnace for the. L. Bullier. Rev. de Chim. Ind. 1896, 7, [83], 340—341.

A RECTANGULAR structure of brick, three of the walls (up-right) being permanently fixed, whilst the fourth is built up as required from loose bricks held in place by an iron plate. An iron grating, covered with a layer of coke, constitutes the sole (as also the negative electrode) of the furnace.

The positive electrode consists of a bundle of carbon rods supported from, and sliding up and down, an iron pillar. The furnace is worked on interrupted circuit, i.e., the positive electrode is raised (after the current has been turned on) until an arc of suitable length is obtained. Subsequently the furnace is charged at intervals with raw material as required, and its open side bricked up to keep the mass in place. In this system the production of carbide takes place within a comparatively limited area (i.e., the confines of the arc), whereby, it is claimed, the action of the current is greatly intensified; whilst the loss of heat is reduced to a minimum on account of the thick non-conducting layer of material, unacted upon, intervening, between the scene of action and the furnace walls. For the same reason the furnace need not necessarily be constructed of highly refractory materials.—H. T. P.

#### Calcium Carbide, The Cost of Production of. D. Korda. Rev. de Chim. Ind. 1896, 7, [83], 341—343.

IN Europe, the sale price of calcium carbide has, hitherto, not fallen below 300—500 francs per ton, and for smaller quantities the price is at least twice as high. As a consequence, the use of acetylene as an illuminant is restricted to one or two special purposes. The more favourable estimates which have been published from time to time as to the cost of illumination by acetylene, for the most part appear to be based on certain calculations furnished by the Willson Aluminium Co., Spray, N.C., as also by Mr. Willson personally, according to which the cost of production of calcium carbide is variously estimated at 75—100 francs per ton. These estimates, the author considers to be far too optimistic, and he draws attention to the high yield of carbide therein reckoned on (20 lb. per electrical horsepower per 24 hours). Indeed, Willson and Sukert say: "... with improved furnaces ... utilising the waste heat of the furnace gases to the fullest extent ... &c., it is hoped to raise the yield, on the large scale, to 30 lb. per H.P.-day." Now, in no European installation has a yield of 4 kilos. (= 9 lb.) per H.P. been sensibly exceeded. Adopting this figure as substantially correct, the author estimates the cost of manufacture to be, at least, 250 francs per ton of carbide. The remaining data—which conform closely to the conditions obtaining in an existing installation—are subjoined. The available H.P. (hydro-electrical) is assumed to be 2,000, corresponding to a daily output of 8 tons of carbide.

Raw Materials:—	Francs.
5 tons of coke .....	62.50
7 tons of lime .....	112.00
Motive Power.—Assuming 75 fr. to be the annual (360 days) cost of 1 H.P., then 2,000 H.P. per diem.....	500.00
Electrodes.—10 fr. per ton.....	80.00
Salaries:—	
75 labourers at 3.50 fr. ....	425.00
25 " " 5.00 fr. ....	
6 foremen at 6.25 fr. ....	
Repairs.....	400.00
Packing, in barrels, at 1.75 fr. per 100 kilos.	140.00
General Expenses, about 100,000 fr. per annum—a low estimate .....	260.00
Daily expenses.....	1,979.50

or, in round numbers, 250 fr. per ton.

Under present conditions, the above figures are by no means exaggerated; although it is probable that, as progress is made, the expenses relating to repairs, and especially in respect to the number of workmen required, will be reduced.—H. T. P.

#### Acetylene in 1896, Summarised Report on. Rev. de Chim. Ind. 8, 8—12.

WHILE acetylene, in common with ordinary illuminating gas, will burn without exploding, and may be exploded by the combustion of detonating mixtures, it is also capable of explosion on decomposition; but in the gaseous state this decomposition has to be effected by mercury fulminate or a similar detonator. As regards its behaviour in the compressed and liquid conditions, there are as yet no reliable data to go upon.

The calcium carbide at present obtainable contains impurities of two kinds: those attacked by water and those—such as graphite, boride and silicide of carbon, and metallic silicides and carbides—unacted upon by that liquid, but reducing by their presence the gas-yielding capacity of the carbide, sometimes by as much as two-thirds. The active impurities—phosphides, nitrides, sulphides, &c.—yield products which, besides lowering the intensity of the acetylene flame, facilitate the action of the gas on copper.

Liquefied acetylene for lighting purposes is purer than the gas generated direct, but is more expensive, and not without danger. Berthelot and Vieille recently found that an incandescent metallic wire would decompose liquid acetylene, and in so doing develop a force approximating to that of gun-cotton, but that the shock due to a fall from a height of 6 metres caused an explosion of the liquid rather of the nature of combustion than of decomposition, whilst acetylene gas under 10 atmospheres pressure did not explode at all. Decomposition of the gas may also be caused by the heat generated when carbide is acted on by very small quantities of water, and local overheating may result in polymerisation. Compression and sudden checks may also generate sufficient heat to induce dangerous incipient decomposition, but the fracture of the cylinder containing the liquid is only likely to have serious results in case sparks are caused by the friction of the metallic fragments. These dangers, however, may be avoided with care, and should not detract from the practical value of the gas.

It has also been found that acetylene forms no stable compounds with the blood, and is therefore without any toxic action, though capable of producing asphyxiation; and in view of the completeness of the combustion of the flame, no toxic action may be expected from the resulting products.

The high illuminating power and degree of whiteness of the flame are due to the high temperature of the solid particles of carbon, which play the same *role* as the rare earths in the incandescent mantle. The consumption of acetylene per candle-hour varies between 0.643 and 0.8 litre, whilst that of coal-gas in different burners is as follows:—Butterfly burner, 11.5; Argand, 10; Siemens, 3.7; Auer, 2.7 litres.

Probably one of the best results to be obtained from this gas is the enrichment of existing kinds of lighting gas, but the results already obtained are discordant; and benzene may prove a formidable competitor, in view of its lower cost. At present, acetylene is too expensive for motor work, but when the carbide can be produced at a cheap enough rate it may be found advantageous for special purposes where lightness of fuel is a consideration, such as for marine engines, automotors, &c.—C. S.

*Acetylene: Its Dangers and their Prevention.* J. für Gasbeleucht. 1897, 40, 149—153.

A CONFERENCE was held under the auspices of the Berlin Section of the "Berufsgenossenschaft der Chem. Ind.," Dec. 29, 1896, for the discussion of the manner in which it was desirable that the manufacture and use of acetylene should be controlled. Dr. C. A. Martins, who presided, feared that the new industry might be crippled by prohibitive legislation, such as the stringent police regulations in force in Berlin. A careful study of the properties of acetylene, for which the researches of Berthelot and Vieille (Comptes Rend. 123, 523; this Journal, 1896, 793) might serve as a starting point, would indicate to what extent legislation was required.

Dr. Frank thought the dangers of gaseous acetylene had been much exaggerated. With regard to its toxic properties, he and Dr. Weyl had shown that air containing 9 per cent. of acetylene could be breathed for a long period without serious results. The phosphuretted hydrogen in the gas evolved from calcium carbide promoted its combination with copper and increased its explosiveness. This impurity could be completely removed by washing with acid solutions of metallic salts. The explosive metallic compounds were only formed in ammoniacal solutions. When acetylene was stored in gas holders, the confining liquid should be brine, in which it was practically insoluble. The impurities

of low-grade carbide were generally carbon and quicklime, and it did not necessarily give an impure acetylene. No explosive decomposition of acetylene took place when it was passed, under atmospheric pressure, through a tube heated to 600°—1,000°. Large pieces of carbide decomposed slowly in water, as a protecting layer of calcium hydrate formed upon them. Carbide could be safely transported in light air-tight drums, whereas liquefied acetylene required heavy cylinders. Acetylene was inferior to benzene for enriching coal-gas. Dealing in carbide should come under similar restrictions as traffic in explosives and poisons, but the manufacturer should not be unduly hampered.

Prof. O. N. Witt thought that accidents with acetylene had always been associated with its compression. Its critical point and temperature did not render its compression difficult, and the danger must be due to its endothermic character. In this respect it was comparable to modern explosives.

Dr. Th. Elkan considered the dangers were confined to the liquefying of the gas. The so-called "condenser" should be emptied when the work stopped, otherwise a rise in temperature was caused and irresistible pressure within it, owing to the very high coefficient of expansion of liquefied gases. The steel bottles should not be overcharged, and the limit of 1 kilo. of acetylene per 3 litres capacity, which had been laid down by the German railways, might well be observed. Bottles and parts which might come in contact with liquid acetylene should be quite free from copper. He thought compression of acetylene need not be prohibited, provided precautions were enforced.

Dr. Krämer advocated brine instead of water for seals.

Dr. Tiefrunck pointed out that it was necessary to keep the pressure low in generating apparatus. Decomposition of liquid acetylene produced a pressure of 5,564 atmospheres. Special precautions were therefore necessary in its production and storage.

Prof. R. Pietet recommended the introduction of the carbide into a relatively large volume of well-cooled water. Ice sufficed for the cooling in a small plant. Absolute purification before storage was essential. It could be carried out by means of solution of calcium chloride, lead compounds, and sulphuric acid, all cooled to -16°C., at which temperature these liquids did not combine with acetylene. For compression he cooled the gas to -20°C., and then pumped it, under a pressure of about 8 atmospheres, into a long tube kept at -80°C. by the evaporation in a vacuum of  $\text{SO}_2$  and  $\text{CO}_2$ . The liquid so obtained was charged into steel bottles at the same temperature. Bottles thus charged with the pure liquid had been subjected to the most violent shocks, and no explosion had ensued. The explosion at his Paris works, which was attended with fatal results, was caused by mechanical injury to a bottle while in a vice for alteration of the valve. The bottle was a full one, accidentally returned to the works with empties. Acetylene in a holder and in bottles in the room where the explosion occurred had been unaffected by it.

Dr. M. Altschul thought purification absolutely essential, whatever the purpose to which the acetylene was to be applied. The steel bottles should be tested at 250 atmospheres, and only two-thirds filled.—J. A. B.

*Thoria in Thorite, Estimation of.* E. Hintz and H. Weber. Zeits. anal. Chem. 36, [1], 27.

See under XXIII., page 357.

## PATENTS.

*Acetylene Gas, Impts. in Means or Apparatus for Use in the Production and Application of.* T. Holliday, Huddersfield. Eng. Pat. 5813, March 16, 1896.

THE improved apparatus consists of a generator in which calcium carbide is put, and a displacement gasholder with superimposed cistern. The gas passes normally through a cooling coil in the cistern direct to the services, but in the event of over-production, the water, and thereafter the surplus gas, escape through a pipe near the base of the generator into the upper part of the gasholder, by forcing

water therefrom into the cistern; and the gas, and thereafter water, return by the same course when the pressure in the generator falls.—J. A. B.

*Acetylene, Improved Apparatus for Generating, and Utilising the same for Lighting and Heating Purposes.* R. Reitmeyer, London. From A. Cerekel, Paris. Eng. Pat. 6719, March 27, 1896.

THE apparatus consists of a generator containing carbide on trays, having at its base a pipe leading to a water reservoir, and at its top a gas-outlet pipe to a bell gasometer. The bell, as it rises, closes a tap on this pipe, and thus causes the pressure to increase in the generator, and force the water therefrom to the reservoir. So soon as all the water has thus escaped, a ball which was floating on the water drops into the mouth of the pipe and prevents the escape of gas thereby. The bell, as it falls, re-opens the gas tap, and as the gas escapes from the generator the water returns thereto.—J. A. B.

*Acetylene Gas, Impts. in Apparatus for Generating and Storing; especially suitable for Use in Portable Installations.* J. C. Bayley, Bourne-mouth. Eng. Pat. 6739, March 27, 1896.

THE object of the invention is to avoid the loss of acetylene due to its absorption by the water in contact with which it is usually stored. It is attained by means of an expandible storage chamber of "concertina" pattern, set within a closed water tank, which communicates with an upper cistern supported by springs, so that this cistern rises or falls, according to the amount of water driven out of, or drawn into, the lower tank by the expansion or contraction of the flexible storage chamber, and thus maintains a constant head of water and uniform pressure on this chamber. It may also be attained by means of a float covering the surface of the water in a storage chamber, and preventing the gas coming in contact therewith. The water taken from the tanks to the generator is replaced from a water main, provided with an automatically operated cock. A double valve operated by a single handle serves to open and shut inlet and outlet water pipes, and gas exit of a generator simultaneously, as required in practice.—J. A. B.

*Acetylene Gas, Apparatus for the Automatic Generation and Distribution of.* A. Tobler, Garenne-Colombes, France. Eng. Pat. 12,662, June 9, 1896.

THIS consists of a series of generators connected at top to a collecting pipe leading to a bell gas-holder, and of a water reservoir closed by a weighted piston. The generators being charged with carbide, water flows from the reservoir through a non-return ball valve into the lower part of the first of the series, and when the carbide therein is exhausted, the water flows on through another valve to the next generator, and so throughout the series.—J. A. B.

*Acetylene Gas or Acetylene and Carbonic Acid Gas combined, A Gas Plant and System to Make and Produce.* R. Goodwin, Dublin. Eng. Pat. 17,644, Aug. 10, 1896.

THE plant consists of one or more lead-lined generating chambers, to be charged with carbide or a mixture of carbide with some substance which produces carbonic acid when treated with acidulated water; a reservoir for such water, with feed pipes to the generators and a purifying vessel containing in one chamber lead wire filling, and in another chamber copper sulphate. The vessels are provided with gas-tight lids, and the feed and exit pipes with suitable cocks and pressure gauges. It is stated that, admixed with carbonic acid, a more perfect combustion of the acetylene is secured, without the deposit formed under ordinary conditions.—J. A. B.

*Acetylene Gas, Impts. in Apparatus for Generating.* E. Quelle, Paris. Eng. Pat. 29,500, Dec. 22, 1896.

SEVERAL patterns of apparatus are described, consisting either of a fixed or movable bell with vertical partitions, or of two or more concentric or contiguous bells; some of the compartments or bells contain a carbide receptacle, and serve as generators; others serve as gas reservoirs. The

generators and reservoirs communicate by a pipe furnished with a tap, which may be actuated by the rise and fall of a gasometer. The carbide receptacle has several vertical compartments, with bars or grids supporting the carbide at different levels, so that the contents of one compartment only, are brought into contact with the water at one time. Several modifications of parts of the apparatus are described.—J. A. B.

*Generating [Acetylene] Gas, Impts. in Apparatus for Use in.* J. Selumacher, Chicago. Eng. Pat. 30,134, Dec. 31, 1896.

THE invention relates to apparatus for producing acetylene gas from calcium carbide and water, or other gas generated by the action of a liquid on a solid, the object being to produce the gas continuously and in practically constant quantity throughout the period of generation and use. The diagram and description given, show the invention embodied in a lamp adapted for use on vehicles. The carbide is contained in an upright cylinder, and is confined therein by two horizontal diaphragms; the upper diaphragm is fixed, and the lower one, which is held in position by means of a spring ring, is capable of moving downwards in the manner of a piston, the sides of the cylinder being continued downwards some distance below the lower surface of the carbide. Above the upper diaphragm is situated a gas-tight water reservoir, from which water flows through an opening (the size of which may be regulated by a valve operated by a milled head outside the lamp) in the diaphragm on to the upper surface of the carbide. The gas liberated, passes down through the unaltered carbide, becoming dried, passes through the lower diaphragm and then to the burner by way of an upright tube which rises from the lowest part of the interior of the apparatus. A branch tube communicates with the upright tube and with the interior of the water reservoir, thus equalising the pressure in the latter and in the carbide chamber. The carbide becomes exhausted at its upper part, and if the quantity of water flowing on to it from the reservoir were kept constant, the amount actually filtering down to the unaltered carbide would become less and less, and the gas would be more and more slowly generated. But the mass swells on being acted upon by the water; this causes the downward depression of the lower diaphragm, which communicates by means of a central rod with the valve through which the water passes from the reservoir to the carbide cylinder. Four forms of the valve are shown, each of which is employed for the same object, namely, to admit a gradually increased amount of water to the carbide as the lower diaphragm is depressed. The rate of generation of the gas is thus kept constant.—H. B.

*Acetylene Gas, Process and Apparatus for Producing, [Calcium Carbide Cartridges].* F. Trendel and J. Mücke, Berlin. Eng. Pat. 139, Jan. 2, 1897.

UNIFORM generation of gas is said to be secured by the employment of a cartridge containing carbide in compartments, with separate water inlets at different levels. The water enters the cartridge by a pipe at top, but passes to the bottom before coming in contact with the carbide, and thus cools the compartments before they come into operation. An increase of gas pressure in the generator depresses the water below the inlet to the cartridge. A siphon with water closure serves to remove air from the generator prior to the development of the gas. The cartridges have their openings sealed to preserve the carbide from the air and moisture until required for use. Special valves and systems of pipes for regulating the water-feed from the reserve cistern, the gas bell, and the generator are described for one form of the apparatus. Another form has a day flame to burn when the burner proper is extinguished. A safety-pipe ends near it, so that in the event of over-production the surplus gas is consumed.—J. A. B.

*Acetylene and Similar Gases, Impts. in Processes of and Apparatus for Forming and Burning.* J. Zimmerman, Chicago, U.S.A. Eng. Pat. 328, Jan. 5, 1897.

THE apparatus consists of generating, gas-containing, and water-holding chambers superimposed in the order named. Above these is a chamber with diaphragm partition; the

diaphragm is attached to a spindle, which actuates the valve admitting water to the generator, and the lower side of the diaphragm is subject to the pressure of the gas in the generator, so that the admission of water is automatically controlled by this pressure. The gas passes from the generating to the gas-containing chamber through a purifier or dryer and cooling-pipe, the outlet of which is closed or opened by a valve automatically actuated by the pressure of the gas in the containing chamber. The burners are supplied from the latter.—J. A. B.

*Reducing Metals from their Ores, and for Obtaining Carbides, Acetylene, Cyanogen, Cyanides, Nitrides, and for fixing Nitrogen; Impts. in Processes and Apparatus for.* [Electrical Blast Furnace.] H. Maxim, New York, U.S.A. Eng. Pat. 1905, Jan. 27, 1896.

See under XI. B., page 378.

*Calcium Carbide, An Improved Method of and Apparatus for the Production of.* [Preliminary Heating.] F. H. Haviland, A. Holloway, J. B. Collier, and W. H. Murch, Bournemouth. Eng. Pat. 15,483, July 16, 1896.

IN this process the mixture of carbon and lime is heated by means of a furnace before or whilst being fed into the electric arc, which is struck between a plumbago pot and a movable carbon electrode. This pot closes the upper part of the furnace, from which it is insulated, and through one side of it passes an inclined feed, which is provided with a jacket which is open to the furnace flue, so that the hot gases surround the tube and also the receptacle into which the mixture of coke and lime is fed. This tube may be provided with a rotating worm to feed the mixture into the arc, or the worm may be dispensed with and the tube itself be rotated. The pot is provided with a lid, which is insulated from the carbon electrode passing through it, and from it a flue carries off the gases to a chamber where they may be treated, which chamber is also connected by a flue with the feed receptacle. The outlet pipe discharges the molten calcium carbide on to two grids placed over each other transversely, these by their motion producing granules of any desired size.—G. H. R.

*Incandescent Gas Lighting, Impts. in.* [Use of Rotary Mixers for Gas and Air.] L. Demayrouze, Neuilly. Eng. Pat. 7463, April 8, 1896.

REFERRING to his Eng. Pat. 4494 of 1895 (this Journal, 1897, 130), the patentee considers that the mixture of gas and air should arrive at the point where it burns under these conditions: physically, there should be complete interpenetration of the two fluids; chemically, the proportion should be 4 or 5 parts of air to 1 part of gas; "the mechanical condition is determined by a pressure scarcely sensible (about 2 mm.) and an average speed of issue from the gauze at the top of the burner of about 4 metres per second." The patentee claims—

1. In the production of incandescent gas light by Welsbach and like mantles, employing the gas and air in their ordinary conditions, or, after having modified these conditions, utilising, if necessary, the gas pressure as the power for effecting intimate interpenetration of the molecules of the gas and air.

2. Effecting the intimate interpenetration of the gas and air by rotary mixers, or by passing the fluids through gauzes or successive diffusion chambers, or through crossing passages, or between blades or baffles which cause the fluids to become broken up, subdivided, and intermingled, while the filamental streams of air and gas may be still further broken up or triturated by rotary movements produced by the simplest mechanism, including chimney draught.

3. The application to incandescent gas lighting of the principles above set forth, employing, instead of ordinary gas, combustible vapours of more or less volatile oils, spirits, and other liquids, or acetylene or other combustible gases.—H. B.

*Incandescent Gas Lights, Impts. relating to.* De R. Hollins, New York. Eng. Pat. 27,269, Dec. 1, 1896.

THIS invention relates to a composition for incandescent devices made of a mineral substance without a cotton fabric or the like. The incandescent material consists of magnesia

(to give incandescence), powdered porcelain and asbestos (to impart durability), lime and sulphate of chromium (to cause diffusion of the light), sulphate of barium or sodium (to give the device "a good weight in proportion to its size"), thorium and zirconium (to help to diffuse the light and give an agreeable white or yellowish light). These materials are mixed together as a dry powder, then rubbed into an organic binder, such as sugar solution, and shaped into incandescent devices, which are dried and baked in suitable ovens in the usual manner. The composition is claimed.

—H. B.

*Incandescent Lights, Impts. in and relating to.* A. Rammoser and A. von Hake, Berlin. Eng. Pat. 29,613, Dec. 23, 1896.

TO produce thread material for incandescent lights adapted to resist shock, falls, &c., a thin wire, composed of one or more of the platinum metals is over-spun with cotton or other suitable fibre, and the material so produced is plaited or woven with a corresponding number of cotton or other threads and made up into suitable shapes. The body is then impregnated with any of the known lighting fluids; or the thread may be impregnated before spinning it on the wire.—H. B.

*Carburetted Water-Gas, Impts. in Apparatus for the Production of.* W. Wheatley, Liverpool, and G. Kros, Leigh. Eng. Pat. 4980, March 5, 1896.

THIS invention relates to improvements on Fourcault's Eng. Pat. 15,169 of 1891 (this Journal, 1892, 149). Two generators are used alternately, the one being under blast for raising the fuel to incandescence and meanwhile heating up the carburetting and fixing retorts, while the incandescent fuel in the other generator is decomposing steam and producing water-gas, which is enriched with oil in the hot carburetting and fixing retorts. The improvements comprise (1) the construction of a generator having an oblong well forming the ash pit, and containing the fire grate running across the base, and having the interior sides of the wall converging towards the grate, and provided with air and steam blast-pipes; (2) the construction of a fixer for the mixed water-gas and oil vapours, consisting of a closed vertical casing fitted with an internal central conduit which communicates with the casing at one end, having chequer-work between the conduit and the casing wall, with inlet and outlet so arranged that the gases, on entering, traverse the length of the conduit inside and then throughout the length of the casing and chequer-work outside the conduit.—H. B.

*Combustible Gas, Impts. [Revolving Hearth] in Furnaces or Apparatus suitable for the Manufacture of.* A. Kitson, Philadelphia. Eng. Pat. 5291, March 9, 1896.

THIS patent describes improvements on the patentee's Eng. Pat. 19,521 of 1893 (this Journal, 1894, 243). The rotating hearth is made ring-shaped, and the opening in the centre of the ring is occupied by a stationary plate, which is provided with a number of radially-projecting wings. The ring-shaped portion of the hearth is inclined to the horizon, and its surface is diversified by elevations and depressions. The walls of the combustion chamber extend downwards below the hearth, encircling and closely fitting it, the opposing surfaces thus formed being sufficiently near to grind the ashes sifting between them. The grinding action is accelerated by cutting helical grooves in the opposing surfaces. The rotating hearth is supported on a hollow shaft resting and rotating about a vertical axis upon ball bearings, and within this shaft is a pipe, depending from the central stationary plate, up which, by suitable means, a blast of air is driven into the fuel. The hearth is rotated by means of a worm wheel attached to the hollow vertical shaft and engaging a worm. These improvements cause the body of fuel to grind continuously upon itself to a much greater degree than was attainable under the above-mentioned patent.—H. B.

*Coke-Ovens, Impts. in.* G. Hilgenstock, Dahlhausen, Germany. Eng. Pat. 6857, March 28, 1896.

THE supply of gas for heating the ovens is admitted to the flues from conduits situated below the furnace and contained

in passages in the basement large enough to admit the attendants for the purpose of regulating the supply to any part, or for cleansing, &c. It is claimed that by this means uniformity of coking is attained, local overheating, and the resultant damage to the brickwork, and decomposition of the coke gases being prevented.—C. S.

*Coke Furnaces, Impts. in.* F. J. Collin, Dortmund, Germany. Eng. Pat. 25,887, Nov. 17, 1896.

To ensure direct firing, without local overheating, in the middle of the furnace, longitudinal and transverse flues are arranged in the walls, and gas is supplied to the centre of the furnace through small pipes between these flues, in which the combustion is effected, the necessary air being delivered through separate pipes opening near the gas-pipe jets. By stopping the gas supply and admitting air, the soot deposited in the gas pipes can be quickly removed.—C. S.

*Petroleum Regenerative Lamps, Impts. in.* [Preliminary Gasification of Oil by an Under Burner.] F. Ludwigs, Berlin. Eng. Pat. 5843, March 16, 1896.

In this (inverted) lamp, the preliminary gasification of the oil is effected by an under burner with asbestos wick, fed by petroleum from the oil reservoir and heating a metal plate supporting the annular gasifier, the supply being then diverted to the latter by adjusting a two-way tap in the supply pipe, whereupon the oil is vaporised and the gas descends through an annular cylinder to the orifices of the main burner, where it is consumed, the heat thenceforward sufficing to renew the supply of gas. By a suitable method of admitting air, the flame is caused to diverge outwards in the form of an arch.—C. S.

*Petroleum Residues for Heating Purposes* [Gasification by Aid of Hot Air], Impts. in Means for Burning. F. Grube, Hamburg. Eng. Pat. 16,574, July 27, 1896.

To gasify petroleum residuum for fuel on ship-board, where atomising is inconvenient, the inventor proposes to induce a current of heated air through the oil reservoir by means of an air pump, which also compresses the resulting gases and delivers them, by way of a reducing valve, to a burner inserted in the fire-box of the boiler. The air necessary for combustion is supplied inside the flame, through a bell-mouthed central pipe projecting beyond the nozzle of the burner and adjustable for the purpose of altering the size of the flame as desired; suitably arranged clack-valves admitting air to the outside of the flame. The flame impinges against a fire-bridge, the desired position being attained by fitting the burner at a suitable height and making it horizontally adjustable.—C. S.

*Gas from Liquid Combustible Materials* ["Petroleum, Spirit, or the like"], Method and Apparatus for Producing. G. Tresenreuter, Berlin. Eng. Pat. 26,516, Nov. 23, 1896.

This patent describes an apparatus suitable for producing from petroleum, &c., a flame adapted for illuminating purposes, particularly incandescence lighting. In the diagram, *a* contains the combustible liquid, and *b* contains atmospheric air, the two vessels being connected by the pipes *c*. Vessel *b* is air-tight, and is traversed centrally by the passage *d*, within which is a chimney, *e*, surmounting the heating lamp, *g*, which is an ordinary petroleum lamp. From *a* rise the pipes *h*, which pass over the heating flame into the chimney, and open into the vaporising chamber *i*, from which the gas passes to a burner provided with the usual air inlets, *s*, and resting, in, say, the manner shown, upon the vessel *b*. The apertures, *q*, in the chimney permit the escape of the gases of combustion of the flame *g*. Between the chimney and the wall of the vertical passage, *d*, there is inserted a metal ring *v*, which conducts the heat from the chimney to the air-vessel. In the tubes *h* there is an insertion of absorbent material, such as asbestos, for conducting the liquid upwards in a cool state, so that vaporisation does not begin until the liquid reaches the chimney, *e*.

On lighting the heating flame, the air in *b* expands and raises the combustible liquid in the tubes *h* to the vaporising chamber. The advantage claimed for the

apparatus is that only cool air comes into contact with the petroleum, &c., which can thus never become hot. At *t* is an outlet for reducing the pressure within *b* on extinguishing the lamp.—H. B.

*Mineral Oils, Impts. relating to the Burning of.*

M. L. Ross, London. Eng. Pat. 26,962, Nov. 27, 1896.

The lamp forming the subject of this invention is intended for vaporising the oil to be burned. To this end, heat is applied to a convoluted metal tube above the lamp, and, by conduction *via* a central tube dipping into the receiver, expands the air in the latter and causes the oil to rise through the said tube (packed with asbestos) into the coil, where it is vaporised, and, issuing through one or more pinholes in the coil, burns, air being admitted into the coil by other pinholes situated below. For heating purposes, a metallic plate pierced by a central aperture is supported over the flame by lugs, or replaced by an incandescent mantle for lighting purposes.—C. S.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*Mineral Oils of High Boiling Point, Effect of Expansion on Flashing-Point Determinations.* D. Holde. Chem. Rev. Fett- u. Harz-Ind. 4, [4], 51.

The author had already shown (this Journal, 1895, 284) that even in the case of petroleum oils boiling as high as 280° C., the expansion of the oil is without any appreciable influence on flashing-point determinations in the Abel and Pensky

test cups, and he now records the results of a further series of experiments, showing that with oils flashing between 172° and 241° C., a variation of even as much as 13 c.c. below the normal filling of the instrument does not alter the flashing point by more than 1° to 1.5° C., concluding therefrom that the influence of expansion may be neglected. —C. S.

*American Petroleum, Some Hydrocarbons from. I. Normal and Iso-Pentane.* S. Young and G. L. Thomas. Proc. Chem. Soc. 1897, [176], 58—60.

THE two pentanes were separated by fractional distillation from the "pentane" supplied by Merck, of Darmstadt. This substance, which is obtained by the distillation of American petroleum, is a complex mixture of butanes, pentanes, and hexanes, with some benzene and a little hexanaphthene. A combination of a dephlegmator with a constant (or rather "regulated") temperature still-head was employed; the apparatus is fully described in the paper.

Some of the constants of isopentane were determined so as to compare them with those of the two specimens prepared synthetically; the agreement was found to be very satisfactory. The boiling points under normal pressure are: isopentane, 27.95°; normal pentane, 36.3°. The specific gravities at 0° are: isopentane, 0.63930; normal pentane, 0.64539.

*The Vapour Pressures, Specific Volumes, and Critical Constants of Normal Pentane: with a Note on the Critical Point.* S. Young. Proc. Chem. Soc. 1897, [176], 58—60.

THE critical temperature of normal pentane is 197.2° C., the critical pressure is 25,100 mm., and the critical volume of a gram. 4.303 c.c. The vapour pressures and specific volumes were determined from low temperatures to the critical point, and the observations were taken as near to the critical point as possible (197.15°), in order to obtain more complete experimental evidence regarding the condition of a substance at and very near that point.

The ratios of the absolute temperatures (boiling points) and volumes to the critical constants, also the ratio of the actual to the theoretical density at the critical point (3.765), lead to the conclusion that, at the critical temperature and in the liquid state, the molecules are simple, like those of the gas.

#### PATENTS.

*Ammonia, An Improved Method or Process of Treating Substances containing Nitrogen for the Manufacture of.* H. H. Lake, London. From C. Pieper, Berlin, Germany. Eng. Pat. 28,199, Dec. 9, 1896.

See under VII., page 329.

*Artificial Asphalt, Impts. in the Process of Manufacture of.* A. Haunemann and G. Boissy, both of Berlin. Eng. Pat. 3597, Feb. 17, 1896.

THE inventors claim "the manufacture of artificial asphalt produced by treating pitch, or the remains of resin or petroleum distillation, first with sulphur and then with chloride of lime, or first with chloride of lime and then with sulphur, the product being ground and mixed with amorphous lime, slag or other stone- or saw-dust, and again heated to boiling point." Such a material is stated to be "superior to natural asphalt." —V. C.

## IV.—COLOURING MATTERS AND DYES.

*Colouring Matters [Vegetable] from Annam.* M. O. Picquet. Rev. de Chim. Ind. 8, [86], 45—48.

THE author describes two natural dyestuffs which he has received from Annam. The first of these is derived from the *cù-nao* or *cù-nar*, a potato-like tuber, weighing from 500—1,000 grms. It is much used in the plains of Tonkin and the provinces of Vinh and Hatinh. The flesh of the tuber is somewhat woody, and resembles a dried beetroot. The *cù-nao* is only used in its fresh state. The tubers are preserved by burying them in moist earth, so that they shall not lose their natural moisture, since by drying they lose much of their tinctorial powers. For dyeing purposes, the natives cut the *cù-nao* into thin slices, which are put into a mortar with six times their weight of water. The liquor is decanted, the cloth steeped in it for 5—6 hours, and it is then spread out on the grass, face upwards, to dry. The side exposed to the light and air is darker than the one turned towards the ground.

To increase the lustre, the cloth is subsequently steamed in a crude fashion, by placing the material on a wooden grid above a vessel of boiling water. For darker shades, these operations are repeated. Sometimes a glutinous substance, *phen-den*, imported from China, is added to the dye-bath.

An aqueous extract of *cù-nao* gives the following reactions:—

*Gelatin.*—Little action.

*Alum and Aluminium Acetate.*—Gelatinous light brown precipitate.

*Iron Salts.*—Greenish-black precipitate.

*Iron Sulphate.*—Brown precipitate.

*Potassium Bichromate.*—Dark yellowish-brown precipitate, slight in the cold, but abundant on heating.

*Lead Acetate.*—Voluminous light brown precipitate.

*Tin Salts.*—Drab precipitate.

*Dilute Acids.*—Dirty yellow precipitate.

*Alkalis.*—Colour much darker.

*Mercury Bichloride.*—Voluminous dirty white precipitate.

*Potassium Ferrocyanide.*—Little action.

*Potassium Ferricyanide.*—Yellowish-brown precipitate; liquor the same colour.

*Bleaching Powder.*—Dark brown precipitate, which quickly turns yellow.

The best method of application is to first dye the cloth, with or without the addition of alum, and then fix the colour with a bichromate. Prints should be steamed.

The other product, called *cay-da* or *cuy-ia*, is the bark of *Bruguiera gymnorhiza*,\* and resembles in appearance the cinnamon of commerce. The colour obtained from it is a reddish-brown of great density, which has a certain analogy with catechu, but the browns are much fuller and more brilliant than can be obtained from the latter. This product, the author says, is more interesting than the former, and might find a useful place among our colouring matters.

The following are some of its principal reactions:—

*Gelatin.*—Voluminous brown precipitate.

*Alum.*—Light brown precipitate.

*Aluminium Acetate.*—As with alum, but a more abundant precipitate.

*Ferrous Acetate.*—Dark greenish-grey precipitate.

*Ferrous Sulphate.*—Purplish-black precipitate.

*Ferrie Sulphate.*—Deep black precipitate.

\* This is one of the so-called Mangrove barks, and is already employed in the form of extract by European dyers.

**Copper Sulphate.**—Blackish-brown precipitate.

**Potassium Bichromate.**—Dark reddish-brown precipitate, slowly thrown down in the cold, but quickly when hot.

**Bleaching Powder.**—Dark brown precipitate, turning yellow on heating.—L. S.

**Stable Diazo Compounds.** C. Gassmann. *Färber Zeit.* **8**, 67–68.

THE Farbwerke vormals Meister, Lucius, and Brüning, in a recent patent (Eng. Pat. 1645 of 1896; this *Journal*, 1897, 40), claim the manufacture of stable zinc chloride double salts of certain diazo bodies. The author states that these double salts have been described by Feer in 1891 (*Bull. Soc. Ind. Mulhouse*, 1891, 221; this *Journal*, 1891, 695), and that similar salts were brought into the market in 1894 by Messrs. Wacker and Schmitt, of Mulhouse, but have now been withdrawn, being found insufficiently stable for long preservation. In the author's opinion, it is better to add the metallic salt, zinc chloride or stannic chloride, to the previously prepared printing colour, and for this purpose other substances besides these two salts give increased stability to the diazo compound, *viz.*, sodium picrate, and the sodium salts of dinitro- $\alpha$ - and  $\beta$ -naphthol. R. B. B.

**Tartrazine, Constitution of.** R. Anschütz. *Annalen*, **294**, 219–243.

THE tartrazines are dyestuffs obtained by the action of phenyl-, tolyl-, xyl-, or naphthylhydrazine sulphonic acid on dihydroxytartaric acid, and have hitherto been supposed to have an analogous formula to the osazone (diphenylizine-dihydroxytartaric acid) produced from dihydroxytartaric acid and phenylhydrazine, *viz.* :—

Knorr (*Ber.* **21**, 1204), however, showed that diphenylizine-dihydroxytartaric acid, even on crystallisation from glacial acetic acid, is very easily converted into an inner anhydride, forming a pyrazolone ring—

which the author (A.) terms 1-phenyl-3-carboxy-4-phenylhydrazonopyrazolone. This is the parent substance of tartrazine, the condensation to the pyrazolone ring taking place much more readily owing to the presence of the sulphonic acid groups. The alternative method for the preparation of tartrazine (Eng. Pat. 5693 of 1893; this *Journal*, 1894, 382) has also been investigated, and the following conclusions are arrived at. The dyestuffs obtained from aromatic hydrazine sulphonic acids and dihydroxytartaric acid are *hydrazonopyrazolones*, and not *hydrazones* or *osazones*. The chromogen of tartrazine is phenyl-phenylhydrazonopyrazolone, which bears the same relation to tartrazine that azobenzene does to amido-azobenzene sodium disulphonate.

The pyrazolone already contains the auxochromic carboxyl group. Tartrazine owes its colour primarily to the fact that it is derived from the osazone of an  $\alpha$ -diketone. This colour is considerably increased by the formation of the pyrazolone ring.—T. A. L.

**Magenta and Malachite Green, Reduction of Colouring Matters of the Type of.** M. Prud'homme. *Bull. Soc. Chim.* 1897, **17**, [6], 376–378.

HOT solutions of colouring matters of the type of Magenta and Malachite Green, treated with zinc dust in the presence of an acid, are completely reduced, and do not regain their colour on exposure to air. If the reduction be effected rapidly and in the cold, after filtering, the solution at once begins to regain its colour; boiling for some minutes, or long standing in the air, gives a solution of which the colour intensity is about half that of the original solution. The nascent hydrogen has reduced a portion of the colouring matter to the leuco base, but in another portion two hydrogen atoms have probably united to each of the  $\text{NH}_2$  groups, giving colourless compounds analogous to those produced by the action of mineral acids. In the case of Parafuch-sine, this substance would have the formula  $\text{C}_6\text{H}_4(\text{NH}_2)_2$ . Boiling at once decomposes this compound, but by standing in the air the hydrogen of the  $\text{NH}_2$  groups can reduce another portion of the colouring matter to the leuco base, thus explaining the observation that boiling effects a greater return of colour than long standing. An increase in colour on boiling with lead dioxide (the solution becoming partially restored to its original colour on standing) demonstrates the presence of the leuco base.

The basic colours not derived from triphenylmethane—such as the Safranines, Methylene Blue, Rhodamines,—after reduction by zinc dust in the cold, regain their original colour.—A. C. W.

**Patent Blue, Constitution of.** E. and H. Erdmann. *Ann.* 1897, **294**, 376–392.

THE authors some time ago discovered a method for manufacturing Patent Blue (Ger. Pat. 64,736), which proves the position in the molecule of the latter of one of the sulphonic acid groups.

The Patent Blue of commerce is the magnesium salt, which, when purified by crystallisation from water and dried at  $110^\circ$ , has a composition corresponding with the formula—

It is not affected by boiling with barium hydrate solution, being deposited unchanged on precipitating the barium with carbon dioxide, filtering and evaporating.

When heated with sodium hydroxide solution, it is readily decomposed into a colouring matter of the rosolic acid group, diethylamine being evolved, and the colour of the solution changing first to violet and then to red. (This *Journal*, 1897, 39.)

*m*-Hydroxy-tetra-ethyl-*p*-diimidotriphenylcarbinol,  $\text{HO}\cdot\text{C} : [\text{C}_6\text{H}_4\text{OH}] [\text{C}_6\text{H}_4\text{N}(\text{C}_2\text{H}_5)_2]_2$ , is produced when Patent Blue is heated with concentrated hydrochloric acid under an inverted condenser, being precipitated on adding an alkali to the solution. It forms, when dry, a dark green powder, which dissolves in alcohol and in very dilute hydrochloric acid with a green colour, changing to yellow on the addition of concentrated hydrochloric acid. It is not decomposed by heating with caustic soda solution.

*m*-Hydroxy-Brilliant Green *p*-sulphonic acid and its leuco compound, prepared from *m*-hydroxybenzaldehyde-*p*-sulphonic acid, are acids of so feeble a character that they may be extracted from aqueous alkaline solutions by means of chloroform. The authors were led by this circumstance previously to regard the compounds in question (and Patent Blue) as sulfonic anhydrides formed by elimination of the elements of water from the *m*-hydroxyl and *p*-sulphonic acid groups. They now find that this view is incorrect, as the analytical results do not accord with it, and the acids do not become dehydrated either when heated alone or with condensing agents.

**Synthesis of Patent Blue from *m*-nitrobenzaldehyde.**—*m*-Nitrobenzaldehyde condenses with diethylaniline, giving *m*-nitro-leuco-Brilliant Green, a compound crystallising from

alcohol in yellow needles (m. pt. 95°—96°) with a yellow-green fluorescence. When reduced, it gives an amido compound, which is converted into Patent Blue by diazotising, boiling, treating the product with fuming sulphuric acid at the ordinary temperature, and finally oxidising and neutralising.

**Synthesis of Patent Blue from *p*-chlorobenzaldehyde.**—This chloro-compound gives, on nitration, *p*-chlor-*m*-nitrobenzaldehyde (m. pt. 62°), which, when boiled with sodium sulphite, forms sodium-*m*-nitrobenzaldehyde-*p*-sulphonate. From the latter, the corresponding *m*-hydroxy compound is prepared by reducing and diazotising, and this, when condensed with diethylaniline, yields *m*-hydroxy-leuco-Bright Green *p*-sulphonic acid, from which Patent Blue is easily obtained by sulphonating and oxidising.—E. B.

**Magenta and Magenta S, Distinction between, by Schiff's Reaction.** P. Cazeneuve. Bull. Soc. Chim. 1897. 17 196—199.

See under XXIII., page 361.

## PATENTS.

**Colouring Matters [Cotton Violets, Blues], Impts. in the Manufacture of.** H. H. Lake, London. From The Farbwerk Mühlheim, Mühlheim-on-the-Maine, Germany. Eng. Pat. 5857, March 16, 1896.

This is an extension of Eng. Pat. 10,669 of 1895 (this Journal, 1896, 445), which referred to the production of red to violet diazo dyestuffs from ethyl amidonaphthol sulphonic acid,  $1'.3'.3''.C_{10}H_7.OH.NHC_2H_5.SO_3H$ , by combining it with diazo compounds of the general formula  $R.N:N.R_1.N:N-$ , where R is the radicle of an amine generally incapable of giving direct azo cotton dyes, and  $R_1$  is an amine radicle which, when combined with diazo compounds, can be further diazotised. It has now been discovered that the ethyl amidonaphthol sulphonic acid can be replaced by one of the three following acids: 2,4',2'-amidonaphthol sulphonic acid, 2,4',2',1'-amidonaphthol disulphonic acid, or 2,4',2'-phenylamidonaphthol sulphonic acid. The last-mentioned is prepared by heating 2,4',2'-naphthylamine disulphonic acid (Eng. Pat. 2614 of 1893; this Journal, 1894, 144) with 1 part of aniline and 0.6 part by weight of aniline salt for six hours to the boil, making alkaline with sodium carbonate, removing the aniline by means of steam, evaporating the solution to dryness, and fusing the residue with 1.5 part of caustic potash lye of 50 per cent. for 1½ hours to 210°—220° C. On acidifying, phenylamidonaphthol sulphonic acid separates from the solution. The following example illustrates the method employed. The amido-azo compound from diazotised *p*-toluidine-*m*-sulphonic acid (from *p*-nitrotoluene sulphonic acid) and  $\alpha$ -naphthylamine, is dissolved in sodium carbonate solution, mixed with the molecular proportion of sodium nitrite, and poured into cold dilute hydrochloric acid. When the diazotisation is complete, the diazo-azo compound is stirred into a solution containing a molecular quantity of amidonaphthol sulphonic acid kept alkaline with sodium carbonate. The violet dyestuff produced is salted out hot.—T. A. L.

**Anthracene Compounds, and of Dyestuffs derived therefrom; The Manufacture or Production of.** H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 7538, April 9, 1896.

LIEBERMANN (Annalen, 212, 14), by acting on quinizarin with hydriodic acid and phosphorus, obtained a product which he termed quinizarin hydride. This substance, according to the present specification, can be much more readily obtained from purpurin by oxidation in an acid solution. Leuco derivatives of quinizarin are formed, which, on oxidation, are converted into quinizarin, and this process can be applied to other hydroxyanthraquinones. Purpurin, when treated with reducing agents, yields two different leuco-quinizarins, designated I. and II. The latter is identical with Liebermann's hydride, and differs from leuco-quinizarin I., which is very easily oxidised, its solution in

sulphuric acid being converted even at the ordinary temperature, and when heated to 70°—90° C. it yields quinizarin very readily, whilst II. requires a temperature of about 120°—130° C. The reduction is effected by suspending 50 kilos. of finely-powdered purpurin in 400 kilos. of glacial acetic acid, heating to 70°—80° C., and gradually stirring in 25 kilos. of zinc dust. When the whole of the purpurin is dissolved, the solution is filtered, and the leuco compound is precipitated by adding water. By dissolving purpurin in 20 times its weight of sulphuric acid, and stirring in twice its weight of zinc dust at -10° to -5° C., and pouring the melt, when reduced, into water, yellow flakes, consisting of a mixture of leuco-quinizarins I. and II., separate out. In a similar manner, other hydroxyanthraquinones, containing hydroxy groups in the 1,2,4 or purpurin position, can be converted into derivatives containing a smaller number of hydroxyl groups. Thus, for instance, alizarin hexaamin yields leuco-alizarin pentaamin, which is readily oxidised. Similarly, leuco derivatives of quinizarin sulphonic acid can be obtained by reducing purpurin sulphonic acid. In the case of Alizarin Bordeaux, however, no elimination of a hydroxyl group takes place, and it is only the ketonic groups of the anthraquinone nucleus which are reduced. The specification further describes the preparation of dyestuffs by condensing the leucohydroxyanthraquinones with primary aromatic amines in presence of a condensing agent, such as boric acid, glacial acetic acid, hydrochloric acid, benzoic acid, or the like. The condensation products thus obtained are readily converted into dyestuffs by oxidising agents. Thus, a green dyestuff, identical with that obtained by fusing quinizarin with *p*-toluidine in presence of boric acid (Eng. Pat. 23,927 of 1894; this Journal, 1895, 1041), is obtained by heating leucoquinizarin II. with *p*-toluidine in presence of boric acid and allowing the mixture to oxidise, or preferably by employing a mixture of quinizarin, leucoquinizarin II., *p*-toluidine, and boric acid. The leuco dyestuffs obtained can also be sulphonated by means of fuming sulphuric acid (10—20 per cent.  $SO_3$ ), and may be used as such for dyeing animal fibres, the colour being subsequently developed by treatment with oxidising agents, such as potassium chromate or the like. They may also, of course, be converted directly into sulphonic acids of the dyestuffs themselves. There are 14 claims.—T. A. L.

**Polyazo Colouring Matters [Cotton Browns to Blacks]. The Manufacture or Production of.** W. E. Heys, Manchester. From The Chemische Fabrik vormals Sandoz, Basel, Switzerland. Eng. Pat. 15,294, July 10, 1896.

The azo dyestuff produced in an acid solution from diazotised 2,1',3,3'-amidonaphtholdisulphonic acid and  $\alpha$ -naphthylamine is combined in equimolecular proportions with a tetrazotised *p*-diamine. The intermediate product so obtained may be combined directly with one molecular proportion of a phenol, amine, or their sulphonic or carboxylic acids, giving valuable trisazo colouring matters which dye unmordanted cotton brown to deep blue-black. In place of combining the intermediate product directly, it may be previously diazotised, and the tetrazo compound thus produced combined with two molecular proportions, either the same or different, of a *m*-diamine, a naphthol, dihydroxynaphthalene, or amidonaphthol sulphonic or carboxylic acid. The octazo dyestuffs thus produced are generally bluer or greener in shade than the corresponding trisazo dyestuffs, and dye unmordanted cotton violet, greenish-blue, and blue-black. The following example illustrates one of the methods employed—34.1 kilos. of the acid sodium salt of 2,1',3,3'-amidonaphtholdisulphonic acid are diazotised with 6.9 kilos. of sodium nitrite, suspended in 500 litres of water, and combined with 14.3 kilos. of  $\alpha$ -naphthylamine dissolved in 12 kilos. of hydrochloric acid (21° B.) and 300 litres of water. The azo dyestuff separates almost completely, and, after standing 24 hours is dissolved by adding 8 kilos. of caustic soda. 24 kilos. of sodium carbonate are then added, and a tetrazodiphenyl solution is run in, prepared from 18.4 kilos. of benzidine. The intermediate product formed, separates as a blackish-violet precipitate, to which is added a solution containing 23.9 kilos. of  $\gamma$ -amidonaphthol sulphonic acid

and 4 kilos. of caustic soda in 300 litres of water. After about 24 hours the combination is complete, and the dye-stuff is separated by salting out the boiling solution. The dye-stuff gives deep violet-black shades on un mordanted cotton from a bath containing salt and soda.—T. A. L.

## V.—TEXTILES: COTTON, WOOL, SILK, Etc.

*Silk, the Weighting of, with Metallic Salts: The Theory and Practice of.* R. Silbermann. *Färber Zeit.* 8, 34—36, 51—53, and 68—71.

(See also pages 297—303.)

The principal substances used for weighting silk are compounds of the heavy metals: bismuth, tin, tungsten, barium, antimony, and lead.

**Weighting with Tin Compounds.**—Silk possesses a great affinity for stannic salts, but very little for stannous salts. The most useful stannic compounds are stannic chloride and "pink-salt" ( $\text{SnCl}_4 \cdot 2\text{NH}_4\text{Cl}$ ).

The silk is weighted in the raw condition, *i.e.*, not boiled-off, since sericin acts as a weak acid and exhibits considerable affinity for metallic bases. The silk is steeped for 2—3 hours in the stannic chloride or pink salt solution at 35° B., wrung out, and washed several times with water. During washing, dissociation takes place, and there is deposited upon the fibre a basic stannic chloride together with small amounts of stannic hydrate and meta-stannic acid. The bath naturally becomes more acid, and for further use, a small quantity of ammonia is added in addition to stannic chloride. When "pink-salt" is used, the strength of the bath in its useful constituent cannot be estimated by the hydrometer, since ammonium chloride is not taken up by the silk in the same proportion as stannic chloride. To bring about further dissociation, the silk is worked in a cold solution of sodium carbonate at 3°—4° B., then soaped in a lukewarm bath with 50 per cent. of soap, or the soap and soda may be used together in one bath. The effect of this treatment is to leave the silk charged with stannic oxide. The operations are repeated as often as desired: a three-fold repetition gives a weighting of 25—30 per cent.; six-fold, 50 per cent.; eight fold, 90—100 per cent.; and ten-fold, 160 per cent.

The silk weighted with stannic chloride before the treatment with soda and soap is extremely sensitive to the action of light, this action causing a tendering of the fibre. The reason of this is not known, but the author considers it probably due to a dehydrating or reducing action whereby the fibron molecule is broken down—a decomposition always accompanied by the liberation of hydrochloric acid, which can be detected upon the tendered fibre. In consequence of this action the weighting is conducted as far as possible in a dim light.

Stannic chloride solution is extremely corrosive, and the workmen should be provided with india-rubber gloves.

After weighting with tin a further weighting may be produced by passing through a tannin bath. By three repetitions of tin and tannin (Chinese galls) baths, souple silk, it is said, may be weighted to 200 per cent. Weighting may also be increased by passing tin-weighted silk into ammoniacal solutions of barium, copper, &c., or solutions of organic lead salts, in order to produce heavy insoluble stannates.

A recent improvement is the substitution of sodium phosphate for sodium carbonate. This stannic phosphate weighting leaves the silk perfectly white, and, it is said, does not injuriously affect the lustre or handle of the fibre. With 4—5 repetitions, a weighting of 120 per cent. results, the fibre is very slightly attacked, and the method is equally applicable to raw or boiled-off silk. After the stannic chloride bath, the silk is entered into a sodium phosphate bath at 55—60° C., worked for 30 minutes, gradually raised to the boiling point, and boiled for 30 minutes. After thorough washing, the silk is again passed into the tin solution, and the process repeated; but in the last fixing bath an addition of  $\text{H}_2\text{SO}_4$  is made, sufficient to liberate one-third of the phosphoric acid from the sodium phosphate. A soluble stannic phosphate, made by dissolving granulated tin or freshly precipitated stannic oxide in phosphoric and nitric acids, may be used for weighting up to 80 per cent.

Nenhaus proposes to treat the silk already weighted with stannic phosphate in a bath containing a soluble silicate. By thus weighting with stannic phosphate and silicate, after five passages the weight is 100—120 per cent. over "pari."

Since the price of tin is somewhat high, the wash-waters should in all cases be treated for the recovery of tin by precipitation with chalk, lime, or soda, and this treatment may also be applied to the tin-catechu baths from black silk dyeing.

**Weighting with Bismuth Compounds.**—These form, it is said, excellent weighting agents, owing to their high molecular weight and the readiness with which they are dissociated. Bismuth nitrate is the most suitable, and is followed by a fixing bath of dilute sulphuric acid; three passages weight to 100 per cent. The price at present precludes the use of this substance.

**Tungsten Compounds.**—Silk can be weighted to 25 per cent. by twice working in a bath of sodium tungstate at 30° B. and rinsing in an acid bath, but the weighting is removed by washing with hot water or soap, since silk has little attraction for this compound. Sodium tungstate is used, however, for rendering light silk fabrics non-inflammable.

**Lead Compounds.**—Weighting with lead by passing through basic lead acetate solution has been practised, but is strongly to be condemned owing to the soluble and poisonous nature of the weighting. Plumbate of soda has also been proposed, and since, on washing, this deposits insoluble lead hydroxide, it is said to be unobjectionable from the hygienic standpoint.

**Antimony Compounds.**—These find little use, in spite of the fact that antimony trichloride can be applied like stannic chloride. It is suggested that use might also be made of the insoluble tannate of antimony.

**Barium Compounds.**—By successive treatment in faintly alkaline solutions of sodium sulphate and barium chloride, a finely divided precipitate of barium sulphate is deposited within the pores of the silk, and gives to the fibre a brilliant white appearance. The weighting is not removed by washing, but comes out as a fine dust on beating the silk.

Silk weighted with vegetable substances should always be treated with an antiseptic solution, such as horic or salicylic acid, otherwise a development of organisms, which will tender or destroy the fabric, will sooner or later take place.

It was formerly the invariable practice to weight silk in the form of yarn, but recently the weighting of piece-goods has been introduced.—R. B. B.

### *Russian Wools, Adulteration of.* U.S. Cons. Reps., March 1897, 353.

The United States Consul at Odessa reports that the Donskoi, Crimean, and other varieties of Russian coarse wools of the clip of 1896, are shorter in the length of the fibre and inferior in quality. He is reliably informed that numerous shipments of wools from Rostoff and Odessa to the United States have, during the present season, been mixed with "sour wools."

In Russia, 90 per cent. of the population wear sheepskin coats, with the woolly side next to the body. In the process of preparing skins for coats, large quantities of chemicals are employed. As the freshly prepared skins on the leather side are perfectly white, the presumption is that arsenic is largely used. When ready to be made up, much of the wool is trimmed, and the skin cut to suit the measure desired. This results in a certain amount of waste material, both in skin pieces and free-wool fibre. The exact quantity of this waste material annually produced must be very large, and the consul calls it "sour wool."

This material is sold largely to a certain class of merchants, who mix it with their Donskoi and Crimean washed wools. When greasy wools are worth at Odessa from 4.50 to 5 roubles per pood (36.112 lb.), these sour wools will cost from 5 to 6 roubles per pood. Should greasy wools be higher or lower in price, the sour wools follow suit. Whenever these sour wools are mixed with other wools sent to the United States, it will be found that the shipment will contain from 10 to 12 per cent. This proportion

has been maintained since wool has been on the free list. During the time there was a duty on wool, the admixture of these sour wools was from 20 to 25 per cent.

The advantage to the shipper in purchasing these sour wools and mixing them with the washed Donskoi and other wools is in this: Donskoi wools in the grease, yield, when washed, from 50 to 52 per cent. of pure wool fibre, while these chemically cleaned sour wools yield 80 per cent. The Donskoi wools when washed are usually worth from 10 to 12 roubles per pool, while the sour wools never cost more than from 5 to 6 roubles per pool. The value of these sour wools to the manufacturer can be very little: the consul thinks not more than 1 rouble per pool (50 cents per 36·112 lb.). It is stated that the chemical treatment to which this wool is subjected, destroys the strength of the wool, leaving it weak and practically worthless.

That the admixture of these sour wools with the other wools shipped from Russia to the United States is done to deceive either the American importer or manufacturer, or perhaps both, admits of no doubt.

#### PATENT.

*Fabrics from Paper Pulp. Impts. in the Manufacture of.* C. Brodbeck, Paris. Eng. Pat. 23,598, Dec. 10, 1895.

THE fabric formed from sulphite cellulose is perforated by rows of needles, which do not cut the fibres, but push them aside, the holes thus formed not weakening the fabric, but allowing the gases and vapours of the skin to escape. To prevent the cellulose from tearing, it may be formed on an open groundwork fabric of cotton, linen, hemp, &c. In order to give the sheet a soft, smooth, fabric-like finish and a silky lustre, it is subjected to an appropriate hammering or beetling, with a slight addition of appropriate finishing ingredients, and subsequent calendering.—S. P. E.

### VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

*Bleaching Jute, &c.* Grothe. Leipziger Färber- u. Zeugdr. Zeit. 46, [3], 115.

ACCORDING to the author, a better white is obtained if the goods to be bleached are treated with sodium silicate than if they are boiled with soda alone. Jute may be bleached satisfactorily with bleaching powder, if it has previously been steeped for 15–20 minutes in a solution of sodium silicate, in the proportion of 6–8 kilos. of silicate for 10 litres of water, at a temperature of 85°–100° C.—L. S.

*Printing of Cotton and Woollen Fabrics, The Use of Turpentine in the.* C. Casanovas. Färber Zeit. 8, 33–34.

IN certain cases where it has been hitherto impossible to print several colours simultaneously, with a machine with several rollers, owing to running of the colours one into another, the author has succeeded in accomplishing this by the addition of turpentine to one or more of the printing colours, since this addition entirely prevents any "bleeding." For example, on a light vat-blue ground there is printed a white or coloured bichromate discharge containing also a resist for aniline black, and an aniline black printing colour is applied in the same machine, an addition being made to this colour of 70–100 grms. of turpentine per litre.

By the addition of turpentine to a sodium citrate discharge, the latter may be printed on mordanted calico immediately after padding with the mordant.

A further effect of turpentine is to prevent the printed colour from penetrating the fabric. This is particularly useful in the printing of woollen cloth, where unevenness frequently results from irregular penetration of the colour during drying, and in order to obviate this defect, in addition to the use of turpentine, drying should be effected by means of a moving current of hot air.—R. B. B.

*Ammonium Phosphate for the Fixation of Mordants.* Leipziger Färber- u. Zeugdr. Zeit. 46, [3], 107.

AMMONIUM phosphate is recommended in place of sodium phosphate for fixing mordants in calico printing, it being

alleged that this salt, being less powerful in its action than the sodium salt, gives better results than the latter.—L. S.

*Albumin at Chinkiang: Manufacture of.* U.S. Cons. Reps., March 1897, 386.

AN enterprising German firm has undertaken the manufacture of albumin at Chinkiang, it having been found that this place offered the best field for the business on account of the cheapness and plentiful supply of eggs. The factory is now successfully established, with possibilities of conducting it on a much larger scale.

The establishment of this albumin factory has made a good market for the eggs, and the country people bring them in by thousands. The factory uses duck eggs in the manufacture of albumin in preference to chicken eggs, solely on account of their greater cheapness. They are bought, not by the dozen, but by the thousand, the factory paying an average of 8 dols. (Mexican) per thousand.

As soon as the eggs are received at the factory they are tested by a very simple but ingenious process. They are held in pairs in front of a circular opening in a tin cylinder open at the top, containing a lamp giving a powerful light, which is concentrated on the opening. Every speck and flaw in the egg is distinctly seen in this process, and all eggs showing the slightest sign of defect are at once rejected. The percentage of rejected eggs is remarkably small, rarely amounting to 50 per 1,000. The good eggs are sent to the rooms prepared to receive them, where a number of Chinese girls are employed to break them and to separate the yolk from the white, placing each into separate vessels. The white then undergoes one of two processes—it is either carefully cleaned of all stray clots of yolk and then put through a course of stirring in a large vessel by means of a heavy rod or paddle worked by hand, when it is ready for the drying room; or, after being cleaned, it is run into large vats and allowed to ferment, the process of fermentation being accelerated by the admixture of certain chemicals, among which are salt, acetic acid, boracic acid, ammonia, and calcium chloride. When it is found in drawing off that all impurities have either been deposited or thrown off in the form of a thick froth, and the resulting liquid is albumin, as clear as water, the albumin is ready for the final process of drying. This is performed in a series of three rooms, each hotter than the last, the temperature ranging from 40° to 50° C. The albumin is run into shallow tin pans about 1 ft. square, which are placed in ranges of shelves in the drying rooms. Frequent examinations are made to see that the temperature is maintained, and that the process of drying is sufficiently gradual, uniform, and complete, a period of 60 to 70 hours being found necessary for that purpose. When thoroughly dry, the albumin, which now presents the appearance of isinglass, with a yellow tinge, is, after cooling, placed in large square packing boxes, lined with tin, holding about 400 lb. each, and is ready for shipment.

The principal use of albumin is in the preparation of fast dyes for superior kinds of cotton goods, and it is shipped to England, Germany, and France.

The yolk of the eggs, after separation from the white, is passed through two sieves—one coarse and one fine—and is then run off into vessels holding about 20 lb. each, in the form of a yellow, even-running liquid of the consistency of rich cream. It is then poured into vats holding about 100 lb., and a 10 per cent. solution of salt, borax, and calcium chloride is then added for the purpose of preservation. The mixture is thoroughly stirred until it assumes the consistency of thick molasses and is of a dark orange colour, and is then poured, or rather forced, through a funnel into a cask holding about 500 lb. net. It is then ready for shipment. This is used in the preparation and dressing of superior leather goods, and is in much demand in England, Germany, and France. No use has yet been found for the empty egg-shells, and they are thrown away.

*Antimonio-Tungstates, and the Separation of Tungsten and Antimony.* L. A. Hallopeau. Bull. Soc. Chim. 1897, 17, 170–175.

See under XXIII., page 358.

## PATENT.

*Gelatinised Paper or other Fabric suitable for the Reproduction, by Printing with Fatty Inks, of Writings, Drawings, and the like; Impts. in the Manufacture of.* C. Raymond, Suresnes, France. Eng. Pat. 1556, Jan. 22, 1896.

THE patentee claims the application to the lower surface of a paper or other fabric which has been gelatinised, of a suitable solution of one or more metallic salts (sulphate of copper, iron, zinc, lead, &c.), with or without a bichromate or chromate.

It is stated that the strength of the paper is thus increased, and also the fineness, firmness, and penetration of the transfer.—A. S.

## VII.—ACIDS, ALKALIS, AND SALTS.

*Sodium Nitrate, Newly Discovered Deposits of, in Colombia.* Zarácristi. Berg.-u. Huttenmann. Zeit. 1896, 55, 391.

DEPOSITS of crude sodium nitrate have been discovered by the author in the San Sebastiano river district, 100 kilom. from San Juan de la Cienaga, and apparently covering an area of about 75 sq. kilom. The beds are found at a depth of 2½–6 m. below the surface of the soil, and resemble in general character the deposits found in Chili and Peru—i.e., consist of a more or less stratified gypsiferous and chalky material impregnated with sodium nitrate, chloride, &c. Clean fragments of the nitrate have the sp. gr. 2.01, and consist of:  $\text{NaNO}_3$ , 23.1;  $\text{NaCl}$ , 34.1;  $\text{CaSO}_4$ , 8.5;  $\text{Al}_2(\text{SO}_4)_3$ , 3.4;  $\text{SiO}_2$ , 24.7;  $\text{MgO}$ , traces, and  $\text{H}_2\text{O}$ , 5.5 per cent. The average composition of the mass is:  $\text{NaNO}_3$ , 11.4;  $\text{CaCO}_3$ , 32.5;  $\text{CaSO}_4$ , 20.1;  $\text{SiO}_2$ , 32.4;  $\text{Ca}_3(\text{PO}_4)_2$ , 2.5;  $\text{Fe}_2\text{O}_3$ , traces, and organic matter, 1 per cent. It will be seen that in point of richness these deposits cannot compete with Chili nitrate.—H. T. P.

*Double Haloid Salts of Lead and Ammonium.* H. Fonze-Diacon. Bull. Soc. Chim. 1897, 17, [6], 346–356.

THE haloid salts of lead are soluble in more or less concentrated solutions of the ammonium haloid salts. On cooling, crystalline double salts separate, generally in the body of the liquid, and the mother-liquors will deposit, on the least fall in temperature, the salts with which they are saturated. Thus the crystalline deposit will be a mixture of several salts. In order to obtain from this the pure double salt, the author washes with a dilute solution of the ammonium compound, which is, however, sufficiently concentrated to prevent the dissociation of the double salt. Microscopic examination shows that the salts so obtained are homogeneous. In the analysis, the salts were converted into sulphates, and ammonium sulphate driven off by the application of a dark red heat. Ammonia was displaced by potash and collected in standard acid. To determine the halogens, the salts were dissolved in potash and excess of acetic acid added; in this solution the total halogens were determined by precipitation with silver nitrate, and also the silver required to precipitate the halogens was found volumetrically, after removal of lead by sulphuretted hydrogen; the two results enabled the amount of each halogen to be calculated.

The following salts were isolated:—

Type  $\text{MX}_3\text{A}$ :  $\text{Pb}(\text{Cl})_2(\text{NH}_4)_2 \cdot 2\text{H}_2\text{O}$  and  $\text{Pb}(\text{Br})_2(\text{NH}_4)_2 \cdot 2\text{H}_2\text{O}$ ; the corresponding acid  $\text{PbI}_2 \cdot 5\text{H}_2\text{O}$  has been identified by Ditte.

Type  $\text{MX}_4\text{A}_2$ :  $\text{Pb}(\text{Br}_2\text{Cl})(\text{NH}_4)_2$ ,  $\text{Pb}(\text{Cl})(\text{NH}_4)_2$ ,  $\text{Pb}(\text{Br})(\text{NH}_4)_2$ , to which the acid  $\text{PbI}_2\text{I}_2$  of Lassaigne corresponds.

Type  $\text{MX}_2\text{A}$ :  $\text{Pb}_2(\text{Br}_2\text{Cl})(\text{NH}_4)_2$ ,  $\text{Pb}_2\text{Cl}_2(\text{NH}_4)_2$ ,  $\text{Pb}_2\text{Br}_2(\text{NH}_4)_2$ ,  $\text{Pb}_2(\text{Br})(\text{NH}_4)_2$ ,  $\text{Pb}_2(\text{Cl})(\text{Br})(\text{NH}_4)_2$ .

Also a fourth group containing the salt  $\text{Pb}_2\text{I}_{10}(\text{NH}_4)_4 \cdot 6\text{H}_2\text{O}$  alone.

No double salts could be obtained from ammonium fluoride, its action gave rise to the salts  $\text{PbClF}$  and  $\text{PbBrF}$ .

—A. C. W.

*Sulphocyanides (Thiocyanates) in Gas Liquors, Conversion of, into Alkali Ferrocyanides.* A. Dubose. J. de l'Eclair. au Gaz. 45, [1], 10–12.

THE extended application of sulphocyanides (thiocyanates) in dyeing, calico printing, match-making, photography, &c. has directed attention to waste gas-liquors as a source of supply, since considerable quantities of these salts are contained in the mother-liquor from which the ferrocyanide has been recovered, and also in the ammoniacal liquor. In the first case, the ferric thiocyanate solution is treated with potash or soda, to throw down the iron, and the clear liquid is evaporated down. The ammonium sulphocyanide in the ammonia liquor is converted into insoluble copper sulphocyanide by the aid of a cuprous salt, and the copper being displaced by an alkali, the liquid is concentrated as before.

For the conversion of these sulphocyanides into ferrocyanides, Tcherniac's method—heating to 450° with finely-divided iron, and treating the mass with water—may be employed.—C. S.

## PATENTS.

*Alkaline Salts, Impts. in Obtaining from Blast-Furnace or other Gases, and Apparatus therefor.* G. Craig, Cumnock, N.B. Eng. Pat. 4489, Feb. 28, 1896.

WHEN coal or coke is burned, as in blast furnaces, whether alkali be added or not for the production of cyanides, the gases blown or drawn off are charged with alkaline salts, chiefly cyanides and carbonates of sodium and potassium. To recover these salts, the gases, after passage through a metal cooling trap, enter a horizontal conveyor tube, in which the salts that deposit are mechanically carried forward, and at the end fall through a short vertical passage into a filter chamber, where they are caught on the uppermost of a series of perforated plates, and spread out evenly by the action of a series of revolving scrapers. The gases, after filtering through the layers of deposited salts and the perforations in the plates, escape into a vertical side passage to the outlet main, whence they may be utilised for heating or other purposes. The excess salts swept off by the scrapers into the corner spaces provided, fall through openings into a conveyor tube for conveyance to a receptacle.

—E. S.

*Bicarbonate of Soda, Impts. in Apparatus for Filtering, Washing, and Drying, suitable for the Treatment of.* W. L. Wise, London. From Solvay et Cie., Brussels, Belgium. Eng. Pat. 4725, March 2, 1896.

THE apparatus, though specially designed for the treatment of sodium bicarbonate resulting from the ammonia process, is also applicable to all substances having similar physical properties. The bicarbonate is kept in aqueous suspension in a trough provided with an inlet pipe, and an overflow vertical pipe. A drum revolves in the trough about a horizontal, hollow axle, receiving a tube at each end connected to a pump or other arrangement for maintaining a partial vacuum within. The periphery of the drum is formed of a perforated metal sheet covered with a fine metallic cloth on which a piece of flannel is secured to form the filtering surface. As the drum revolves, the internal

suction draws in liquid to a higher level within than without, and a coating of the bicarbonate forms on the surface. To prevent too great obstruction of the pores of the filtering material, from time to time internal pressure is substituted for the suction, or the pressure of the higher liquid internal level is allowed to act, on the principle of counter currents, so as to reopen the pores.—E. S.

**Basic Lead Carbonate, Improved Process of Producing and of Obtaining certain Bye-Products [Caustic Soda and Nitric Acid].** The Chemical and Electrolytic Syndicate, Lim. O. J. Steinart and J. L. F. Vogel, London. Eng. Pat. 6657, March 26, 1896.

See under XIII. A., page 340.

**Sulphuric Acid Making Apparatus, Improved Joint or Connection for Use with Pipes in.** P. Duggan, Rochester, Kent. Eng. Pat. 5012, March 5, 1896.

The pipe leading the gas from the pyrites kiln to the acid tower is constructed at the end entering the Glover's tower with a hollow jacket, closed at its outer end by a cover plate, made in halves and bolted on, into which plate two small tubes pass, one for the entrance and the other for the exit of a flow of water. Alternatively, the cover plate may be removed, so as to admit a current of air only into the hollow jacket. The lead sheathing of the acid tower is worked out to a flange surrounding the water jacket, and is kept in place by an iron strap.

Instead of the connecting pipe being taken from the brickwork of the stack, it is preferably taken from a metal dome erected on the top of the stack, and the end of the pipe that enters the acid tower is made as a separate piece, and is connected to the dome by means of a removable intermediate piece. This arrangement facilitates the renewal of the pipe, when that is necessary.—E. S.

**Bay Salt, An Impt. in the Treatment of.** A. MacNab, London. Eng. Pat. 7464, April 8, 1896.

The larger are separated from the smaller crystals of bay salt by sifting or screening in brine.—E. S.

**Zinc and Alkalis, Impts. in the Electrolytic Production of.** [Two Diagrams.] O. Dieffenbach, Darmstadt, Germany. Eng. Pat. 25,804, Nov. 16, 1896.

See under X., page 335.

**Ammonia, An Improved Method or Process of Treating Substances containing Nitrogen for the Manufacture of.** H. H. Lake, London. From C. Pieper, Berlin, Germany. Eng. Pat. 28,199, Dec. 9, 1896.

The customary processes of treating nitrogenous matters for obtaining ammonia, consisting in successive drying, destructive distillation, and in steaming the coke produced, as distinctly performed operations, are modified by conducting the processes in a series (six being specified) of connected retorts, so as to admit of continuous working. The steam generated in the first retort of the series is conducted through a superheater, and then to other retorts in a specified order, which may be modified for adaptation to a "parallel connection method," or to a "series connection method"; in the first system, the superheated steam enters first that retort which is in the last stage of the steaming process; while in the second method the order is reversed, though later on the first-described order is adopted. The "steaming" process is stated to require a temperature of over 500° C.—E. S.

## VIII.—GLASS, POTTERY, ENAMELS.

**Kaolins [Pottery], Knowledge of, from a Manufacturing Point of View.** Seger. Monit. Céramique, 28, 53 and 64.

ANALYSES of kaolins, which state merely the composition of the clayey matter and neglect the subsidiary mineral substances, are insufficient to afford an explanation of the different behaviour of the various classes in practice: nor does the ultimate analysis of the whole mass of the substance assist the manufacturer, who desires rather to know the proximate constituents of his raw material. The subjoined table shows the variable nature of different kaolins

used for pottery, and demonstrates the approximately regular composition of the actual clay in all, revealing at the same time a wide range in the proportion of the three proximate constituents, sufficient to explain the considerable differences of the kaolins when subjected to manufacturing processes.—C. S.

**Glass Pots and Trough Furnaces, Clay for.** H. Seger and E. Cramer. Thonind. Zeit. 21, [6], 47—49. The chief qualities requisite in clay for making glass pots are:—Capacity to withstand the highest temperatures necessary for fusing the most refractory glass; sufficient plasticity to permit of the admixture of some 50 to 60 per

cent. of granular burnt fireclay; a comparatively low sintering point; and power of resisting the solvent action of the fused charge. This latter property is possessed in the highest degree by the clays approximating in composition to the formula  $Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$ .

Concerning the fineness of the burnt fireclay, it is found advisable to use up the fine powder formed during the grinding, as well as the coarser particles, in order to ensure a more perfect cohesion of the materials by reducing the shrinkage of the clay. The addition of burnt fireclay raises the sintering point of the clay considerably. For example, the sintering point of a clay, initially the same as the No. 1 Seger cone, was raised to the equivalent of the No. 5 cone, by mixing with 120 per cent. of burnt fireclay, and another from No. 6 cone temperature to that of No. 15 cone, by addition of 50 per cent. of burnt fireclay.

The best clays for this purpose are found at Vallendar, Mehlem, Gross-Almerode, Montabaur, Grünstadt, Passau, Deggendorf, Klingenberg, Saarau, &c., in Germany; Pilsen, Melnik, Goltvech, and Leoben, in Austria; Gluchow in Russia; Högarna in Sweden; Stourbridge and Garnkirk in Great Britain; Forges les Eaux in France; and Huy in Belgium.

A comparative examination of several samples of Belgian and Girode (German) clay showed that in the burnt condition the former contained between 52.72 and 78.1 per cent. of silica, 19.5 and 42.39 per cent. of alumina, and 0.9 to 1.4 per cent. of iron oxide; whilst the Girode clay contained per cent., 52.72 to 55.89 of silica, 40.44 to 44.85 of alumina, and 1.17 to 2.07 of iron oxide. The fusing points coincided in the former case with Nos. 28 to 39 Seger cones, and in the latter with Nos. 34 and 35. In respect of plasticity, shrinkage, and sintering temperature the Girode clay was approached only by the best of the Belgian samples, the remainder containing too much sand and requiring too high a firing temperature to be suitable for glass pots.—C. S.

#### *Sheet-Glass Making, German and Belgian Methods of.*

W. M. Sprechsaal, 30, [1], 3.

The chief difference between these methods is in the form of the cylinder from which the sheet is prepared, the practice in the one case (German) being to make a short wide tube, the length of which forms the shorter dimension of the sheet, whilst in the Belgian system the tube is long and narrow, the length of the cylinder being that of the sheet. The advantages of the latter method are:—The facility with which long sheets can be made—it being very difficult with the German system to make them over 1.5 m. long, whereas 2-metre lengths can be easily made by the other process—and the diminished proportion of waste in the shoulder, which, in the case of wide cylinders, amounts to  $\frac{1}{4}$  per cent. of the mass. The Belgian method has, it is said, almost entirely supplanted the other, even in Germany.—C. S.

*Oven, An Improved, for Burning or Fusing Lettering, Designs, Colours, and the like into or upon Articles of Glass, Earthenware, and other Glazed or Enamelled Goods.* F. Albrecht, Liverpool. Eng. Pat. 4189, Feb. 25, 1896.

This oven is intended more particularly for use in carrying into effect Mr. Knapp's process for the production of designs upon glass (Eng. Pat. 13,838 of 1893; this Journal, 1893, 927). The oven is a square box of sheet-metal plates, strengthened by angle-iron bars. It is provided with a pair of doors, is mounted upon a firebrick setting, and is cased in brick, a space being left all round to allow of the circulation of the products of combustion.—V. C.

*Glass, Impts. in Furnaces [Utilisation of Heat] suitable for Use in Manufacture of.* F. Radcliffe, Plumstead, Kent. Eng. Pat. 4945, March 4, 1896.

A CHAMBER is added between the melting and the working chamber, which serves as an exit flue. This added chamber is nearly surrounded by the working chamber, whereby the hot gases from the melting chamber "travel" practically over the whole surface of the molten metal in the working chamber, before escaping therefrom.—V. C.

*Ceramic Stone Objects, Manufacture of, by Devitrification of Glass.* L. A. Garehey, Lyons. Eng. Pat. 5772, March 14, 1896.

The objects are produced by *first*, partly devitrifying the glass powder in a furnace; *secondly*, completing the devitrification and fusing at a high temperature; *thirdly*, moulding under pressure in a frame with a movable bottom plate. By stirring in fused coloured glass, veined marble may be imitated.—V. C.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

*Mortar, Influence of Sea-Water on.* Thonind. Zeit. 21, 128—130 and 142—144.

THE results of the experiments carried out at La Rochelle since 1856 with cubical blocks (0.6 m. linear) of masonry, cements, and mortars of different composition, are summed up by Viennot in the following conclusions: (1) Cement employed without any admixture crumbles sooner than certain mortars; (2) Mortars containing either 1 or 2 volumes of sand per volume of cement—650 or 1,300 kilos. of cement per cb. m. of sand (volume being taken by reason of the variable amount of moisture in sand)—offer the greatest resistance to sea-water; some of the blocks lasting for 38 years. The same authority also concluded from a second series of experiments with cement, concrete, and slag cement, between 1889 and 1895, that: (1) Hydraulic lime mortars begin to decay in sea-water after one or two years, and are completely disintegrated after a maximum period of 15 years; (2) Concrete, on account of the compression effected, resists better than masonry; (3) Quick-setting cements begin to decay after five to eight years' exposure; (4) Slow-setting cements begin to crumble after six to eight years, but resist disintegration for over 38 years; (5) The best proportions for cement and sand are those given above.

One most important fact revealed by these experiments is that not one of the hydraulic cementing materials known is capable of resisting the action of sea-water when impregnated by the latter; and another is the necessity for the absence of free lime capable of slaking after the cement is mixed, whether due to an insufficient amount of silica and alumina to saturate the base, or to the irregular admixture of separately calcined materials. The danger arising from the presence of such free lime increases in proportion with the calcining temperature employed, especially in the case of the natural Portland cements, the expansion occurring on the absorption of sea-water resulting in disintegration of the mass. For minimising the permeability of the cement, the best results are obtained by using a coarse sand, the mass being less porous than when fine sand is employed; and as far as the cement itself is concerned, Portland cement is superior to Roman cement, Teillime, &c., though theoretically these latter should be the best. The reason for this is to be found in the ratio between the amount of water required for mixing and that actually taken into combination with the cement: Portland cement, for example, combining with 18 to 20 per cent. out of the 25 per cent. necessary for mixing, whilst hydraulic lime and Roman cement retain only 8 to 10 per cent. out of 40 to 60 per cent., and slag cement only 5 to 6 per cent.; and one of the advantages possessed by coarse sand over fine, consists in the maintenance of this ratio, the amount of water required by the former being comparatively small; whilst the porosity of the mass is slight, amounting in the case of a mixture of 650 kilos. of cement and 1 cb. m. of sand, to only 9 per cent., whereas with lime in the same proportion the porosity is 21 per cent. To the same circumstance the superiority of concrete is due. The brittleness of unmixed cement is due to excessive crystallisation and the expansion of the free lime during hydration, the advantage of an admixture of sand being shown by tests wherein pure cement, after four years' exposure in sea-water, resisted a pressure of 6.4 kilos. per sq. cm., whilst that mixed with an equal weight of lime withstood up to 54.7 kilos.—C. S.

*Bricks and Brickwork, Incrustations on, or Efflorescence, through Weathering.* B. Deutsche Bau Zeit.; Thonwaren Industrie, 11, 21 and 35.

This subject was treated by H. Günther in an inaugural address at the University of Rostock. Vegetable growths appear on light-coloured stone surfaces exclusively, and require for their development moisture and shade. Mineral incrustations are mostly white or grayish, more rarely yellow or green, these latter being due to vanadium. In appearance these incrustations vary, according to the solubility of the component salts, from floury or woolly powders to stalactitic masses, and may result from various causes present either in the raw clay, or introduced in the water employed in brickmaking, or from pyrites in the clay or fuel, or from the ash of the latter material. Again, the infiltration of soluble substances from the mortar, or combination of the alkalis in the latter with the gypsum in the bricks; or finally the absorption of nitrates from the soil and ammonia or sodium chloride (near the sea) from the air may give rise to incrustation.

The sulphates and other soluble salts in crude clay are brought to the surface of the bricks by the evaporation of water in the drying process, and if this is conducted irregularly so that the water evaporated in one part of the kiln is condensed in another and re-evaporates as the heat diffuses, the bricks practically undergo a process of lixiviation, which results in the formation of injurious cracks. In burning, the sulphur of any pyrites present in the clay or coal becomes finally oxidised to sulphuric acid, which combines with the bases, and especially with lime, this being particularly the case in the continuous system of burning, by reason of the excess of air admitted. This reaction is outwardly manifested by an intense red coloration on the affected surfaces.

From the mortar, a portion of the caustic lime may be extracted and on exposure to the air may form an incrustation of carbonate; or the other caustic alkalis may by reaction on the gypsum of the bricks give rise to an efflorescence of sulphates, especially of sodium. Nitrates are formed by bacterial action on ammoniacal compounds absorbed from the air, or may be taken up from the ground with which the bricks are in contact.

Whilst incrustations of calcium carbonate do no harm beyond spoiling the appearance of the bricks, the soluble alkali salts, by the repeated solution and recrystallisation in the interior, resulting from atmospheric changes, cause disintegration on exposure to the weather. The tendency to rot from this cause increases with the percentage of lime or magnesia in the clay.

To prevent these incrustations, pyrites and sulphates can either be removed by the slow process of seasoning the clay by prolonged exposure to the weather before making up into bricks, or by adding barium salts to the clay before burning, so as to produce the insoluble barium sulphate. Another means of assistance is the prevention (by restriction of the air supply) of the oxidation of the sulphur beyond the SO<sub>2</sub> stage; and finally by burning the bricks very thoroughly, since in that state they are less disposed to absorb the moisture necessary for the extraction of the soluble salts.—C. S.

## PATENTS.

*Artificial Stone [from Sand and Lime].* Impts. in the Manufacture of. S. Neffgen, Mülheim-on-the-Rhine, Germany. Eng. Pat. 3972, Feb. 21, 1896.

NEARLY dry slaked lime is mixed with quartz sand, moulded in the required shape, and placed in a heating chamber. The temperature is then raised so as to attain 50° C. in 5 or 6 hours, and 80° C. after a further 12 hours. This temperature is maintained constant for 2 or 3 hours, and then the heat is rapidly increased to 95° C., and there maintained for from 4 to 6 days. The last operation produces a smooth, compact surface of calcium silicate. The pieces have a uniform colour throughout, and the smooth surface does not require any finishing operation.—V. C.

*Compressing Wood and Utilising Certain Waste Products therefrom.* Impts. in. A. de Pont, Lancaster, Eng. Pat. 5973, March 17, 1896.

THE inventor claims (1) "the process of compressing wood to increase its density, which consists in subjecting it to an equal pressure from both sides whilst it is maintained at a high temperature, sufficient to soften or liquefy the gums therein, and retaining such pressure until it is cool and the gums have set"; and (2) "the process of constructing or manufacturing a product resembling wood, which consists in mixing with or adding to sawdust or wood refuse a quantity of gums, resins, or other suitable agglutinants, either in a dry state or dissolved, and subjecting the compound to a great pressure at a temperature sufficiently high to soften or melt the gums or resins."

—V. C.

*Readily Fusible Composition or Cement.* Impts. in or connected with. T. Smith, Richmond, Surrey. Eng. Pat. 8595, April 23, 1896.

"A FUSIBLE composition or cement [of the class known as 'Spence's metal'], composed of sulphides, sulphur (or bitumen, resin, refuse wax, or shale grease), slate dust or silica, alumina, bitumen, and wax." No coal or coke is mixed with the materials, which, in this improved process, are heated in a closed vessel.—V. C.

*Artificial Stone.* Impts. in, for Street Pavements, Pathways, and like Purposes, and in the Method of Producing the same. A. J. Boulton, London. From J. Jungbluth, Cologne. Eng. Pat. 18,714, Aug. 24, 1896.

"AN artificial stone consisting of a top layer of pulverised asphalt, a binding material of ground Portland cement, powdered unslaked lime, and ground trass, and a ground-material of hard porous stone in the form of powder and small pieces of about 5 mm. and 10—12 mm. in diameter." The binding materials are introduced in a very slightly wetted condition, the top material being introduced very hot. Combination is brought about by a pressure of about 300 atmospheres, and the setting, after removal from the mould, takes place under the action of a water spray.—V. C.

*Drying or Sterilising Wood, A New or Improved Process and Means for.* A. L. C. Nodon and L. A. Bretonneau, both of Paris. Eng. Pat. 19,047, Aug. 28, 1896.

THE wood is steeped in a concentrated solution of soda soap, and afterwards in a solution containing a soluble salt of an alkaline-earth base, and is then dried in air. It is stated that "the density of the wood has increased; the colour has not changed; it has a silky appearance; it does not crack, nor does it split; wet does not affect it, nor sun; and it is unattackable by insects."—V. C.

*Slating Compounds [Writing Slates].* Impts. in. W. P. Thompson. From W. H. Brawley, J. R. Coles, and C. N. Coles, New York, U.S.A. Eng. Pat. 22,157, Oct. 6, 1896.

THE inventor proceeds as follows:—To about 1 lb. of shellac,  $\frac{1}{2}$  lb. of borax and about 1 gal. of water are added, and the solids allowed to dissolve. The solution is then diluted with about  $\frac{1}{2}$  gall. of water, and  $\frac{1}{2}$  lb. of alumina or eryolite is added. This liquid is applied as a first coating to the earlboard or other sheet, which is then allowed to dry. A second coat of material is then put on, which makes the paper thoroughly waterproof, the surface being smooth and even, and the texture of the paper not being destroyed. The surface of such material is also capable of taking the marks of a lead pencil, which may be readily erased or rubbed out again.—S. P. E.

*Paving and like Purposes: Impts. in the Manufacture of Compositions for.* [Tar Paving.] J. A. Just, Syracuse, New York, U.S.A. Eng. Pat. 23,105, Oct. 17, 1896.

A COMPOSITION prepared by treating tar with sulphur at from "138° C. to 204.5° C.," adding rosin, also a sulphurised heavy hydrocarbon, and agitating the mixture. The asphalt-like material, mixed in the proportion of about 15 parts to 85 with fine sand, forms a paving material.

—V. C.

*Burning Cement, Lime, and the like, and for Smelting Ores; Impts. in Furnaces for.* A. Stein, Wetzlar, Germany. Eng. Pat. 27,219, Nov. 30, 1896.

INSTEAD of using a lining of fire-proof material, the inventor seeks to protect the furnace shell from overheating by means of open passages *outside* the shell, and "by means of the draught or current of air rising up in the same, or it may be by radiation of the heat, there is produced an effective cooling action."—V. C.

## X.—METALLURGY.

*Gold in Formosa.* Eng. and Mining J. 1897, 139.

ALTHOUGH the present alluvial gold-fields have only been discovered about 10 years, there are now engaged more than 3,000 workmen collecting gold on the upper reaches of the Tam-sui river. According to the Chinese Customs returns, over 700,000 taels of gold-dust have been exported to Hong Kong and Shanghai. In addition to this, large quantities have been smuggled from the island, and it is anticipated that, with the use of suitable machinery and with proper supervision, the output of gold will greatly increase.—A. W.

*Gold, Cyanide of: Solution and Precipitation of.* S. B. Christy. Trans. Amer. Inst. Mining. Eng. 1896, 1—38.

THE paper is divided into three main sections, with sub-headings:—

### I. THE SOLUTION OF GOLD IN CYANIDE SOLUTIONS.

1. *Solution of Metallic Gold in Potassium Cyanide.*—The author confirms Ellsner's well-known reaction ( $4\text{KCy} + 2\text{Au} + \text{O} + \text{H}_2\text{O} = 2\text{AuKCy}_2 + 2\text{KHO}$ ), and finds that pure potassium cyanide dissolved in pure water is entirely without action on metallic gold; but when oxygen is admitted to the solution, the metal dissolves at a rate proportional to the oxygen added, but without immediately oxidising the cyanide to cyanate, as MacArthur had assumed.

2. *Effect of Oxidising Agents.*—Oxidising agents, like oxygen itself, when added to the cyanide solution, increase the solubility of the gold. Among the most convenient and efficient of these were found to be the peroxides of sodium and manganese, and potassium ferricyanide; but the chlorate, nitrate, permanganate, and bichromate of potash, and the peroxides of barium and lead, were also effective. It thus being apparent that the essentials of the cyanide process were free cyanogen to form gold cyanide, and free potassium cyanide to form the double cyanide, cyanogen bromide was added to potassium cyanide liquors in order that nascent cyanogen might be formed (this Journal, 1895, 14, 870); this was so successful (in 1894) that experiments were extended, and bromine water was used in place of the bromide. The chemical effect of the two reagents is the same, and the author prefers the bromine water, in opposition to the opinion of Teed. The bromine solution must be added little by little as required, otherwise cyanogen is generated faster than it can be used, great loss of this substance takes place, and para-cyanogen and dark-coloured oxidised compounds are formed. Both bromine and cyanide liquors must be very dilute. The reactions are as follows: (a)  $2\text{KCy} + \text{Br} = \text{KBr} + \text{Cy} + \text{KCy}$ ; and (b)  $\text{Au} + \text{Cy} + \text{KCy} = \text{AuKCy}_2$ , rather than as given by Mulholland (this Journal, 1895, 14, 662), in which the influence of oxygen is postulated. The relative gold-dissolving values of bromine, chlorine, and oxygen are shown by the fact that 1 oz. of each element, respectively, will lead to the solution of 2.45, 5.52, and 24.5 oz. of gold. Oxygen is often to be preferred, and is usually present in the cyanide solution in sufficient quantity for the treatment of low-grade ore; in treating higher grade ore the greater solubility of the halogens gives them the advantage; but the solution must not be too strong, for the reason given above, and because secondary actions may result from the presence of sulphides, &c., with the generation of cyanicides. Even with rich ores, unless used with the nicest discrimination, the addition of oxidising agents may do more harm than good.

3. *Solubility of Gold Sulphide in Potassium Cyanide.*—The occurrence of gold as sulphide is sometimes disputed, although it is known to be found as telluride. The combination of sulphur and gold in the dry way could not be effected, and therefore experiments were made with  $\text{Au}_2\text{S}_3$  precipitated from solution by hydrogen sulphide. This compound was found to dissolve in a 5 per cent. solution of KCy in 4 minutes, in a 1 per cent. solution in 10 minutes, and in a  $\frac{1}{2}$  per cent. solution in an hour. No oxygen is necessary to the action, which is somewhat complex; three reactions having been observed, depending upon the strength of the cyanide solution used:—(a)  $\text{Au}_2\text{S}_3 + 4\text{KCy} = 2\text{AuKCy}_2 + \text{K}_2\text{S} + \text{S}$ ; (b)  $\text{KCy} + \text{S} = \text{KCyS}$ ; (c)  $\text{Au}_2\text{S}_3 + \text{K}_2\text{S} = \text{Au}_2\text{K}_2\text{S}_2 + \text{S}$ . The presence of suspended sulphur was most apparent in dilute cyanide solutions.

4. *Solubility of Gold Telluride in Potassium Cyanide.*—Tellurides of gold and silver, prepared by direct combination of the elements, or obtained from natural sources, are only dissolved by the cyanide liquor with the greatest difficulty. This is probably because the affinity of tellurium for potassium is less than that of sulphur, and because tellurous acid is formed by oxidation, and retards the oxidation of the potassium and the solution of the gold.

5. *Solubility of Gold Antimonide in Potassium Cyanide.*—This compound behaved like the telluride, a copious precipitate of antimony oxide forming in the solution, and retarding the action.

### II. THE PRECIPITATION OF GOLD FROM CYANIDE SOLUTIONS.

Potassium aurocyanide solutions contain the gold in a most stable form, and text books are wrong in stating that the yellow gold cyanide is precipitated on acidification with sulphuric acid from (say) a 1 per cent. cyanide solution. Only hot concentrated sulphuric acid causes such a separation; and the cyanide of gold ( $\text{AuCy}$ ) is more stable than the telluride, requiring the strongest hot sulphuric acid to decompose it, with the deposition of metallic gold. All indications tend to show that the gold exists in the solution as aurocyanhydric acid ( $\text{HAuCy}_2$ ) rather than as the double cyanide ( $\text{AuCy.KCy}$ ).

1. *Regeneration of Potassium Cyanide from Dilute Solutions by Acidification.*—A 1 per cent. solution of KCy was not found to give any apparent trace of HCy when acidified with sulphuric acid; yet, if such a solution be allowed to stand for several weeks near an open vessel containing caustic potash, nearly all the KCy may be absorbed by the alkali. By passing air and steam first through the acidified solution and then through the solution of caustic (using the same air over and over again to eliminate the action of carbon dioxide), the free hydrogen cyanide in the stock solution could be reduced from 1 per cent. to 0.07 per cent. in 3 hours; without steam the same result was obtained in from 8 to 10 hours. On a large scale, absorption towers could be used. In this way a concentrated solution of any strength of KCy or  $\text{CaCy}_2$  may be regenerated from a 1 per cent. stock solution with a loss of only 10 to 20 per cent. of cyanide. Alkaline sulphides must, however, be removed before treatment, by the addition of lead carbonate or sulphate.

2. *Precipitation of Gold from Aurocyanhydric Acid.*—Although free HCy could be removed by the last process down to 0.01 per cent., all the gold, even up to \$603 per ton (0.1 per cent.), would remain dissolved in the clear, colourless solution. Oxalic or sulphurous acids or hydrogen sulphide fail to precipitate the gold, which can, however, be partially thrown down by nitrate of lead or mercury, and completely so by an excess of silver nitrate. The use of the silver salt would be practicable on the large scale if it were not for the cost of the reagent. Oxidising agents, such as potassium permanganate or the peroxides of lead and manganese, facilitate precipitation in acid solutions. Filtration through massicot was patented by de Wilde in 1894.

3. *Precipitation of Gold from Potassium Aurocyanide by means of Charcoal.*—An American patent was granted to W. D. Johnson in 1894 for the recovery of gold from cyanide liquors by passing them through a series of charcoal filters, the material from which, after calcination, was to be

smelted. It was claimed that 25 per cent. of the gold was removed by a single filtration, and that by repeated filtration 95 per cent. could be recovered. It is now found that the charcoal is capable of precipitating a certain percentage of its own weight of gold rather than a definite proportion of the metal present. Thus, with a 0.1 per cent. solution of gold (\$603 per ton of solution), only 15 per cent. of the gold present was extracted after four filtrations when the liquid was acid, and only 6.5 per cent. when it was alkaline, the charcoal after filtration assaying 0.21 per cent. and 0.091 per cent. of gold respectively. But by employing 2,000 c.c. of a 0.001 per cent. gold solution (auro-cyanide), in one case without, and in another case with 0.2 per cent. of free KCy, and filtering the liquid through glass tubes (10 cm. long and 2 cm. in diameter) containing 10 grms. of charcoal dust, it was found that the recovery of gold from the former solution amounted to 99.95 per cent., and that from the liquor containing free cyanide was 93.03 per cent., whilst the free cyanide in the latter instance was reduced to 0.118 per cent. The charcoal contained 0.2 per cent. and 0.187 per cent. of gold in the two experiments respectively. Filtration was effected under constant head. The first 800 c.c. took two days to filter, and then contained 0 and 0.01 mgrm. of gold in the two cases respectively; the remaining 1,200 c.c. required five days, and afterwards contained 0.01 and 1.4 mgrm. respectively. It would thus seem that free acid slightly raised the absorbing power of the gold, whilst free cyanide diminished it. The limit of saturation was probably reached in these experiments at about 0.2 per cent., which compares unfavourably with the concentrated material obtained by zinc, cuprous, or electrolytic precipitation.

4. *Precipitation of Potassium Aurocyanides by Mercuric Chloride.*—Fremy gives the following equation:—

But the reaction takes place very slowly in the cold. It is found to be hastened by warming; and on boiling for a few minutes, almost the whole of the gold may be precipitated as the easily filtered yellow cyanide. For practical work potassium cyanide could be regenerated in the filtrate by precipitating with just sufficient potassium sulphide to throw out all the mercury as sulphide; in this case the small quantity of gold left in the solution would not be lost. The yellow cyanide of gold may be ignited to pure gold at a low red heat. Free cyanide, however, prevents the precipitation, and the heating of the solution introduces complications industrially.

5. *Precipitation of Potassium Aurocyanides by Copper and its Compounds.*—Copper immersed in the aurocyanide solution causes the deposit of a yellow sediment, not upon the metal, but in the solution; in one experiment 75 per cent. of the gold was thus precipitated in three days, and then the copper was removed, but the deposit continued to increase for over a week, until only 11 mgrm. of gold remained dissolved. The successful use of cupric sulphide as a precipitant in the chlorination process led the author to experiment with it for cyanide work. Using freshly precipitated CuS and an aurocyanide solution containing 0.25 grm. of gold and 0.02 per cent. of KCy, the whole of the gold was precipitated from the solution when acidified with sulphuric acid, and two-thirds from neutral or alkaline solutions, after agitation with the CuS for four hours. The solution must contain free mineral acid, and not more than 0.1 per cent. of free HCy. The CuS, Aq produced by the action of  $\text{H}_2\text{S}$  on a solution of  $\text{CuSO}_4$  is added to the gold solution, the mixture is stirred at intervals for several hours, and the gold will then be found in the residue. In one case 5 grms. of CuS completely precipitated 1 grm. of gold from 1,000 c.c. of acidified solution. The gold was readily recovered from the residue by digestion with sodium sulphide, in which the precious metal dissolved, leaving the CuS ready for further use. Electrolysis precipitates the gold from the sulphide solution, the more readily from concentrated solutions. Filtration through CuS may suffice for the precipitation of the gold in the first case; but agitation is preferred, and in the absence of free HCy, the gold is precipitated by the copper, atom for atom. It is noteworthy that not more than a trace of copper passes into solution when the gold is

deposited, and it appears that the gold-containing precipitate is mainly a cuprous aurocyanide, or the corresponding sulpho-salt. For this reason cuprous chloride or cyanide (or other cuprous salt) is equally effective with the cupric sulphide. Cuprous thiosulphate (hyposulphite) could also be used, but the resulting precipitate is soluble in excess of either potassium cyanide or thiosulphate, so that complete precipitation is almost impossible, except after acidification. The author uses and prefers cuprous chloride as a precipitant, and adds it to the acidified solution (from which free HCy has been removed) until a drop of the filtrate from the resulting yellowish precipitate gives a red precipitate with potassium ferrocyanide. De Wilde (see this Journal, 1895, 14, 163) also uses cuprous chloride, but forms it in the solution, and acidifies at the same time by means of sulphurous instead of sulphuric acid. The recovery of the excess of cyanide recommended by de Wilde is possible, but is said to be thoroughly impractical. When de Wilde's gold precipitation method is used, the gold comes down very slowly, and the solution must be allowed to stand longer before and after filtering, it is said (the latter to ensure that precipitation is complete), than when the author's process is used.

6. *Use of Electricity for Precipitating Gold from Cyanide Solutions.*—The difficulties to be encountered here are the high resistance and low concentration of the solution, and the gradual change in its composition. Large electrodes must be used to reduce the resistance; but even then gold is sometimes deposited on the anode as well as on the cathode, and is partly contained in a deposit which forms in the solution. The cause of this is that the salt,  $\text{KAuCy}_2$ , breaks up under electrolysis into K, which is deposited at the cathode, and the ion  $\text{AuCy}_2$ , which tends to separate at the anode, the deposition of gold on the cathode being due to the secondary chemical action of the potassium upon the solution. High current-density and long treatment are therefore required to separate all the gold. By acidifying the bath with sulphuric acid, the recovery of the gold is practically complete (on a small scale) in 12–24 hours, with either soluble or insoluble anodes; but the cyanide is lost unless special means be used to recover it. In the absence of such technical skill as was shown by Siemens and Halske, failure, it is believed, is almost certain to result from an attempt to introduce a new electrolytic recovery process.

7. *Precipitation of Gold from Cyanide Solutions by Means of Zinc.*—The difficulties in this precipitation are well known; but sufficient attention has not been paid to the incompleteness of the precipitation of gold by zinc. The usually accepted equation—

is apparently incorrect. It is found that burnished zinc gives no gold deposit, whilst the same zinc, as rough turnings from the lathe, works satisfactorily; and that the reaction proceeds best in the presence of a little free cyanide. But, at best, precipitation is irregular and incomplete. The author considers it probable that the double cyanide tends to dissociate in part into the ions K and  $\text{AuCy}_2$ , and that these then react with zinc and water as follows:—

The rough surface of the zinc turnings is here supposed to facilitate the escape of the hydrogen, and the presence of free cyanide to cause the solution of an insoluble film of zinc cyanide, which, otherwise, would prevent further action. When once started, a further reaction between the zinc cyanide and caustic potash would set in, so that the complete reaction would be thus represented:—

Hydrogen is undoubtedly produced, but it may partly result from the action of the gold-zinc couple upon the double cyanide of potassium and zinc. It is probable also that KCy is dissociated, forming KOH and HCy, and that methylamine is produced by the action of nascent hydrogen upon the latter. It may be noted that phenolphthalein gives no coloration with either pure potassium aurocyanide or

with water containing zinc turnings; but on mixing the two liquids, the usual deep rose colour is seen in the neighbourhood of the zinc. This may be due to caustic potash, methylamine, or possibly to zinc-potassium cyanide. The enormous consumption of zinc in the process is caused by the action of potash, potassium cyanide, and oxygenated water upon this metal. In practice, it is impossible to remove all gold from a cyanide solution within (say) 24 hours, unless there be 0.1 to 0.2 per cent. of free cyanide present.

8. *Recovery of Potassium Cyanide from Strong Solutions by Zinc Sulphate.*—When strong solutions of cyanide are used (1 per cent.), the cyanide should be recovered before precipitating the gold by the cuprous method. This may be done by Hant's process (patented in 1895). Alkaline sulphides are first removed from the cyanide liquor by means of lead sulphate; excess of zinc sulphate is then added, and the resulting precipitate of zinc cyanide is separated by decantation or filtration, which is easily effected if the zinc sulphate be in excess, but not otherwise. The zinc cyanide is then decomposed by sulphuric acid, and the hydrocyanic acid is recovered in caustic potash as already described. Even when 0.1 per cent. of gold is present in the liquor, only a little separates with the zinc cyanide, and this passes into the zinc sulphate solution (as  $\text{H}_2\text{AuCy}_2$ ), from which it is recovered by precipitation with sulphurous acid and sulphate of copper, or with cuprous chloride direct. This process is altogether superior to that of de Wilde, but gives trouble when the liquors contain potassium ferrocyanide, which yields zinc ferrocyanide, that settles and filters only with great difficulty, having the consistency of lard. When this substance is present, simple acidification of the original solution, with direct absorption of the  $\text{HCy}$ , would give a better result than the preliminary zinc sulphate precipitation.

9. *Precipitation of Aurous Cyanide by means of Zinc Chloride.*—This is the basis of Rinder's patent (1895). The author found that zinc chloride formed by solution of zinc in hydrochloric acid produced only a trace of aurous cyanide precipitate in aurous cyanide liquors; but that when prepared by treating an excess of zinc oxide with hydrochloric acid, so that an oxychloride was formed, 99.4 per cent. of the gold present was precipitated. The process is, however, inferior to the cuprous method, because the gold cyanide precipitate is soluble in excess of either acid or alkali. Before adding the zinc chloride to the liquor, the silver in the latter must be removed as sulphide by the addition of iron sulphide.

### III.—THE TREATMENT OF ORES.

An extraction efficiency of 60 to 70 per cent. may be sufficiently good for the treatment of low-grade tailings in South Africa, but would not be satisfactory in the case of ores assaying 100 dols. per ton, such as those to which the author has directed his attention. By studying each ore carefully the author has been able to bring up the efficiency of the cyanide process as follows:—From 70 per cent. to 99 per cent. in the case of Idaho mine concentrated sulphurets assaying 120 dols. per ton; and from 75 per cent. to practically 100 per cent. with Alaska Treatwell concentrates assaying 50 dols.; whilst Bald Eagle (Alaska) concentrates assaying 280 dols. yielded 97 per cent. On the other hand, Bay State concentrates (California) assaying 160 dols. have at present given only a 90 per cent. extraction efficiency. There is every probability that in time equally good results may be obtained on a large scale. The cyanide process may not displace, but it should supplement, existing methods, and has a promising field in the treatment of low-grade ores.—W. G. M.

*Alloys containing Zinc, On the Freezing-Point Curves of.* C. T. Heycock and F. H. Neville. *Proc. Chem. Soc.* 1897, [176], 60—62.

THE paper is divided into two sections, the first dealing with cases where the freezing point of zinc is depressed by the addition of another metal, the second with the cases where it is raised by such an addition.

In section I., complete binary alloys of the following pairs of metals, zinc-cadmium, zinc-aluminium, zinc-tin, and zinc-bismuth, are given. In the first three cases the metals appear to be miscible with each other in all proportions, but for zinc-bismuth the freezing point curve shows the horizontal line of identical freezing points characteristic of the state when the alloy has separated into two conjugate liquids.

Taking the freezing point of zinc as  $419^\circ$ , the authors find for the temperatures of freezing and the composition of the eutectic mixtures the following:—

Alloy.	F.P.	Atomic Percentage of Zinc.
Zn—Cd .....	264.5	74.0
Zn—Al .....	281.0	11.0
Zn—Sn .....	198.0	84.0
Zn—Bi .....	254.5	91.8

They do not consider that there is any indication of these metals combining chemically to form definite compounds when they are melted together.

Dilute solutions of the following metals in zinc were also examined:—lead, thallium, antimony, magnesium.

The authors find that, with the exception of aluminium and cadmium, all the above-mentioned metals, when added in small quantities to molten zinc, cause the same atomic fall; that is, an alloy containing 1 atomic weight in solution in 99 atomic weights of zinc has a freezing point lower by  $5.1^\circ$  than that of pure zinc. Cadmium causes a somewhat smaller and aluminium a decidedly smaller depression. The atomic depression of  $5.1^\circ$ , when used with Van't Hoff's equation for the latent heat, gives 28.3 calories for the latent heat of fusion of zinc, instead of Person's value of 28.13.

In section II., dilute solutions of copper and of gold in zinc are considered, and also a complete freezing point curve for all alloys of zinc and silver.

When small quantities of any one of these three metals are added to molten zinc the effect is the same: the freezing point is raised, and the whole mass of metal appears to solidify at a temperature above the freezing point of pure zinc. The rise in the freezing point, moreover, is proportional to the amount of the second metal present. But when as much as 2 atomic per cents. of silver or of copper or 3.3 of gold have been added, the phenomenon alters, apparently abruptly. There are now two freezing points, a higher one which is very fugitive, and which is followed by the precipitation of much solid, and a lower one which is very constant, and which is independent of the amount of the added metal so long as the above-mentioned minimum is present. In the zinc-silver curve singularities are also found near 70 and 60 atomic per cents. of zinc, indicating the existence of more or less stable compounds, but the formula of these compounds is uncertain. Near 37.5 atomic per cents. of zinc there is another well-marked angle and a series of eutectic second freezing points, the phenomenon being possibly due to the separations of the alloy into conjugate liquids.

The authors also describe briefly some of the physical properties of the zinc-silver alloys, which appear to change in character at the angles of the curve.

The composition of the silver-zinc alloys at each freezing point was determined by extracting a portion in the liquid state, and estimating the percentage of silver by a volumetric analysis.

*Gold or Auriferous Mineral, Method for Estimation or Extraction of.* E. Serrant. *Comptes Rend.* 1897, 124, [9], 180.

THE process consists in adding to the crushed mineral a mixture of sodium chloride, sodium nitrate, and sulphuric acid, in proportions approximately calculated according to the richness of the mineral. When the reaction is complete, water is added to dissolve the chloride of gold, and the gold is precipitated from this solution by ferrous sulphate, oxalic acid, or sulphuretted hydrogen.—C. A. M.

*Melted Copper and Copper Alloys, Removal of Oxide from, by Phosphorus.* S. Kern. Chem. News, 1897, **75**, 57.

THE phosphorus used for removing oxide from melted copper and copper alloys is first submitted to the following treatment:—The phosphorus is cut into pieces weighing about 3 oz. each, and placed in a concentrated solution of copper sulphate, where they are left until they are covered with precipitated copper. The phosphorus is thus rendered easy and safe to handle, and also, when thrown into the pots, does not take fire at once, but safely reaches the molten metal.

About two pieces are usually sufficient for 1 cwt. of metal in the pot, the phosphorus playing the part ferromanganese does in steel.—A. S.

#### PATENTS.

*Gold, Silver, and other Metals, the Extraction of, from Ores and the like; Impts. in.* A. B. Torres, London. Eng. Pat. 3086, Feb. 11, 1896.

THE ore, crushed to pass a 20-hole per linear inch sieve, is placed in a tank with perforated walls covered with a filtering medium, and set within a larger tank. It is here subjected to the action of an electrolysed solution of sodium fluoride and sodium chloride, and, subsequently, to further action of the hydrofluoric acid solution, to which a mixture of potassium cyanide and potassium bromide has been added. Carbon or other anodes stand in the ore compartment, and lead or other cathode plates receive the electrolytic deposit in the outer cell.—W. G. M.

*Gold Ore, Amalgamating and Extracting Gold or other suitable Metals from, when Dry-crushed; New or Improved Process for.* F. L. Oppermann, London. Eng. Pat. 4165, Feb. 25, 1896.

THE crushed ore falls from a hopper into a vertical steam-jacketed chamber, in which is a perforated spiral pipe. A mixture of mercury vapour and steam is projected through the perforations, and the ore and condensed vapours fall over a series of sloping zig-zag plates through a vertical amalgamating chamber. The lowest sloping shelf is provided with a gutter to retain mercury, and the tailings passing from this plate come in contact with a blast of cold air, which serves to condense any mercury vapour still remaining. Steam and mercury vapour may also be introduced through subsidiary pipes in the amalgamating chamber if necessary.—W. G. M.

*Aluminium, or Metals alloyed with Aluminium, Soldering of.* F. C. Barnes and F. Campbell, Greenwich. Eng. Pat. 4667, March 2, 1896.

THE basis of an aluminium solder must be zinc. The best results are obtained with an alloy of 95 per cent. of Zn and 5 per cent. of Al, or, for a solder with a better colour, 80 per cent. of Zn, 5 per cent. of Al, and 15 per cent. of Ag. Tin must be absent, or the joints will be unsound and will lack permanence. The surfaces to be joined are filed or scraped, and are then heated "to the right temperature," when the solder is applied without flux.—W. G. M.

*Alloys, Impts. in.* [Copper] J. C. Bull, Erith. Eng. Pat. 4899, March 4, 1896.

A tin amalgam, containing from 2 to 4 per cent. of mercury, is added to molten electrolytic copper, to the extent of

2 to 1½ per cent. Less pure copper may be used, but then phosphide of copper must be added before the amalgam, taking care that no appreciable amount of phosphorus be left in the metal. Such an alloy is said to roll and work well at a red heat, and to be sufficiently hard for ordinary purposes when cold.—W. G. M.

*Sewage and other Waste Liquids, The Utilisation of By- and Waste Products [Flue Dusts] from Iron and Steel Industries for the Manufacture of Improved Precipitants for the Purification of.* W. E. Adeney, and W. K. Parry, both of Dublin. Eng. Pat. 5955, March 17, 1896.

See under XVIII. B., page 349.

*Aluminium Alloys, Manufacture of; Impts. in.* W. Pearson, Birmingham, and J. A. Bott, Colwyn Bay. Eng. Pat. 6033, March 18, 1896.

TO alloy aluminium with 0·1 to 5 per cent. of cobalt, the former metal is melted in a closed nickel crucible, and is then poured into a crucible containing the required quantity of cobalt in a state of fusion.—W. G. M.

*Metals, Volatile; Apparatus for Separating from their Alloys.* J. Murray, London. From M. A. J. Roux, Paris. Eng. Pat. 6572, March 25, 1896.

A HORIZONTAL distillation-chamber is supplied with charcoal and heated to the temperature necessary to volatilise the metal required; at one end is a smaller and separate melting chamber connected with it by a U-shaped channel that serves both as a liquid seal and as a means of conveying the melted alloy or amalgam into the larger chamber. At the opposite end is a second U-shaped seal for the withdrawal of the residual alloy, and a line leading to a condensing chamber for the reception of the volatilised metal.

—W. G. M.

*Chemically Pure Gold from Fine Gold and Alloys rich in Gold, An Improved Process for Obtaining. [Hot Gold Chloride Bath.]* W. P. Thompson, of the Agency for Foreign Patent Solicitors, London. From Dr. E. Wohlwill, Hamburg, Germany. Eng. Pat. 7783, April 13, 1896.

—G. H. R.

*Ores, Refractory; Improved Process for Treating.* E. Govett, Melbourne. Eng. Pat. 12,106, June 3, 1896.

THE crushed ore, dried if necessary, is mixed with from 1 to 4 per cent. of charcoal, and is then passed into a bath of molten lead. From 15 to 70 per cent. of the silver present is retained by the lead, which is then withdrawn and treated accordingly. The residue, which contains 1 to 10 per cent. of the lead used, is concentrated to remove zinc and gangue (if present), and the concentrates are then smelted.—W. G. M.

*Zinc and Alkalis, Impts. in the Electrolytic Production of.* O. Dieffenbach, Darmstadt, Germany. Eng. Pat. 25,804, Nov. 16, 1896.

THE electrolytic vessel is divided into three parts by two diaphragms, the anode and cathode compartments containing respectively sodium sulphate and an alkaline solution of zinc, while the centre compartment contains sodium sulphate, or a solution of alkaline chlorides or dilute alkaline lye. In the first case, on the passage of the current, zinc is deposited in the cathode compartment, and the strength of the solution in zinc may be maintained by heating it together with zinc oxide, zinc hydroxide, or even metallic zinc. Simultaneously with the separation of zinc, caustic soda is formed, which passes into the centre compartment instead of being neutralised by the free acid formed in the anode compartment, as is the case when only one diaphragm is employed. The anode solution is kept constantly circulating and the acid is neutralised with lime, &c., as soon as it is formed. The solution in the centre compartment is regularly drawn off, and the caustic soda there formed separated by evaporation from the sulphate of soda, which crystallises out.—G. H. R.

sulphuric; the selenates would then be used instead of the sulphates." The formation is completed in a "bath composed of dilute sulphuric acid and a proportionately small quantity of an acid sulphate, as that of sodium or potassium." "Such of the positives as are intended to become negatives are reduced in this same electrolyte or bath, by being connected with the negative terminal of the charging current."—J. C. R.

*Electric Batteries* ["Dry"]. Impts. in. P. Schmidt, Berlin, Germany. Eng. Pat. 10,095, May 12, 1896.

THE improvements relate to the construction of a "dry" cell. A carbon cylinder closed at top is placed in the annular space between an outer zinc cylinder and (capping) an inner zinc cylinder (previously filled with a solution of sal ammoniac). The space between the carbon and outer cylinder is filled with an exciting paste, consisting, "in addition to finely-divided quebracho wood, of extract of tannin infused in boiling water, and purified by filtering together, with the addition of a small quantity of a solution of chloride of zinc, the wood particles acting to prevent polarisation." By turning over the cell and placing it upright, the solution of sal ammoniac is transferred from the inner zinc cylinder to the annular space between it and the carbon cylinder, "thus reviving the cell by the gradual sinking of the liquid in the said annular space, because it passes through the porous carbon, and keeps the paste moist." The zinc cylinders are in electrical connection at the bottom. The carbon cylinder rests on a layer of paraffin run into the annular space between them.—J. C. R.

*Oxygen and Hydrogen by Electrolysis* [Perforated Metallic Diaphragm]. New and Useful Impts. in the Apparatus for the Production of. P. Garuti and R. Pompili, Naples, Italy. Eng. Pat. 23,663, Oct. 24, 1896.

THESE improvements on Eng. Pat. 16,588 of 1892 (this Journal, 1893, 768), relate to means for separating oxygen and hydrogen in electrolysis by metallic diaphragms placed between the electrodes, the said diaphragms being perforated in their lower part, up to a little height, by small holes as near as possible to each other.—J. C. R.

*Electric Insulating Compound*. L. Honig, St. Louis, Missouri, U.S.A. Eng. Pat. 23,868, Oct. 27, 1896.

100 PARTS contain—alcohol, 30; gum shellac, 25; wheat flour, 20; powdered asbestos, 20; glue, 2; varnish, 2; glycerin, 1.

The shellac is dissolved in the alcohol, then the asbestos is added, then the glycerin and glue, and lastly the varnish and wheat flour. The compound is applied with a brush. The flour is added merely to give body, and the proportion is varied as required. The varnish may be omitted, or varied in quantity, as it is only used as a finish. Glycerin makes the mixture flow smoothly, and the glue tends to make the material tough.—L. A.

*Storage Batteries* [Preparation of Active Material with Sulphates]. Impts. in the Manufacture and Production of Elements or Plates for Electrical Storage Batteries. C. Brault, Paris, France. Eng. Pat. 29,907, Dec. 29, 1896.

THE claims are for manufacturing electrodes "by compressing between the parts of conductive grids, active material or material to be rendered active, prepared from a mixture of oxide of lead or litharge and sulphate of an alkali or of an alkaline earth, treated with a solution of ammonia, or of ammoniacal salt (with or without bisulphate of mercury according to the denomination of the plate . . .)." For the negative plates 1 to 2 per cent. of bisulphate of mercury is added. Before forming the compressed material, it is steeped for a few hours in a weak solution of sulphuric acid to which is added 2 to 3 per cent. of the salt employed in the preparation of the plates. To provide for expansion in the course of "formation," the tablets of active material, or material to be rendered active, are perforated.—J. C. R.

*Ozone* [Electrolytic-Cooling Gas Arrangements], Impts. in and Apparatus for Producing. J. V. Johnson, London. From the Electric Rectifying and Refining Co., Camden, New Jersey, U.S.A. Eng. Pat. 29,966, Dec. 29, 1896.

THE process consists essentially in subjecting oxygen gas to an electric current in the form of a brush discharge, the oxygen gas being, by preference, at a low temperature while it is being subjected to the action of the current. Apparatus for carrying out the process is also fully described and shown. The oxygen gas may be cooled by passing through a cooling medium, or compressed, then cooled and permitted to expand either directly into the ozone generator or into a supply chamber therefor, thereby cooling it to the desired degree. "As a rule, the lower the temperature, the better the result." It is preferred "to use oxygen gas of as pure a character as can be manufactured on a commercial scale . . ." The process and apparatus, it is said, are particularly adapted for use in purifying and decolorising and deodorising alcoholic and other liquids, and for general application where ozone gas is required.—J. C. R.

### (B.)—ELECTRO-METALLURGY.

*Electrical Resistivity of Electrolytic Bismuth at Low Temperatures, and in Magnetic Fields*. J. Dewar and J. A. Fleming. Proc. Roy. Soc. 60, (1897), 425–432.

THE authors have measured the electrical resistance of a wire of pure bismuth placed transversely to the field of an electro-magnet and at the same time subjected to low temperatures. The electro-magnet was a powerful one provided with adjustable pole-pieces; it was excited by a constant current and the intensity of the field was varied by varying the interpolar distance. The bismuth (electrolytically pure) was in the form of a wire about 5 mm. in diameter and 3–4 cm. long, looped in a single turn. By wrapping it in cotton-wool and pouring on this liquid air, the temperature was reduced to 185° C.; by enclosing it in a small glass vacuum vessel a further reduction of temperature to 203° C. was attained. The following results were obtained:—

If the transverse field be zero, then cooling the bismuth always reduces its resistance. If the bismuth be then transversely magnetised, the resistance is increased, and for every temperature below the normal one (about 20° C.) there is some particular strength of transverse field which just annuls the effect of the cooling, and brings the resistance of the bismuth back again to the same value it had when not cooled, and not in any magnetic field. Hence the curves showing the resistance at any temperature lower than the normal one (20° C.) as a function of the transverse field, cross the curve showing the resistance as a function of the field when taken at a normal temperature. These crossing points are, however, not identical for different resistance-temperature fields. The lower the temperature the less is the strength of field which will bring the bismuth back to its original resistance when not cooled and not in the field.

In a transverse magnetising field having a strength of 22,000 C.G.S. units, the resistance of bismuth taken in liquid air is 150 times greater than its resistance in a zero field at the same temperature. The lower the temperature the greater is the multiplying power. In this respect bismuth is a remarkable exception to other metals. Thus in the case of zinc, iron, and nickel, the resistance is affected by magnetisation to a small degree; but the authors do not find any effect which is sensibly greater at low than at ordinary temperatures.—D. E. J.

*Aluminium, Recent Determinations of Electrical Conductivity of*. J. W. Richards and J. A. Thomson. J. Franklin Inst. 1897, 143, 195–199.

THE authors attribute the variable figures which have been given for the electrical conductivity of aluminium to:—1st. The use of impure metal, as only in recent years has 99 per cent. aluminium been obtainable. 2nd. The reference

of the conductivity to copper or silver standards, without the indications of chemical or physical condition. 3rd. The lack of an accurate standard of absolute resistance. 4th. Imperfect methods of measurement.

They have therefore carried out a series of experiments with the object of more accurately determining the conductivity by the help of more efficient and better appliances as indicated above.

The results are expressed in absolute measurement. A certified standard resistance coil of 1 "international" ohm, with a possible error of 0.02 per cent., was used.

The Carey Foster method of comparison was adopted. The metal in the form of wire (50 ft. lengths, the diameter measured by micrometer, checked by weighing and specific gravity), was wound on wooden bobbins, immersed in an oil bath, temperature of which was carefully noted. The standard coil was immersed in water, and temperature of room kept constant. The bridge wire was carefully calibrated, and a reflecting galvanometer employed.

Two separate wires were used of the first specimen, and the results only differed by one hundredth per cent. from each other.

Analysis.						Resistance at 0° C. of a Wire 1 metre long by 1 mm. Diameter in Ohms.	Specific Resistance at 0° C., i.e., Resistance of 1 c.c. in Absolute (C.G.S.) Units of Resistance.	
Aluminium.	Iron.	Copper.	Silicon.	Sodium.	Zinc.	Hard.	Hard.	Annealed.
99.66	0.10	0.00	0.16	0.008	..	0.031245	2433.7	2432.2
99.58	0.25	0.00	0.16	0.052	..	0.03250	2581.0	2535.0
98.77	0.20	0.57	0.45	0.012	..	0.03427	2848.0	..
97.16	0.25	2.26	0.30	0.032	..	0.03550	2849.6	..
94.39	0.25	3.07	0.24	0.052	1.50	0.03583	3011.4	2984.7

The authors show, after comparing their figures with those of previous experimenters, that when the impurities are taken into account, the results are fairly in agreement.

McGee determined in 1890 the conductivity of aluminium of 98.52 per cent. purity to be 54.8 per cent. that of copper, when unannealed.

The authors were led to the conclusion that the conductivity of hard-drawn commercial aluminium was strongly affected by impurities, being approximately:—

	(Copper = 100)
98.5 per cent. of aluminium.....	55.0
99.0 .. .. .	59.0
99.5 .. .. .	61.0
99.75 .. .. .	63.0 to 64.0
100.00 .. .. .	probably 66.0 to 67.0

Annealed wire was found to have a conductivity very nearly 1 per cent. greater than unannealed.—(O. H.

#### *Platinum in Russia. Production of.* Handelsmuseum, through Imp. Inst. J., April 1897, 132.

The Russian Ministry of Finance has recently issued a report on the production of platinum. Russia is the most important country in the world as regards platinum, producing forty times as much as all the other countries together. In 1880 the amount was 2,946 kilos., and in 1895, 4,413 kilos., whilst in 1891 the production was 5,208 kilos. The rare metal is found entirely in Southern Ural. Its manufacture is not carried out in Russia, but in Germany, where it is imported in the ore; and what Russia requires in the shape of prepared platinum has to be purchased in Germany. The price of platinum has been very high during recent years; at present, raw platinum costs 900 marks per kilo. The still rarer metal, iridium, is also found with platinum, but in very small quantities. In 1895 the amount was 4.1 kilos., and in 1894 but very little more.

#### PATENTS.

*Reducing Metals from their Ores, and for Obtaining Carbides, Acetylene, Cyanogen, Cyanides, Nitriles, and for Firing Nitrogen; Impts. in Processes and Apparatus for.* [Electrical Blast Furnace.] H. Maxim. New York, U.S.A. Eng. Pat. 1905, Jan. 27, 1896.

The apparatus consists of a primary heater, an electrical superheater, and a blast furnace, all arranged under one gas-tight casing. The primary heater consists of a furnace in which either solid or gaseous fuel may be burnt, and which heats a long series of pipes arranged transversely across it, through which the gaseous fluid on its way to the blast furnace is passed. The furnace is adapted to work with a blast under pressure, and fuel is supplied to it by means of a screw feed provided with valves. The primary

heating pipe communicates with two electric furnaces placed side by side, and connected by a pipe at their upper end, and the gas, after passing through them, leaves the second at the bottom, and enters the blast furnace, and thence passes through scrubbers into a gasometer, from whence it is passed back under pressure through the heating apparatus, or otherwise treated as desired. The linings of the gas passage and the electric furnace are composed of some material which will not be acted on by the gaseous fuel; for instance, it is carbon if carbonic acid is employed. In the first electric furnace which is filled with carbon blocks or other refractory material, the carbon electrodes are placed preferably at the top and bottom. In the second they are arranged spirally, and the furnace is filled with fireclay. When calcium carbide is to be manufactured, the blast furnace is fed with lime and coke by means of a screw feed, and the passage through it of the highly-heated carbon monoxide forms calcium carbide, which is drawn off at the bottom, or can be blown off by an atomiser in a flocculent form. The electric superheater may also be arranged horizontally and be rotary. Several modifications of the apparatus are given, and the applications of it to the manufacture of carbides, acetylene, fixation of nitrogen, production of cyanogen, cyanides, and illuminating gas are described and claimed.—G. H. R.

*Electro-plating or Metallisation of Wood, An Improved Process for the.* H. A. V. Wirth, Paris. Eng. Pat. 5263, March 9, 1896.

The wood is immersed in a bath of boiling wax which fills the pores. On cooling it is brushed over with plumbago, washed with alcohol, and plunged in the electrolytic bath.

—V. C.

*Refining Metals [Copper, &c.] by Electrolysis, Impts. in Apparatus for.* A. S. Elmore, Leeds. From J. O. S. Elmore, Kapurthala, India. Eng. Pat. 5673, March 13, 1896.

In this process the electrodes are arranged as follows:—On a rectangular frame of wood is laid a sheet of lead, or iron covered with lead if the sheet be large. On this is placed a plate of the crude copper or other metal to be refined, which is shorter than the lead plate, and is surrounded by a wooden frame thicker than itself. Several pads of rubber or other elastic insulating material are laid on the copper, and then another lead plate carrying a copper plate in a wooden frame as before, apertures being provided in the lead plate at the opposite end to that in which they were provided in the previous plate. These frames and sheets are piled over one another and clamped firmly together, the lowest and uppermost sheets being connected respectively to the positive and negative terminals of a

dynamo. As the apertures for the passage of the electrolyte are at opposite ends of adjacent plates, it is forced to flow in a zigzag course through the frame, and the metal dissolved on the crude anode is deposited on the lead cathode above it. The solution enters through a pipe at the top, and is discharged at the bottom into a rocking trough which breaks the electric circuit through the electrolyte, and discharges its contents into a tank, whence the liquid is pumped back with or without filtration, into the inlet pipe. The arrangement of the electrodes may be vertical instead of horizontal, and they may be bipolar, in which case the intermediate lead sheets are dispensed with.—G. H. R.

*Metals, Impts. in the Electro-deposition of, particularly applicable to the Deposition on Wires.* [Rapid Circulation.] J. C. Graham, London. Eng. Pat. 8410, April 21, 1896.

THE current strength employed in electro-deposition on wires, strips, sheets, tubes, or cylinders may be greatly increased, and the rate of deposition accelerated by causing the electrolyte to circulate rapidly through tubes or troughs over the whole surface of the anode and cathode. The tube itself may form the anode, or it may contain pieces of metal which act as anodes, and the wire or matrix forming the cathode is led through it resting on suitable supports. One end of the tube is connected to a reservoir placed about 2 feet above it, and the other with a centrifugal pump which returns the electrolyte to the reservoir. Baffles placed in the tube maintain a uniform distribution of the electrolyte, and the current strength which can be used depends on its density and rate of flow.—G. H. R.

*Gold and Silver from their Cyanide Solutions, Impts. in the Electric Precipitation of.* [Lead Anodes.] A. James, Glasgow. Eng. Pat. 1535, Jan. 20, 1897.

LEAD anodes are employed, as it has been found that the coating formed on them during electrolysis, protects them. The cathode may be lead, as in the Siemens and Halske process, and the gold and silver may be recovered in the same way. Or aluminium cathodes may be used, when the voltage required is about  $\frac{1}{2}$  volt higher than in the former case, and the precious metals are recovered by scraping.—G. H. R.

## XII.—FATS, OILS, AND SOAP.

*Oleic Acid, Industrial Transformation of, into Stearolactone and Monohydroxystearic Acid.* David. Comptes Rend. 1897, 124, [9], 466–468.

WHEN sulphuric acid is mixed in molecular proportion with oleic acid cooled to zero, and water is added to the sulpho acids produced, with precautions to prevent much rise of temperature, two layers are formed, the lower of which contains 50 per cent. of the sulphuric acid taken, whilst the upper is an oily liquid consisting of 50 per cent. of a sulpho acid not decomposed by water and 50 per cent. of one or more of the three isomerides of hydroxystearic acid.

The author considers that the  $\alpha$ - and  $\gamma$ -isomerides are present, and his experiments have led him to the conclusion that the [OH] group is transposable according to the temperature, so that the  $\alpha$ -acid may be transformed into

the  $\gamma$ -acid (or more strictly speaking its inner anhydride). To a mixture of oleic acid and sulphuric acid an equal volume of cold water was added and the whole left for an hour. The lower layer of acidulated water was removed and an equal volume of pure water added. This dissolved the oily layer, and the clear solution, when left for 12 hours at  $-4^{\circ}$  to  $-5^{\circ}$  C., yielded a quantity of small white crystals of stearolactone—the inner anhydride of  $\gamma$ -hydroxystearic acid, the amount being about 18 to 20 per cent. of the weight of oleic acid taken. When the stearolactone was removed the clear liquid still contained hydroxystearic acid (30 per cent.). On boiling this liquid for about an hour and then leaving it over night, granular crystals were produced, which melted at  $80^{\circ}$  C. and solidified at  $68^{\circ}$  C. (Fremy's hydroxystearic acid). If, on the other hand, the clear liquid, instead of being boiled, was kept overnight at a temperature of  $-4^{\circ}$  to  $-5^{\circ}$  C., a fresh crop of crystals of stearolactone was formed, and the filtrate from these on being exposed to the cold for 24 hours yielded still more, and so on as long as any hydroxystearic acid remained in the liquid.

On an industrial scale the author has thus obtained 50 per cent. of solid products from a given weight of oleic acid, and he considers that by using sulphuric acid of  $66^{\circ}$  B., instead of a little over  $65^{\circ}$  B. (which was the strongest he could procure), the yield would be increased to 70 or even 80 per cent.—C. A. M.

*Vegetable Tallow, Chinese.* G. de Negri and G. Sbrulati. Chem. Zeit. 1897, 21, [1], 5–6.

VEGETABLE tallow is obtained from the fruit or seed of a variety of plants in many parts of the world: a more or less complete enumeration of which is given in the paper. By far the most important is the Chinese, from the so-called yarcou tree (*Croton sebiferum*, Linn.). The commercial article often contains an admixture of linseed oil. The seeds are husked and roughly broken, steamed till soft, beaten with wooden hammers, and the paste put into warm sieves, through which the melted tallow drops into pots. Or the seeds are bruised and boiled with water; the oil collects at the top and solidifies to a cake on cooling. The yield is from 20 to 30 per cent. In some places 30 or 40 per cent. is got by hot-pressing. Yet another method consists in steaming the seeds in a perforated inner vessel surrounded by an outer one. The "tallow" which envelops the seeds drops through the perforations into the outer vessel. From the remaining substance, by pressure, an oil called "ting-you" is got; this is used for lighting, and also in making varnishes.

Samples of commercial vegetable tallow are white or greenish, and all are destitute of smell and taste. They appear usually as egg-shaped masses of from 55 to 60 kilos., which are covered with rice-straw and wrapped in rush mats. Hannan, De Negri and Fabris, and more recently Hobein, have investigated the properties of vegetable tallow. Some of their figures are given in the following table, with a summary of the results obtained by the present authors from 10 samples. These 10 samples left a faint greasy mark on paper, and showed a slightly acid reaction. They all dissolved freely in warm absolute alcohol, but almost completely separated out again on cooling. They were easily soluble in ether, benzene, chloroform, and carbon bisulphide. Their specific gravity at  $15^{\circ}$  was from 0.9182 to 0.9217, and 10 grms. yielded from 8.2 grms. to 8.7 grms. of fatty acids, which were white or yellowish.

The difference between Hobein's figures and those of Negri and Fabris arises from the fact that the ether extracts not only the tallow but also some of the oil contained in the endosperm of the seeds. Hobein prepared some of this latter oil as a brownish-yellow fluid of sp. gr. 0.9498, saponification No. 203.8, iodine No. 145.6.

The differences among commercial vegetable tallows arise partly from their being mixtures of tallows from different plants, partly from the different processes of extraction, and partly from changes which they undergo with the lapse of time.—J. T. D.

*Hyoscyamus Nigr.*, Oil extracted from the Seeds of: Properties of. A. Mjoen. Arch. de Pharm. 234, 286.

This fatty oil has a density of 0.939 at 15° C. It is very easily soluble in ether and chloroform. 1 part requires for its solution 56 parts of absolute alcohol, or 200 parts of 90 per cent. alcohol. When saponified, the oil yields glycerin, and a mixture of oleic and palmitic acids, together with a third acid, the exact nature of which is, as yet, undetermined. —H. T. P.

#### PATENT.

Washing Material, an Improved, and Process for Making the Same. G. Rezek, Vienna, Austria. Eng. Pat. 123, Jan. 2, 1897.

125 KILOS. of "ammonia soda" are mixed with 60 kilos. of ground resin and the powder is kneaded with 120 kilos. of water to the consistency of soft-soap. Glycerin, "benzine," fats, oils, perfumes, and colours may be added. This represents substantially the claim.—L. A.

### XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

#### (A).—PIGMENTS, PAINTS.

##### PATENT.

Basic Lead Carbonate, Improved Process of Producing and of Obtaining Certain By-Products. The Chemical and Electrolytic Syndicate, Ltd. O. J. Steinart and J. L. F. Vogel, London. Eng. Pat. 6655, March 26, 1896.

Pig lead is oxidised, and the oxide is dissolved in nitric acid. The solution of lead nitrate, about saturated in the cold, is treated with finely divided lead to remove silver and other foreign metals, is heated nearly to boiling and run into a similarly heated solution of sodium carbonate, containing sufficient excess of alkali to produce a basic lead carbonate precipitate free from nitrate, and the liquid containing the precipitate is thoroughly stirred and boiled for some time. The precipitate is then separated. The solution of sodium nitrate and excess of sodium carbonate is evaporated to dryness (sodium carbonate being partly separated by crystallisation if desired), and the dry residue is ground with enough ferric oxide to prevent fusion at a high temperature. The mixture is then furnaceed in an inclined retort described in Eng. Pat. 7273, 1895, when nitric acid and caustic soda are obtained as final products.

—L. A.

#### (B).—RESINS, VARNISHES.

Acaroid (*Xanthorhœa*) Resin, Yellow and Red. K. Hildebrand. Arch. Pharm. 1896 [12]; Chem. Rev. Fett u. Harz Ind. 4, [4], 53.

The author finds that the yellow resin contains free cinnamic and paracumaric acids, the latter being also present (to the extent of 80 per cent.) as an ester of xanthoresinotannol ( $C_{18}H_{15}O_9(OH)$ ). No methoxyl group could be detected in this alcohol, and the acetyl- and benzoyl-derivatives demonstrated the existence of only one hydroxyl-group. Styacin (cinnyl cinnamate) and the phenylpropyl ester of cinnamic acid, together with paroxybenzaldehyde and vanillin—the latter, however, not being identified with certainty—are present in the yellow resin.

The red resin is characterised by the absence of cinnamic acid, styacin, and the cinnamic acid ester. Paroxybenzaldehyde was found, but the bulk of the resin consists of an ester of paracumaric acid with erythrosinotannol ( $C_{40}H_{39}O_9(OH)$ ). Benzoic acid is present in the combined state.—C. S.

Shellac, Behaviour of the Resin Acids of, in Separating Fatty and Resin Acids by Gladding's and Twitchell's Processes. F. Ulzer and R. Defris. Zeits. anal. Chem. 36, [1], 24.

#### (C).—INDIA-RUBBER, &c.

##### PATENT.

India-rubber, Impts. in the Manufacture of, and in Machinery and Apparatus therefor. W. J. Clapp and F. S. Dauncey, Newport, Mon. Eng. Pat. 6830, March 28, 1896.

In order to render india-rubber proof against the action of "heat, steam, and other vapours, fluids, and liquids," the raw rubber is dissolved in a suitable solvent and mixed with from 2 to 10 per cent., or any other suitable quantity, of "silicate, slag wool, silicate cotton, Bessemer basic or other suitable slag, mica, platinum, alum, borax, pitch, tar, petroleum, or like materials." The mass is then raised to a suitable temperature according to the purpose for which the manufactured goods are to be applied.—L. A.

### XIV.—TANNING, LEATHER, GLUE, SIZE.

Fermentation Phenomena in Tan Liquors. F. Andreasch. Imp. Research Station, Vienna. Der Gerber. 22, [526], 174.

The following table gives the more important results, oakbark and sumac being selected as examples.

The values are given in grms. per 100 c.c. of liquor. The small differences result from the inexactness of the method for estimation of alcohol, and in the lactic acid, because of its instability. In the column headed "Class," I. = Original tan liquor; II. = Original tan liquor with addition of mineral nutriment; III. = Sterile, uninoculated solutions. In class III. no change occurred in these liquids; hence it is unnecessary to represent the figures in the table. (See next page.)—J. T. W.

Tanning, The Chromate Process of; Its Advantages and Disadvantages. F. Jean. Rev. de Chim. Ind. 1896, 7, [83], 343—345.

SINCE its introduction into America in 1892, the chrome tanning process (in which the hides are soaked in an acid solution of potassium bichromate, subsequently in an acid bath of sodium sulphite, the result being that chromium oxide is deposited on the fibre) has made great advance there, and to some extent has been introduced into Europe—notably into Germany. The process certainly merits consideration on account of its cheapness, the comparatively short time required for its completion, and because the leather produced by it possesses superior tenacity, great resisting power to moisture and heat, and is not liable to crack. For these reasons (the validity of which is generally

admitted) it is very suitable for certain purposes, *i.e.*, for engine belts, straps, and the like. For general purposes, however, chrome leather must be pronounced less suitable than leather produced with bark; and it is particularly in the boot manufacturing industry that it requires to be most carefully tested. Chiefly on account of its imperviousness to moisture and air, chrome leather is not likely to be used extensively in the manufacture of boots. Besides, it is stated that, in respect to elegance of appearance and finish, chrome leather boots compare unfavourably with those made from bark-tanned leather; that in shaping and

trimming, the cut edges are not smooth, but rough and fibrous; and that difficulties are met with in the stitching and chasing processes. It is noted that Cavalier in 1853 used a chromate bath with ferrons sulphate to reduce the chromic acid.—H. T. P.

*Formalin, Experiments with.* W. Eitner. Der Gerber. 23, [541], 67.

SINCE the introduction of formalin or formaldehyde as a trade product it has been proposed to use it for tanning leather as a substitute for alum.

The author finds that, although it has a hardening effect on the skin fibre, in no case can leather be produced by its use alone. It may, however, be used with advantage in certain tannages to "fix the swelling" produced by the sour liquors; the hides may then be worked in sweet extract liquors without losing the characteristic appearance of the Bohemian pine sole-leather. A solution of 1 kilo. of commercial formalin (40 per cent.) in 1,000 litres of water is used, and the hides are soaked in it for 24 hours after coming out of the sour liquors; the tanning may then be finished in the usual way or in extract liquors. In this way a very solid, hard sole-leather is produced, which is not brittle. The tanning is considerably hastened.

The chief use of formalin for tanners is as an antiseptic, though for preventing putrefaction other materials are cheaper. Hides infected with anthrax may be rendered harmless by painting with a 2½ per cent. solution. The most remarkable result was that skins treated with a dilute solution remained quite fresh, without the slightest smell of putrefaction, and yet in four weeks they could be unhaired completely.

A bacteriological examination of the Malpighian layer showed absence of putrefactive bacteria, but presence of some ferment in large amount. The reaction was acid. This is regarded as a proof that the sweating process need not be accompanied by putrefaction, and that the alkaline products of putrefying bacteria are not necessary for the process, as has been supposed.

The best general use of formalin in leather manufacture, at present, is for preserving glazes and seasonings.

## PATENTS.

*Tanning, Impts. in or relating to.* Alexandre Levinstein, Paris. Eng. Pat. 10,263, May 13, 1896.

In rapid tanning processes in drums, if the temperature be high, the leather becomes brittle; if low, the tanning proceeds slowly.

The temperature is therefore kept between 20° and 40° C. by injecting steam or air into the drum whilst rotating, or by varying its speed of revolution by means of conical pulleys.—J. T. W.

*Tanning Apparatus, Impts. in.* Alexandre Levinstein, Paris. Eng. Pat. 10,390, May 14, 1896.

DETAILS are given of the blower for introducing cold air into the tanning drum (see preceding abstract), and also of means for taking samples of extract, and for ascertaining the temperature of the interior while the drum is rotating. The drum can be rotated at three different speeds by means of the usual conical pulleys.—J. T. W.

*Tawing Hides and Skins, An Improved Process of and Compound for.* G. W. Adler, Philadelphia, U.S.A. Eng. Pat. 11,293, June 27, 1896.

The tawing liquor is prepared by dissolving 5 lb. of bichromate of potash in 7½ lb. of sulphuric acid, diluted with double the volume of water; this solution is then reduced by the addition of about 1 lb. of white sugar, or 1½ pints of alcohol, until effervescence ceases. The solution is then rendered neutral by the addition of 20 lb. of sodium carbonate dissolved in 7½ gals. of water; the mixture is allowed to stand several hours until precipitation of the "chromium oxycarbonate" is completed.

Hydrochloric acid (6—7 lb.) is then added, so as just to dissolve the precipitated chromium compound. The density of the liquor produced is about 20° Baumé, and its composition is probably best represented by the formula—

The skins are prepared in the usual way, and the tawing liquor diluted to 5°—6° B., and used as in the one-bath chrome process.

It can be used for pickled or for fresh skins. The sodium chloride and sulphate present modify the astringent effect of the chromium salts. The organic acid present acts in a similar way, and greatly aids the tanning action.—J. T. W.

## XV.—MANURES, Etc.

*Injurious Effect of Chili Nitrate of Soda.* A. Stutzer. Deut. landw. Presse, 1896, No. 66.

AN examination of fields which had received Chili nitrate of soda, showed that of the various crops so manured, the injury was confined almost entirely to rye. The greater the amount of nitrate applied, the greater the injury. The results of analyses of the nitrate of soda, indicated that its composition was normal, and the author supposes that the damage was caused by deficiency of moisture in the soil, and possibly, also, by the unequal distribution of the manure.

Lemmermann (Bied. Centr. 1897, 26, 78) calls attention to the experiments of Sjölema (this Journal, 1897, 152 and 163), indicating that the damage is due to the presence of perchlorate in the nitrate of soda. He suggests that it would be of interest to ascertain in what form the perchlorate is present; and that by means of a heavy application of potassium salts, the perchlorate might be rendered sparingly soluble, and so comparatively harmless.

## PATENT.

*Fish and other Offal or similar Refuse, Impts. in or relating to the Treatment of.* The Fish Utilisation Syndicate, Ltd. and J. C. W. Stauley, London. Eng. Pat. 7268, April 2, 1896.

THE fish offal is first sorted upon a sieve; extraneous matters are picked out, whilst blood, &c., drains through into a suitable receptacle. It is then boiled with water in a boiler having a perforated diaphragm, which keeps the solid matters below the surface of the water, but allows oil to rise and flow off into a settling tank, where it is separated from the rest of the water and subsequently used for making soap, &c. The solid matter is removed from the boiler, squeezed in a press to get rid of most of the water, then dried and sifted. The finer parts, which pass through the sieve, constitute *fibre guano*; what remains on the sieve is crushed fine and sold as *bone guano*. The water out of the boiler may be precipitated with alum cake.—L. A.

## XVI.—SUGAR, STARCH, GUM, Etc.

*Saccharogenic Diastase in the Beetroot, Hypothesis of a.* G. Arachequesne. Bull. de l'Assoc. des Chim. de Sucr. et de Dist. 1897, 14, 670—673. (See also this Journal, 1897, 252.)

WITH regard to the hypothesis of a saccharogenic diastase to account for the difficulty of fermentation of certain beetroots, the author points out that it leaves a number of facts unexplained, particularly the premature running to seed, generally attributed to sudden changes of temperature, but which may be caused by the rootlets being torn or atrophied.

As to claims of priority, the existence of this diastase in the beetroot and other plants, was demonstrated by Pasteur and his pupils, and the theory was published long ago by Duchaux in his *Microbiologie*.—L. J. de W.

*Sugar-Cane Juice, Clarification of.* J. L. Beeson, J. Amer. Chem. Soc. 1897, 19, 56—61.

THE clarification of cane juice being mainly an empirical method, the nature of the bodies removed and the chemical changes involved not being understood, it was the object of this investigation to compare the juice expressed by the mill with that obtained from the same large sample of cane by the process of diffusion with hot water, and to compare these juices before and after clarification, and study the products removed. The total proteids and albuminoids were obtained by multiplying the total and albuminoid nitrogen by the factor 6.25, the difference being termed amides; the "gums" were obtained by subtracting the total proteids and ash from the "solids not sugars."

The diffusion juice was found to contain less solids not sugars, less total proteids, and less albuminoids and amides than the mill juice, indicating that the hot water had coagulated and left in the bagasse about one-third of the albuminoids and gums. Bagasse from the diffusion process showed, on analysis, more proteids than that from the mill. The diffusion juice, after clarification with lime, showed rather less albuminoids, but a slight increase in ash and gums, attended by a lowering of the coefficient of purity. The skimmings showed a relatively small amount of proteids, indicating that these bodies had been partly broken down by the clarification.

The effect of adding lime before applying heat was now tried. One litre of mill juice required 10 c.c. of lime water to remove acidity, when a dark green precipitate formed and continued to form until 190 c.c. had been added and a faint alkalinity was reached. To remove slight excess of lime from the filtrate, superphosphate solution was added until the juice began to brighten. On heating for 20 minutes at 90° to 95° C. a small coagulum was formed. Sulphur dioxide bleached the juice, but caused no further precipitate.

The lime-heat clarification showed a marked improvement, there being an increase of 4 per cent. in the coefficient of purity, the lime having removed nine-tenths of the total non-sugars eliminated. Of the gummy bodies precipitated by nitrate of mercury, and albuminoids by copper hydroxide, one-half consist of bodies not rendered insoluble by lime or heat. It is the further work of the sugar chemist to discover some cheap, non-poisonous agent which will remove this class of bodies from cane juice.—L. J. de W.

*Masseccutes and Syrups, Tables for Determining Water in.* E. Gravier. Bull. de l'Assoc. des Chim. de Sucre, et de Dist. 1896-7, 14, 664—669.

TABLES are given showing the water in masseccutes and spun syrups for degrees of apparent purity from 93 to 60, based on a number of determinations in which the water was estimated by heating 5 grms. mixed with ground glass at 105° to 110° C. for 18 hours, other results being obtained by interpolation.

In using the tables, 50 grms. of masseccute or syrup are dissolved in water, and made up to 250 c.c., and the density obtained by Mohr's balance at 15° C., water at 15° C. being taken as unity. The apparent purity is found by help of Scheibler's tables (*ibid.*, Dec. 1890), the sugar being estimated on the same solution as the density.

The purity being known, it is merely necessary to find, in the column corresponding to it, the density, and to read off the percentage of water. The maximum error is 0.4 per cent.—L. J. de W.

*Masseccutes, Calculation of the Quantity of Syrup added to First Runnings.* O. Mitrestdt. Bull. de l'Assoc. des Chim. de Sucre, 1897, 14, 708—710.

As the practice of returning centrifugalised syrups is very general, it is of interest to be able to calculate the real quantity of first runnings masseccute after having added, in the pan, a certain quantity of first runnings syrup, and further, to calculate the amount of syrup added.

The first question is easily solved, if one knows the dry solids of the finished masseccute and that of the syrup added. If 20 tons of masseccute have been obtained, of 6 per cent. of water, and quotient 91.4, this corresponds to  $20 \times 0.91 = 18.8$  tons of dry solids, with  $18.8 \times 0.914 = 17.183$  of sugar, and  $18.8 - 17.183 = 1.617$  of non-sugar.

If there were added, during the boiling, 1.8 tons of syrup of 78 per cent. dry solids and quotient of purity 74, there is introduced into the masseccute  $1.8 \times 0.78 = 1.4$  tons of dry solids, containing  $1.4 \times 0.74 = 1.036$  tons of sugar, and  $1.4 - 1.036 = 0.364$  ton of non-sugar. Deducting these figures from those of the finished masseccute, we obtain 16.147 tons of sugar and 1.253 of non-sugar, which form the dry solids of the original masseccute from the beetroot. Its quotient of purity must have been  $16.147 \times 100 \div (18.8 - 1.4) = 92.8$ .

The calculation becomes more complex if the quantity of syrup added is not known. Neglecting the sugar destroyed by the boiling, the quotient of that part of the masseccute from the beetroot alone must be equal to that of the syrup boiled (Dg). The quotient of the finished masseccute (Fg) will depend on the quotient of the green syrup (Sg) and its quantity. Let  $x$  denote the quantity of added syrup contained in 100 of dry solids of masseccute, there will be  $100 - x$  of original masseccute dry. We have thus the equation:—

$$100 \text{ Fg} = (100 - x) \text{ Dg} + x \times \text{Sg},$$

$$\text{whence } x = 100 \frac{\text{Dg} - \text{Fg}}{\text{Dg} - \text{Sg}}$$

For example, if the quotient of the finished masseccute be  $\text{Fg} = 91.4$ , that of the concentrated syrup  $\text{Dg} = 92.8$ , and that of the added syrup  $\text{Sg} = 74.0$ , we get, on putting these values in the above formula,  $x = 7.45$  dry solids in the added syrup in 100 parts of finished masseccute, supposed dry. If the added syrup contained 78 per cent. of dry solids, the actual amount added is  $7.45 \div 0.78 = 9.54$ . If the finished masseccute contained 6 per cent. of water or 94 of dry solids, we have  $(100 - 7.45) \times 0.94 = 87.0$  per cent. of dry solids derived from the concentrated syrup.

—L. J. de W.

*Sulphurous Acid, Inversion of Sugar Solutions by.* K. Stiepel. Bull. de l'Assoc. des Chim. de Sucre, 1897, 14, 706—707.

THE author has made a very long and interesting study of the inversion of sugar in pure and impure solutions, and arrives at the following conclusions:—(1.) In pure sugar solutions: Their inversion by sulphurous acid, and by all other known acids, takes place according to the law of inversion formulated by Wilhelm and the law of Guldberg and Waage. Pure solutions of sugar undergo with sulphurous acid, at a very low temperature, very slow inversion. (2.) In impure sugar solutions there are to be distinguished: (a) The influence of the salts and non-sugars present. As far as these influences are concerned, similar relations exist for  $\text{SO}_2$  in particular, as for other acids, according to the general observations of Spohr. (b) The inverting effect of the acid sulphite of potash formed. It is much weaker than that of free sulphurous acid. (c) The inverting effect of organic acids liberated from their combinations by sulphurous acid. Leaving out the secondary effects produced by these influences, it follows that the inversion by free sulphurous acid, even in impure solutions, takes place according to the law of Guldberg and Waage.

It is therefore certain that the smallest quantity of  $\text{SO}_2$ , even in impure solutions (juice, syrup, and molasses), produces inversion, even in the cold. Although the secondary influences of the non-sugars, acid sulphite, and free organic acids are so small at low temperatures as to be practically negligible, the inversion may become very sensible at higher temperatures.—L. J. de W.

*Saccharose, Inverting and Decomposing Influence of Heat on Aqueous Solutions of.* B. Rayman and O. Šulc. Rozprawy ceske akademie, 1896, 5, Cl. II., 33.

THE rate of inversion is dependent on the nature of the containing vessel. Thus, the polarisation of a 20 per cent.

solution of cane sugar fell from  $+11.66^\circ$  to  $+5.94^\circ$  when the liquid was boiled in a glass flask over a flame for 61 hours, to  $+6.82^\circ$  when heated in a water-bath. In a platinum flask, the rotation fell from  $+13.25^\circ$  to  $-3.42^\circ$  in 25 hours, the rate of inversion being fairly uniform throughout. Concentrated solutions are decomposed more rapidly. Under pressure, inversion proceeds less rapidly (at  $100^\circ$  C.) than in open vessels. The decomposition products formed when aqueous solutions of levulose and dextrose are heated under pressure were examined. At  $105^\circ$  C., levulose suffers appreciable decomposition, and at  $120^\circ$  C. yields formic acid, furfural, carbon dioxide, pyrolevulinic acid, and brown ( $C_{25}H_{32}O_{10}$ ) or reddish-brown ( $C_{25}H_{30}O_9$ ) humin substances. At  $120^\circ$  C., dextrose yields very little furfural, mere traces of non-volatile acids, and no humin bodies. At the same time a substance, having smaller (dextro) rotatory power and reducing power than dextrose, appears to be formed. At  $140^\circ$  C., furfural and small quantities of humin substance ( $C_{23}H_{22}O_{11}$ ) are produced, whilst above  $150^\circ$  C. formic acid appears amongst the products. At  $160^\circ$  C., more humin substance ( $C_{23}H_{20}O_9$ ) is formed, whilst at  $180^\circ$  C. the dextrose is entirely destroyed in about  $3\frac{1}{2}$  hours, about one-half of it being converted into formic acid and black humin bodies—

Amido acids invert cane-sugar slightly at  $100^\circ$  C., distinctly at  $105^\circ$  C., under pressure, the effect being the less pronounced the larger the molecular weight of the acid used.

—H. T. P.

*Wood Gums, The Composition of.* P. Truchot. Rev. de Chim. Ind. 8, [86], 43—44.

In Germany, and more especially in America, great attention is paid at the present time to the preparation of gums extracted from wood and other ligneous bodies, as it is believed that these products might be utilised as substitutes for some of the more expensive gums now employed, for example, by the calico printers, &c. The gums obtained from maize cobs and birch bark have recently been studied by G. W. Johnson (see this Journal, 1896, 605).—I. S.

## PATENT.

*Saccharine Solutions and other Liquids, Impts. in and Apparatus for Purifying and Decolorising.* J. V. Johnson, London. Eng. Pat. 28,763, Dec. 15, 1896.

A CONVENIENT quantity of the saccharine liquid is introduced into a vessel provided with plates of suitable material for positive and negative electrodes. The tank is connected with a reservoir containing ozone and also with a vacuum pump. It is preferable to employ aluminium, the irregular

and pitted surface of which has been filled up with alumina, for the positive electrode, because the electrolytically formed alumina has a decolorising effect on the liquid. Favorable results are also obtained with zinc pitted in the same way as the aluminium and filled with oxide of zinc. The negative plate is generally made of carbon, provided with openings, &c. in which the impurities are deposited together with alumina or oxide of zinc, which may subsequently be recovered.

The liquid to be treated should not have a density above  $40^\circ$  B., and, if dark, may be heated from  $70^\circ$  to  $90^\circ$  C. In carrying out the process, from 4 to 10 minutes are usually required to complete the treatment, if the electrolysis be carried on simultaneously with the passage of ozone through the liquid, and from three to five hours if the ozone treatment follows the electrolysis. A current of 50 to 60 ampères at 5 to 10 volts is used per square metre of electrode. The effect of the ozone is to immediately oxidise the impurities, thereby completing the defecation which has been partially accomplished by the electrolysis.

If a high degree of defecation be required, it is best to treat the electrolysed juice with ozone *in vacuo* in a second tank. The liquid is run in by means of a sprayer simultaneously with the introduction of ozone, the two being thus thoroughly incorporated.—J. L. B.

## XVII.—BREWING, WINES, SPIRITS, Etc.

*Fermentation: A Reply to a Criticism by Prof. Duclaux* (this Journal, 1896, 664—665). A. J. Brown. J. Fed. Inst. Brewing, 1897, 3, 99—110.

In a paper on the "Influence of Oxygen on Alcoholic Fermentation" (this Journal, 1892, 257), the author described some experiments which appeared not to agree with Pasteur's well-known theory that fermentation is a consequence of "life without air." In a subsequent paper on "The Specific Character of the Fermentative Functions of Yeast Cells" (this Journal, 1894, 824), evidence was brought forward to show that the argument on which Pasteur based his theory was unsound. This theory depends entirely on the question of his determinations of fermentative power being independent of time. The fermentative power of a yeast, according to Pasteur's definition, is expressed by the proportion of sugar decomposed, to the weight of yeast which has decomposed it. If, however, the time be taken into consideration, together with the yeast formed and sugar fermented, the fermentative activity is determined—a property quite distinct from the fermentative power.

The author considers that Pasteur, in calculating his fermentative powers, had overlooked the fact that a yeast cell, like other living organisms, does not produce energy directly, but merely transmits it. The energy necessary to carry on the life work of living organisms is derived from the aliment they consume: the action of their functions, so far as the organisms are concerned, is a continuous action, and may be compared to the working of an engine fed with fuel. The decomposition of sugar by a yeast cell is a continuous function so far as the cell is concerned, and consequently it must depend on time, like all continuous phenomena under similar conditions.

In an ordinary fermentation, yeast cells multiply rapidly at first, their rate of multiplication gradually slackening until it ceases. Meanwhile fermentation continues during the existence of each individual cell so long as there is fermentable sugar in the liquid. Since fermentation is a continuous function of the yeast cell, those cells which came into existence first will have a longer time at their disposal to decompose sugar than those which are formed later, but the time factor rules the process for each individual cell, however long or short an existence it may have. It will be apparent on these grounds that time controls the ultimate result.

The author is of opinion that the expression *fermentative power*, as defined by Pasteur, should be abandoned and *fermentative activity* be retained to express the fermentative power of an organism in unit time.—J. L. B.

*Yeasts. Carbonaceous Feeding of Budding.* Th. Bokorny, Dingler's Polyt. J. 1897, 303, 115—119; 140—143; 163—167.

NAEGELI and LOEW have found (Sitz Ber. d. math. phys. Kl. Munich, July 1879) that simply constituted organic compounds, such as acetic acid, can afford the necessary carbonaceous food to yeast-moulds; and Loew states that, whilst formaldehyde behaves as a strong poison to certain bacteria, yet, as the author has shown, the sodium sulphite compound of formaldehyde can be assimilated. Acids, alcohols, carbohydrates, acid amides, and bodies related to albuminoids are carbonaceous foods to yeasts; and, in the opinion of Loew (Die chem. Kraftquelle im leb. Protopl., Loew and Bokorny, Munich, 1882), these bodies primarily split off a  $\text{CH}_2\text{O}$  group, which then becomes changed into more complex carbon compounds. The author concludes from his work that only those substances can be assimilated by yeasts resembling to some extent the constituents from which the yeast-cell wall is built up. The salts containing the necessary nitrogen, sulphur, phosphorus, potassium, and magnesium were made into a 0.2 per cent. solution, the organic compound being often in larger quantity. The reaction of the resulting solution should be slightly acid or neutral, but not alkaline, as moulds would then flourish. The author's experiments were carried out in an incubator at  $25^\circ$ — $30^\circ$  C. with the substances shown in the following table, which gives his results, together with those of other observers:—

Methyl alcohol (0.2 per cent.) Not a carbonaceous food for yeast.

Ethyl alcohol (0.2 per cent.) Not a carbonaceous food for yeast.

Amyl alcohol (0.2 per cent.) Not a carbonaceous food for yeast.

Propyl alcohol. Not a carbonaceous food for yeast.

Benzyl alcohol (0.2 per cent.)

Ethylenglycol. Doubtful.

Glycerin (0.2 per cent.) Yeast flourishes freely.

Phenol (0.05 per cent.) Not a carbonaceous food for yeast.

Catechol (0.05 per cent.) Not a carbonaceous food for yeast.

Resorcinol (0.05 per cent.) Not a yeast food.

Gallic acid (0.05 per cent.) Not a yeast food.

Tannin (0.05 per cent.) Not a yeast food.

Pyrogallol (0.05 per cent.) Not a yeast food.

Quinol (0.05 per cent.) Not a yeast food.

Orthoxyleneol. Poisonous.

*o*- and *p*-cresol. Poisonous.

The nutritive value of the following organic acids was ascertained, neutral solutions of the salts being used:—

Propionic acid (0.2 per cent.) Not a carbonaceous food for yeast.

Succinic acid (0.2 per cent.) Not a carbonaceous food, and unfavourable to yeast.

Aspartic acid (0.2 per cent.) A yeast food.

Quinic acid [ $\text{C}_6\text{H}_7(\text{OH})_4\text{COOH}$ ]. Not a yeast food, but favours moulds and fission fungi.

Parahydroxybenzoic acid (neutralised). A carbonaceous food for bacteria, but not for yeast.

Acetic acid. A yeast food.—*Naegeli*.

Citric acid. A yeast food.—*Naegeli*.

Tartaric acid. A yeast food.—*Naegeli*.

#### Aldehydes.

Acetaldehyde. A poison to yeasts.—*Bokorny*.

Formaldehyde. Poisonous.—*Bokorny*.

Hydroxybenzaldehyde. Not a carbonaceous food.—*Bokorny*.

*o*-Nitrobenzaldehyde. Poisonous.—*Bokorny*.

Glyoxal. Not suitable as a mould food.—*Loew*.

#### Carbohydrates.

Cane sugar. Budding yeast flourishes freely. Favours the production of glycogen.—*Naegeli and Loew*.

Glucose. Is easily assimilated by yeast, with production of glycogen.—*E. Laurent*.

Glucose. A trace of yeast develops within four days in a 0.2 per cent. solution to a considerable sediment.—*Bokorny*.

Fructose (levulose). A good food for yeast.—*Bokorny*.

Galactose. A carbonaceous food for yeast.—*Bokorny*.

Milk-sugar (0.2 per cent.) A yeast food.—*Bokorny*.

Milk-sugar (0.2 per cent.) Yeast produces from 1 to 40 per cent. solution of glycogen.—*E. Laurent*.

Rhamnose (0.2 per cent.) Is fairly easily assimilated by yeast.—*Bokorny*.

Sorbose (0.2 per cent.) Yeast grows feebly therein.—*Bokorny*.

Arabinose (0.2 per cent.) A yeast food.—*Bokorny*.

Maltose. In 1 to 5 per cent. solution is assimilated by yeast, with a considerable production of glycogen.—*E. Laurent*.

Inositol. Is feebly assimilated by yeast in 1 to 2 per cent. solution, without production of glycogen.—*E. Laurent*.

Mannose.—Assimilated by yeast.—*Bokorny*.

Xylose. Assimilated by yeast.—*Bokorny*.

Mannitol. Assimilated by yeast, with formation of glycogen.—*E. Laurent*.

Erythritol. Is feebly assimilated by yeast, without formation of glycogen.—*E. Laurent*.

Erythroextrin. Is assimilated by yeast, with production of glycogen.—*E. Laurent*.

Salicin. Is assimilated by yeast, with production of glycogen.—*E. Laurent*.

Amygdalin. Is assimilated by yeast, with production of glycogen.—*E. Laurent*.

#### Amido Compounds.

Peptone. A good carbonaceous food for budding yeast.—*O. Loew*.

Asparagine. An excellent carbonaceous food for budding yeast.—*Birner*.

Asparagine. Is assimilated, with production of glycogen.—*E. Laurent*.

Lencin (1 per cent.) Is somewhat assimilated by yeast, with formation of glycogen.—*E. Laurent*.

Asparaginic acid (1 per cent.) Is assimilated, with formation of glycogen.—*E. Laurent*.

Glutaminic acid (1 per cent.) Is assimilated, with formation of glycogen.—*E. Laurent*.

Glutamine. Is assimilated, with slight formation of glycogen.—*E. Laurent*.

Casein. Assimilated, with formation of glycogen.—*E. Laurent*.

Egg albumin. Assimilation, with slight production of glycogen.—*E. Laurent*.

Aniline. Unsuitable for a yeast food.—*E. Laurent*.

*o*-Toluidine neutralised (0.1 per cent.) Not a carbonaceous food for yeast. Good nitrogenous food for moulds.—*Bokorny*.

*p*-Anisidine (0.1 per cent.) A nitrogenous, but not a carbonaceous food for yeast.—*Bokorny*.

Nitraniline (0.1 per cent.) A nitrogenous, but not a carbonaceous food for yeast.—*Bokorny*.

Methylamine. Not a carbonaceous food for yeast.—*E. Laurent*.

Ethylamine. Not a carbonaceous food for yeast.—*E. Laurent*.

Propylamine. Not a carbonaceous food for yeast.—*E. Laurent*.

Formamide. Not a carbonaceous food for yeast.—*E. Laurent*.

Acetamide. Not a carbonaceous food for yeast.—*E. Laurent*.

#### Other Organic Compounds.

*o*- and *p*-nitrocinnamic acid. Not a carbonaceous food for yeast.—*Bokorny*.

*p*-Nitrotoluene. Not a carbonaceous food for yeast.—*Bokorny*.

Benzene. Not a carbonaceous food for yeast.—*Bokorny*.

—J. L. B.

*Wine Yeasts. Researches on the Differential Characteristics of.* C. Forti. *La Bière*, 5, [1], 9.

THE author having, from previous researches, been led to form the opinion that the morphological and physiological characteristics of wine yeasts are insufficient of themselves to determine the suitability of the yeasts to ferment musts of different composition, and that for this purpose practical experiments in fermentation are necessary, made a number of investigations with natural musts at different temperatures, as well as with varying quantities of sugar, degrees of acidity, kinds of antiseptic bodies, and nitrogenous matter; also with mixed yeasts and with wines still containing sugar. He finds that each yeast varies in behaviour as the temperature, nature of nitrogenous food, acidity, and alcoholic content of the medium are modified. So far as temperature is concerned an exposure to 35° C. for 5 to 15 days weakens all wine yeasts, the longer period proving fatal; and prolonged exposure to a temperature of 25° C. is also injurious. In presence of nitrogenous matter the yeasts adapt themselves in different degrees, each yeast needing a special amount of nitrogen varying with the kind of nitrogenous matter provided. The influence of the degree of acidity varies with the nature of the ferment, the temperature, and the amount of sugar. The yeasts differ in their behaviour towards sugar in presence of alcohol, some being able to perform their functions when the medium contains 12 or 13 per cent. of alcohol, whilst others are rendered inactive by a much smaller quantity. On the other hand, the production of spores at 25° C., and the appearance of the colonies on gelatin, form an insufficient basis for classification.—C. S.

*Beer Yeast, Composition of the Fat present in.* E. Gérard and P. Dorexy. *J. de Pharm. et de Chim.* 1897, [6], 275—280.

THE fat extracted from ordinary brewery yeast is brownish in colour, semi fluid, and distinctly acid in reaction. It consists largely of the glycerides of stearic and palmitic acids (in about equal proportions), together with traces of butyric acid. In addition, yeast fat probably contains small proportions of these acids in the free state.—H. T. P.

*Distillery Work, Study of Several Fungi utilisable in.* E. Sorel. *Rev. Chim. Industr.* 8, 13—17.

THE ragi employed in Java for the production of arrack consists of particles of the mycelium of *Chlamydomucor Oriza*, accompanied by yeast cells and bacteria. This fungus, like *Rhizopus Oriza*, has very little action on ordinary rice or potato starch, but converts cooked starch into glucose. Neither of the organisms has the power of producing alcohol, this function being discharged in the present instance by *Monilia Javanica*, which ferments dextrose, lerulose, maltose, and raffinose (but not lactose), but ceases to act when the alcohol reaches 5 per cent. of the medium; and by *Sacch. Vordermanni*, a very active ferment, capable of eliminating 18 to 19 per cent. of sugar in three days at 25 to 30° C., and of retaining its power in presence of 9 to 10 per cent. of alcohol.

Japanese saké is prepared by the aid of the diastase secreted by *Aspergillus Oriza*—an organism living on and saccharifying all classes of rice. (See this Journal, 1886, 170, and 1890, 754.)

Referring to the researches of Juhler (C. Bi. f. Bakt. 1895, Oct. 9), on the evolution of saccharomycetic yeasts from *Aspergillus Oriza*, the author finds that when the fungus is rendered incapable of growing under normal conditions, the yeast is always developed, although under more favourable circumstances no yeast is produced. Thus, whilst conidia sown on malt extract containing 0.030 grm. of hydrofluoric acid per litre, gave yeast in three or four days, the production of yeast was retarded to 10 days in presence of twice the above quantity of antiseptic, and ceased altogether when a five-fold quantity was used; whereas an unproductive fragment of mycelium from a wort culture with 0.030 grm. of HF transferred to a medium with 0.060 grm. of the acid, although initially free from yeast, gave yeast cells on the following day, and when re-washed and placed in a wort with 0.090 grm. of HF, produced rapid fermentation and a considerable deposit

of active yeast cells, itself finally disappearing after conversion into a compact tissue of short cells. The results obtained in experiments with aerated media also confirm the statement that the formation of mycelium always precedes that of the yeast, and that when the development of the former is arrested, the size of the filaments decreases, and they subdivide into budding cells having the properties of yeast. The absence of direct formation of yeast cells from the conidia, as observed by Juhler, is attributed to the difference in the media employed.

Further researches in connection with the converse development of the yeast cells into the original form of the mould confirm the results previously obtained by the author (*Comptes rend.* 121, 948). He finds that the yeast becomes incapable of saccharifying starch in solution, but that it will give (even after an existence of over a year), with cooked rice in an almost dry state, a mycelium possessing diastatic power. The development of the mycelium is, however, slow, and unless the water, carbon dioxide, and alcohol formed are immediately removed, it becomes paralysed, and the untransformed yeast sets up fermentation. This was proved by experiment in a series of four flasks, aerated by a single current passed through each in succession, where the yeast developed conidia of *Aspergillus* in the first, a little mycelium in the second, but only produced alcohol and carbon dioxide in the remaining two; whereas on the interposition of condensers and washing tubes containing baryta water, between the flasks in a parallel series of experiments, conidia were developed in all four.—C. S.

*Denaturing of Spirits.* *Zeits. f. Spiritusind.* 1897, 20, 19.

THE members of the acetone group recommended by Lang for denaturing spirit may be divided into two classes, namely, (1) ketones of the type of ethylmethylketone, which are readily soluble in water; and (2) the acetone or ketone oils which are insoluble, or nearly so, in water. Experiments have shown that the complete removal of ethylmethylketone from spirit cannot be satisfactorily effected; and brandy spirit (for Cognac, &c.) to which this ketone has been added cannot be completely renatured either by filtration, rectification, or by treatment with ether, light petroleum, benzine, by treatment with acids, alkalis, paraffin oil, animal charcoal, &c. Filtration is impracticable, as at least 600 kilos. of charcoal would be required for the treatment of 100 kilos. of spirit. Experiments have also been made with crude ketone oil, distilling between 75° and 230°, and with the different fractionated constituents obtained from it. One per cent. of oil was used for denaturing the spirit, and it was found that when the constituent of lowest boiling point (75°—105°) had been used, a partial renaturing could be effected by careful rectification of the previously diluted spirit. This was not the case, however, when the crude oil or a fraction boiling above 150° had been used. In the experiments on filtration through charcoal, the denatured spirit was diluted to about 30 per cent., and passed through 5 kilos. of charcoal; each litre of filtrate was tested with phenylhydrazine, and those samples which gave no reaction were regarded as renatured. The following results show the weight of charcoal required to renature 100 kilos. of spirit to which 1 per cent. of oil had been added:—

	Kilos.
1. Denatured with methylethylketone required at least .....	600
2. Denatured with acetone oil (b. pt. 75°—230°) required at least .....	100—120
3. Denatured with acetone oil (b. pt. 75°—105°) required at least .....	140—150
4. Denatured with acetone oil (b. pt. 105°—150°) required at least .....	100—110
5. Denatured with acetone oil (b. pt. 150°—200°) required at least .....	70—80
6. Denatured with solvent naphtha required at least .....	9—10

In the case of spirit which had been denatured by the addition of 1 per cent. of ethylmethylketone and 2 per cent. of acetone oil, it is calculated that 1,000 kilos. of charcoal would be required for the complete renaturing of 100 kilos. The addition of chemicals, such as sodium sulphite, potash, or ammonia also fails to effect the removal of this mixture.

Lang's experiments have been repeated and, in the main, confirmed by Heinzelmann.—A. K. M.

*Wine, Solvent Action of, on Metallic Zinc.* L. A. Levat. *Comptes Rend.* 1897, 124, [5], 242—243.

A STRIP of ordinary sheet zinc when placed in a bottle of red wine (sealed down) was found to be attacked to a marked extent, hydrogen being slowly evolved (sufficient at the end of 10 days' contact to blow the cork out of the bottle). After a month, the wine had become turbid and possessed a metallic flavour. The surface of the zinc was corroded and bright, but studded here and there with granules of a zinc salt. The use of zinc or galvanised taps and fittings for wine tuns, &c. must therefore be condemned. —H. T. P.

*Wines, Loss of Colour in (La Casse), produced by a Soluble Oxidising Ferment of.* P. Cazeneuve. *Comptes Rend.* 1897, 124, [8], 406—408.

THE malady known as *la casse des vins*, and which consists in the oxidation of the red colouring matter of the wine, has been attributed by Gouiraud to the action of a diastase. Martinaud admits the presence of an oxidising ferment—*oxydase*—in ripe grapes, whilst Bertrand confuses this ferment with laccase. The author has examined a large quantity of a Beaujolais wine affected by this malady. By treatment with strong alcohol, a gummy precipitate was obtained, consisting mainly of the normal gum of wine impregnated with oxydase. The aqueous solution exhibits the fundamental properties of laccase, but it would be premature to assume the identity of the latter with the oxydase of wine which the author terms *anoxydase*. This substance acts upon wine at temperatures even below 0°; it is instantly destroyed at 70°—75°. From a comparative study of the wines from different vineyards, the author is led to the opinion that the abundance of *anoxydase* in the Beaujolais wines last year is to be attributed to certain vegetative conditions favouring its formation, rather than to the presence on the grapes of cryptogamic parasites which might secrete oxydase. The author's observations invalidate the conclusions arrived at by Laborde. (*This Journal*, 1897, 156.)—A. K. M.

*Malt Wines.* List. *Chem. Zeit.* 1897, 21, [1], 4—5.

THE statement that by Sauer's method, a product containing 16—17 per cent. of alcohol could be obtained by direct fermentation has been confirmed by the work of Dr. Möslinger, of Neustadt.

Sauer sterilises a 20 per cent. wort, warms to 50°, and sows it with a culture of lactic acid bacilli. When the lactic acid content reaches 0.8 per cent., the liquid is heated to 70° to stop the action, quickly cooled to 20°, and sown with a pure yeast culture derived from Tokay or

Spanish grape fermentation. As the action slackens, more sterilised wort is added, and the sugar-content kept up by cane-sugar, till fermentation will go on no longer. The products come into the market as "Malton Tokay" and "Malton Sherry" respectively. The following figures have been obtained by Fresenius, Möslinger, and the author on analysis of the commercial article or of a privately fermented product.

	Sherry.	Tokay.
Total extractive .. { F. ....	12.47	28.29
{ M. ....	11.52	28.25

{ L. ....		

These wines have been found of value medicinally, and must, from their purity, and their content in "extractive," alcohol, and sugar, be regarded in many cases as preferable to the sweet Southern wines.—J. T. D.

*The Sparging Process and its Influence on the Yield of a Mash.* W. Windisch. *Wochenschr. f. Brauerei*, 1897, 14, 1.

IN this article the author refers to two points, the importance of which has not been sufficiently emphasised in his previous papers. 1. A primary condition for obtaining a good yield depends upon the thorough draining of the first wort from the grains before any sparging liquor is added to the latter. 2. The second condition mentioned is that sufficient time be allowed for the sparging process. If this be hastened, the wort contained within the pores of the grains will not have time to diffuse into the sparging liquor, and a loss will thus occur.—A. K. M.

*Beer, Japanese.* A. Lang. *Zeits. f. d. ges. Branwesen*, 20, [2], 27.

THE cultivation of barley in Japan has greatly increased of late years, and a large quantity is now used for malting and brewing. Two samples of Japanese beer, one from the Asahi and the other from the Yebisu brewery have recently been analysed with the following comparative results (after driving off the carbon dioxide):—

	Saccharometer Reading.	Alcohol.	Extract.	Maltose.	Dextrin.	Total Acid (calculated as Lactic Acid).	Protein (N. 6.25).	Ash.	Phosphoric Acid.	Glycerin.	Calculated.		
	° Balling.	%	%	%	%	%	%	%	%	%	Original Wort. Balling.	Apparent Attenuation.	Actual Attenuation.
Asahi beer .....	3.39	4.60	5.642	1.725	2.41	0.133	0.454	0.214	0.0718	0.145	14.44	75.14	60.83
Yebisu .....	3.12	4.56	5.23	1.29	2.41	0.161	0.491	0.222	0.051	0.120	13.98	77.7	62.6

The concentration corresponds with that of Bavarian lager beer, and the high attenuation with that of North German beers. In flavour the Yebisu is vinous, whilst that of the Asahi beer recalls apple must (due to pasteurisation). The latter was not clear and had deposited a sediment consisting of gluten without any living organisms.—C. S.

*Mechanical Clarification of Beer by Wood Chips and Filtration.* *Amer. Brewer's Review*, 10, [7], 245—246.

THE use of chips and filters is very extensive in American breweries and gives satisfactory results. German brewers, however, according to a recent address by Dr. Will at Munich, while adopting chips, do not take kindly to the

use of filters. Chips of hazel or beech wood are the most commonly used and act as a good clarifying medium, holding the sediment down fast, so that if they are properly arranged in the cask the liquid can be drawn off clear to a lower level than in such casks as have no chips. The aluminium chips recently introduced obviate the risk of infection by the use of dirty wooden chips, and have been proved to be without effect on the flavour of the beer. According to Dr. Will the filtration of beer causes a deterioration of taste, and the beer loses in fullness and in the consistency of the foam. From a biological point of view the beer also suffers deterioration, since the filter retains only the large vigorous yeast cells whilst wild yeasts

and bacteria, for the most part, pass through without obstruction and afterwards develop all the more vigorously owing to the absence of yeast.

These views of Dr. Will are by no means, however, borne out by the experience of United States brewers, which is that the beer suffers no detriment whatever by filtration.

—J. G. W.

*Butyl-Alcoholic Fermentation.* O. Emmerling.  
Ber., 1897, [4], 451—453.

THE author previously (Ber., 1896, 2726) stated that he could not obtain the bacillus described by Fitz which produced butyl-alcohol from glycerin; he has now, after examining a number of materials, obtained the bacillus from hay from Alsace. As it was only present in a comparatively small proportion in the hay infusion, this was increased by growing the mixed bacteria in a 5 per cent. glycerin solution *in vacuo*.

As *bacillus subtilis* is aerobic, whilst the butyl-alcohol bacillus is anaerobic, the proportion of the latter was increased, and after three cultivations, plate cultivations were made and the bacillus which was sought, obtained in a pure state.

The bacillus agrees fairly well with Fitz's description being slightly elliptical rods; it gave 6 per cent. of butyl-alcohol from glycerin, and 10 per cent. from manitol, whilst when acting on dextrose only ethyl alcohol was produced. The author thinking that this organism might be identical with that described by Beyerinck (C. B. Baet. 15, 177) as *granulobacter saccharobutyricum*, has compared the two, but finds that though resembling one another in appearance, they possess very different functions.

The bacillus was also obtained from rotten wood, but is not the one which causes the destruction of the cellulose.

—A. L. S.

*Mould Fermentation.* O. Emmerlich. Ber. 1897,  
[4], 454—455.

As is well known, moulds, when grown under anaerobic conditions in sugar solutions, act as yeasts and produce alcoholic fermentation. The author considered it would be of interest to determine if glycerin and succinic acid were produced.

He employed *Mucor Racemosus* growing in a cane-sugar solution and replaced the air by hydrogen. After three weeks' fermentation at 25° C. the fermented solution was found to contain alcohol, glycerin, and succinic acid in the proportion of 22.0, 1.83, and 0.31 respectively.—A. L. S.

*Extracts.* A. Rogers. J. Fed. Inst. Brewing, 1897,  
3, 129—133.

AN average malt will yield 78 per cent. extract, but in practice about 70 per cent. is obtained, the remaining 8 per cent. of the starch being incompletely modified. The author recommends that fluted rollers should be used in the malt mill, as they help to catch smaller grains that might otherwise escape; also that the mash tun should be provided with rakes. The lower the striking heat of the water can be arranged to suit the resulting beers, the higher will be the extract obtained. For brewing a strong beer with a full tun, the following method is suggested:—

The mash is run into the tun with a minimum quantity of one and a half barrels of water to a quarter of malt. It is allowed to stand the usual time and no underlet used, unless the initial heat requires to be raised. The taps are then set, the tun drained dry and the goods sparged. This operation is repeated, the sparge, however, not running while the taps are flowing, care being taken that when this is finished no wort is left in the tun. Under these conditions a full extract is said to be obtained.—J. L. B.

*Corks [Beer and Wine], Dangers occasioned by.*  
H. Will. Zeits. f. d. ges. Brauw., 20, 93—96.

BEER, unlike wine, is not stored long enough in bottles to become "corked," but may, if the corks are not sealed, be contaminated by extractive matter which causes turbidity, and may also be infected with wild yeast and fungi contained in the cracks and fissures of twice used corks. As pointed out by Wortmann, at the late Congress of German

wine producers, the porous nature of cork permits diffusion so that export beers, even though pasteurised, may, by the intrusion of oxygen, have any dormant micro-organisms present revived with disastrous results.

Wine left in bottle for 25 or 30 years has been found when uncorked, to contain living organisms in full activity and especially mould fungi capable of eliminating alcohol and of imparting to the liquid, unpleasant flavours and odours, even when present in small numbers. Similar effects may be produced in beer from the presence of mycoderma, a few individual organisms sufficing to develop a musty flavour.

Wortmann investigated the causes of "corkiness" in wine and found that it may either be due to organisms in the wine without the cork being more than a passive assistant (by permitting the admission of oxygen), or else directly, to defective corks without the aid of any organism. In the first instance, however, mould fungi may penetrate to the wine by pushing their fibres through the natural channels existing in the cork, and Wortmann found infection from various kinds of penicillium, dematium yeasts, raecidium cellare, and eladosporium herbarum, communicated in this way, each of which developed musty and unpleasant flavours differing with the kind of wine exposed to the infection. A similar ease of infection by penicillium has been observed in bottled beer, a strong growth appearing on the underside of the cork, and a mycelium developing in the beer, which was quite spoiled.

It is therefore advisable to select corks with great care, rejecting those in which the natural fissures run longitudinally, and controlling the sealing process so as to preserve the elasticity of the material.

When wine is spoiled by defective corks without the agency of any organism, the effects are due to decomposition of the matter contained in the fissures and the gradual extraction of the products by the adjacent liquid. This may be prevented by steeping the corks in paraffin, or paraffin and wax.—C. S.

*White Wines, Testing for Coal-Tar Colours in, and the Difference between these Colours and Caramel.* A. d'Aguilar and W. da Silva. Comptes Rend. 1897, 124, [8], 408.

*Rice and other Grain or Seed for Brewing and other Purposes, Impts. in the Treatment or Preparation of; and in Means or Apparatus to be employed therein.* A. Perry and H. Perry, Bow, Middlesex. Eng. Pat. 5615, March 12, 1896.

THE object of this invention is an improved process for "flaking" rice or other grain in order to render it more suitable for use in distilling, brewing, &c.

The rice or other grain is fed into the upper part of a perforated cylinder immersed in a tank of boiling water, and in order that the scalding may be regularly performed the cylinder is divided by a horizontal partition which does not quite reach to the end. The material which is being treated is conveyed by screws through the upper chamber thus formed until it falls through the opening left by the short partition into the lower portion of the cylinder, and is then conveyed by screws until it is delivered into an elevator at the other end of the cylinder.

The scalded material is then conveyed in the same manner through another perforated cylinder immersed in cold water; this treatment removes the stickiness of the grain, and enables it to be handled and passed through the machinery without trouble.

The final operation consists in passing the grain between highly heated pressure rollers of large diameter. The rollers are kept hot, by passing heated sand through them, the sand as it passes from the rollers being returned to the furnace, and after passing through these is again led through the rollers.

The daked grain is removed from the hot rollers by scrapers and carried away on an endless belt. The machinery is fully described by the aid of drawings.

*Wines and Spirits, Apparatus for Removing Saccharine and other Impurities from.* From J. T. Bennett, Cape Town. C. H. McEuen, London. Eng. Pat. 22,403, Oct. 9, 1896.

This apparatus consists of a funnel-shaped vessel provided with an air-tight cover, and inlet and outlet valves. The latter is in combination with an open vat, also fitted with an inlet and draw-off. In the operation, the vat is filled with water to a height above the outlet of the funnel, whilst the funnel itself is filled with the wine or spirit to be purified. The inlet tube is then closed. Under these conditions the wine and water, though in contact, will not mix, but the heavier saccharine or vegetable impurities will descend into the vat.—J. L. B.

*Malt Liquors, Impts. in Apparatus and Process for Treating.* A. E. Feroe, New York, U.S.A. Eng. Pat. 21,022, Sept. 22, 1896.

The beer having arrived at that stage of the fermentation when it is nearly ready to rack into casks, it is confined under a pressure greater than that produced by fermentation, and allowed to deposit the yeast. It is then cooled to cause the semi-soluble albuminoids to separate, and the beer still under pressure, passes upwards through a filter. The beer is then racked into casks without loss of pressure. The inventor has devised an elaborate apparatus for performing these operations, which is fully described.—A. L. S.

*Mash-Tubs and Conversion Vessels for Brewers' and Distillers' Use, Impts. in or connected with.* [Lining with Silver.] R. D. Bailey, Gloucester, and L. P. Ford, London. Eng. Pat. 27,275, Dec. 1, 1896.

The inventors propose to coat with silver all metallic parts of mash-tubs or conversion vessels.—A. L. S.

*Alcoholic Beverages, A New or Improved Process and Apparatus for Rapidly and Economically Ageing or Maturing.* F. C. Haack, Brussels. Eng. Pat. 1162, Jan. 15, 1897.

This alcoholic liquid to be matured is subjected to a progressive and prolonged heating (40°–55° C.) in an apparatus warmed by hot-water pipes and provided with a cover, whereby the volatile substances which evaporate may be removed from the heater. There are also discharge orifices which permit the separate withdrawal from the apparatus of the treated liquid, the noxious matters of lower specific gravity than the liquid (propyl, butyl, and amyl alcohol), and the deposited dregs. The objectionable constituents having been thus separated, the liquid is drawn off into hermetically closed barrels and allowed to remain at a low and constant temperature for several weeks, when it is filtered or clarified, and bottled.—J. L. B.

### PATENTS.

*Albuminous Substances, A Process for the Preparation and Extraction of, from Animal and Vegetable Mixtures and Products.* D. Pinkler, Bonn, Germany. Eng. Pat. 5749, March 14, 1896.

This process consists in converting into soluble products, or completely decomposing, such substances contained in albumin as are unpleasant and injurious to health. This is effected particularly by heating or boiling the albumin with hydrogen peroxide of such a strength that it is without action on the albumin itself; the soluble product may then be removed by washing, leaving albuminous substances, which, when well dried, are free from smell and taste, rich in albumin, and nourishing as food.—J. L. B.

*Coffee, Impts. in the Manufacture of.* H. Boisselier, Middlesex. Eng. Pat. 7904, April 15, 1896.

EQUAL weights of washed coffee, and an oil or fat melting at about 90° F., are mixed and ground between two horizontal stones; when a sufficient degree of fineness has been attained, there results a semi-liquid paste, perfectly smooth and free from grit. This is collected whilst warm, placed in bags or cloths, and submitted to hydraulic pressure, whereby the whole of the fat is removed. The coffee remaining in the cloths is pulverised and sifted, and yields a product readily miscible with hot water for making the beverage.

—J. L. B.

*Food Products and Beverages, An Improved Process for Sterilising and Preserving.* W. Nageli, Mombach, Germany. Eng. Pat. 6496, March 24, 1896.

AN acid (or alkali) is placed in the preserving vessel whilst being heated in the sterilising chamber. A basic (or acid) substance is inserted in the stopper of the tin or glass containing the sterilised food, in such a manner that on turning the bottles or tins, combination of the acid and base takes place. This process can also be used for saturating non-alcoholic beverages with carbonic acid, the bicarbonate being placed in the stopper and dissolved after the sterilisation and closing of the vessel. By the distillation of fermented beer, and by its subsequent sterilisation and saturation with carbonic acid as described above, non-alcoholic beer may be prepared.—J. L. B.

### (B).—SANITATION; WATER PURIFICATION.

*Ozone, Atmospheric; Estimation of, on Mont Blanc.* M. de Thierry. Comptes Rend. 1897, 124, [9], 460.

*Water Softening and Purifying Apparatus, Impts. in.* F. H. Tyneke, Old Broad Street, E.C., and C. E. Gittins, Iverson Road, West Hampstead. Eng. Pat. 5849, March 16, 1896.

THE apparatus comprises a tank to contain the purifying reagent, a mixing and settling tank having vertical partitions extending alternately from the top and bottom so as to form a zig-zag passage for the water, a storage tank for the softened and purified water, an elevator adapted to discharge the reagent in a suitable proportion into the mixing and settling tank, a water motor (preferably a bucket wheel) adapted to drive the elevator and actuated by the water to be purified, and a supply valve automatically controlled by a float located in the storage tank, for admitting the water to the motor and mixing tank.—K. A.

*Sewage and other Waste Liquids, The Utilisation of By- and Waste Products [Flue Dusts] from Iron and Steel Industries for the Manufacture of Improved Precipitants for the Purification of.* W. E. Adeney and W. K. Parry, both of Dublin. Eng. Pat. 5955, March 17, 1896.

THE flue dusts produced in the manufacture of iron, ferro-manganese, and steel, are digested with hydrochloric or

sulphuric acid in sufficient proportion to dissolve the chief basic substances present. The treated mass may be dried, and applied direct for precipitating sewage and the like; or the soluble salts may be dissolved and separated from the residue, and applied in like manner. "Besides treating the flue dust with sulphuric acid or with hydrochloric acid, it may be fused with bisulphate of soda."

Sewage precipitants may also be obtained by mixing manganiferous flue dusts, containing higher manganese oxides, with crude sulphates or chlorides of iron in about equal proportion. The action of the higher oxides of manganese, when mixed with wet sewage sludge, is described in Eng. Pat. 21,635, 1894 (this Journal, 1895, 983).—E. S.

*Filtering Material and Process for Making the Same, An Improved.* F. Jurschina, L. Schnitzer, and F. Hirsch, all of Vienna. Eng. Pat. 6934, March 30, 1896.

See under I., page 315.

*Purifying Water by Boiling it in Open Vessels, Method and Apparatus for.* A. Derraux, Brussels. Eng. Pat. 24,474, Nov. 2, 1896.

The water is boiled in an open vessel by means of steam admitted near the bottom, the steam being continually condensed before it reaches the surface of the water, by admitting a fresh supply of the water to the vessel. The water may be admitted either at the top or the bottom of the vessel, the purified water being drawn off through a pipe at the side.—R. A.

#### (C).—DISINFECTANTS.

*Ferrous Sulphate, Employment of, for the Destruction of Cryptogamic Parasites of the Vine.* Croquevielle. Comptes Rend. 1897, 124, [8], 418–419.

The following treatment to be applied to the vine in the winter is recommended as a preventive of the maladies known as *black rot*, *oidium*, *mildew*, *anthracnose*, &c.:—  
1. The stems are washed or sprinkled with a solution containing at least 10 per cent. of sulphate of iron.  
2. Powdered sulphate of iron is applied to the soil in quantities varying from 500 to 1,000 kilos. to the hectare, according to the nature of the soil.—A. K. M.

*Formaldehyde, Methods for the Estimation of.* G. Romijn. Zeits. Anal. Chem. 36, [1], 182.

See under XXIII., page 366.

#### PATENT.

*Albumin and Protein Bodies, Production of Formaldehyde Compounds of the.* Dr. A. Classen, La-Chapelle, Germany. Eng. Pat. 7712, April 11, 1896.

By the action of formaldehyde, or of substances capable of yielding it, on albumin or protein bodies, at a temperature of 110°–130° C., compounds are formed which are quite innocuous and are gradually decomposed by tissue and secretions, giving off formaldehyde. For instance, 50 c.c. of purified albumin or blood serum are mixed with 50 c.c. of a 40 per cent. formaldehyde solution and evaporated on a water-bath until the mass appears dry. It is then heated in a digester for 24 hours to 120° C., finely powdered, stirred up again with formaldehyde solution, and treated a second time in the digester. The product obtained is finally heated for some time to 120°–130° C., after which it is freed from formaldehyde by washing with water. The products are said to possess a durable disinfecting action and animal blood, when treated therewith, even after standing several days at 40° C., maintains a light red tint and remain perfectly odorless.—T. A. L.

#### XIX.—PAPER, PASTEBOARD, Etc.

*Paper-making, The Results of Grinding Fibres for* W. Herzberg. Mitt. K. t. Versuchsanst. zu Berlin, 14 [5 and 6], 306–308.

As is generally known, fibres, especially linen, when ground in the beating engine with blunt blades and dense stuff, are so crushed that it is almost impossible to state their origin. This grinding is done mostly in order to obtain strong writing paper, cigarette paper, &c., the pulp being known as "greasy." In blotting- and similar papers a greasy pulp is carefully avoided, the grinding being performed with sharp blades, and with thin stuff so as to separate the fibres without crushing them.

The appearance of the fibres is different in different cases, owing to the various methods and degrees of grinding.

An examination shows that the fibre is ground to such a degree, in some cases, as to make it difficult to find any whole filament.

By the use of numerous micrographic reproductions, it would, no doubt, be possible to obtain normal standards of grinding, which would be of great utility to paper-makers, as it would be possible to compare results without taking a micro-photograph each time.

In the table following, are given the strength of the papers compared with those of the fibres:—

Name of Paper.	Composition of Pulp.	Middle		Resistance against Crumpling.
		Breaking Length.	Stretching.	
Dutch bank-note paper .....	Cannot be ascertained with certainty on account of grinding. Possibly linen.	M. 7.275	Per Cent. 11.1	Extremely strong.
Normal I. ....	Linen, some cotton fibres, rather strongly ground.	6.215	4.7	Very strong.
Document paper made from unbleached rags.	Linen, and a little cotton .....	8.425	5.6	Extremely strong.
Normal I. ....	Linen and cotton .....	6.050	4.2	Very strong.
" .....	Cotton, with a little linen .....	6.825	7.2	Extremely strong.
Photographic paper .....	Linen, with very little cotton .....	2.600	3.8	Weak.
" .....	Linen, with very little cotton .....	4.350	4.5	Weak.
Wrapping paper .....	Manilla hemp .....	6.750	4.5	Extremely strong.

The three normal papers were made in different mills.

—S. P. E.

#### PATENTS.

*Paper, Process for Increasing the Suppleness or Pliability of.* O. Tietze, Ratingen, near Düsseldorf, Germany. Eng. Pat. 1437, Feb. 28, 1896.

HARD paper is rendered pliable and more suitable for concert and other programmes, &c., by impregnating it with soap made from castor oil, or a mixture of castor and other oils, and resin. The paper is soaked in, or brushed

over with a strong aqueous solution of the soap, and dried. By varying the relative proportions of fatty oil and resin, various degrees of suppleness may be produced.—L. A.

*Fabrics from Paper Pulp, Impts. in the Manufacture of.* C. Brodbeck, Paris. Eng. Pat. 23,598, Dec. 10, 1895.

See under V., page 327.

*Alkali-Cellulose, Impts. in the Manufacture of.* C. F. Cross, London. Eng. Pat. 4713, March 2, 1896.

THE cellulose fibre or pulp is treated for some time with dilute hydrochloric or sulphuric acids; until the cellulose

is in a brittle condition. It is then washed, and treated in an edge-runner with caustic soda, in such proportions as to give a compound containing 40 to 50 per cent. of cellulose, 10 to 12 per cent. of caustic soda, and 38 to 50 per cent. of water. The product is then in a pulverulent condition, favourable for treatment with carbon bisulphide for the preparation of chloroformate. It has approximately the composition  $C_{10}H_{16}O_2NaOH$ .—S. P. E.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

*Lavage, Essential Oil of.* E. Braun. Archiv. der Pharm. 235, 1.

LAVAGE oil is found to contain (a) a terpene,  $C_{10}H_{16}$ , resembling limonene, but not giving crystalline compounds with the halogen acids; (b) cineol,  $C_{10}H_{18}O$ ; (c) isovaleric acid; (d) acetic acid, as an oxidation product; and (e) benzoic acid. The oil commences to boil at  $170^\circ$ , but begins to decompose at  $200^\circ$  C.—J. O. B.

*Belladonna, Alkaloidal Value of.* Kremel. Pharm. Zeit. 41, 686.

AN examination of the individual parts—roots, stem, leaves, and fruit—of a belladonna plant, gathered in July, and bearing some unripe fruit and flowers, resulted as follows:—

The root gave .....	1.750 per cent. of alkaloid.
The stems gave .....	0.616 " "
The leaves gave .....	0.700 " "
Unripe fruits gave .....	0.600 " "

These results apply to dry material.

The fluorescent substance, chrysotropic acid, was also obtained from all parts of the plant, by washing the acid extracts with chloroform. Subsequently, a part of the fresh root remaining over from the above analysis, was dried at  $100^\circ$  C., losing 84 per cent. of water, and was then examined for its alkaloidal percentage. This last was found to be 0.95 per cent.—a fact indicating that 45.71 per cent. of its alkaloids had been decomposed in the process of drying; a piece of the same root upon re-examination after having been kept for the space of one year, yielded only 0.70 per cent. of alkaloid—a further loss of 26.26 per cent. However, the decomposition of alkaloids brought about by keeping the drug, would seem not to go beyond a certain limit. Samples kept for a year showed on an average between 0.50 and 0.70 per cent., others kept for eight years 0.60 per cent., and still others, in the form of powder, kept for a period of ten years also showed 0.60 per cent. of alkaloids.

A solid extract of belladonna with 2.60 per cent. of alkaloids was kept for a space of three years, at the end of which time the amount of alkaloids was found to be 2.45 per cent.

With a view of ascertaining the relative percentage of alkaloids contained in belladonna roots gathered at different periods of the year, specimens were gathered in June and October from the same spot. After drying, both were examined for the quantity of alkaloid, as well as for that of extractive matter. The former yielded 0.88 per cent. of alkaloids, and the latter but 0.225 per cent. That gathered in June gave 26.6 per cent. of solid extract, assaying 3.32 per cent. of alkaloids; that in October gave 16.6 per cent., with but 1.30 per cent. of alkaloids.

—J. O. B.

*Apiol.* W. Dulière, Jonas, and François. J. Pharm. Chim. 1897, 5, 229.

VERY dissimilar substances are sold under the name of apiol, varying in density, colour, action of solvents and reagents, and action of heat, which decomposes adulterated apiol, the true apiol being volatile. Essential oil of parsley contains apiol and a terpene in varying proportions; according to Dulière some essences contain no apiol. Jonas states that whilst the density of apiol, according to the Belgian Pharmacopœia, is 1.07—1.08, that of the French product is much lower. The property of apiol of sinking

in water does not serve for the detection of impurities, a sample mixed with an equal volume of olive oil behaving, in this respect, exactly like pure apiol.

François has studied the properties of apiol prepared in the following manner:—1 kilo. of ground parsley fruit was twice macerated with 1 litre of 92 per cent. alcohol for 24 hours, the alcoholic solution shaken with 100 grms. of animal charcoal for 24 hours, and filtered; then one quarter of the liquid was distilled off, the remainder being mixed with its own weight of chloroform, and left to settle for 24 hours. After filtering, half the liquid was distilled off. The residue was warmed at  $100^\circ$ — $110^\circ$  C. until chloroform and alcohol were driven off, and to the cooled liquid one-eighth of its weight of litharge was added, the mixture digested for 24 hours, and filtered through a thick layer of animal charcoal. Thus obtained, apiol is a complex product, on fractional distillation 5—6 per cent. of a light yellow oil of strong odour and pungent taste passing over at  $150^\circ$ ; this crystallised on cooling, and is the German "pure crystallised apiol." At  $170^\circ$ , a fatty oil of slight odour and bitter taste, and non-crystallisable, distils over. According to François, this is apiol. At about  $190^\circ$ , a brown-coloured mixture of resinous substances passed over.

The apiol of commerce is generally coloured green by chlorophyll, due to imperfect purification, or use of ether instead of chloroform. The principal adulterants are castor oil, linseed oil, glycerin, and gurjun balsam. The density is 1.08 at  $15^\circ$  C.; it is insoluble in water and benzene, gives a cloudy solution in alcohol; is soluble in ether and chloroform, and very soluble in acetic acid. If apiol be allowed to run down the sides of a tube into nitric acid, at the point of contact a blood-red coloration is produced, turning to rose and then to yellow.—A. C. W.

*Citral, Action of Alkalis on; Methylheptenone Preparation of.* A. Verley. Bull. Soc. Chim. 1897, 17, 175.

By boiling with weak alkalis, citral is decomposed into acetaldehyde and methylheptenone; the latter substance may thus be readily prepared from the citral of lemon-grass oil. 500 grms. of citral, 500 grms. of potassium carbonate, and 5 litres of water were boiled for 12 hours with a reflux condenser; acetaldehyde is evolved during the whole course of the reaction, and may be collected by allowing the condenser to become slightly warm and attaching a receiver cooled by ice. When the operation is over the product is steam-distilled, and the crude ketone, on fractionation in *vacuo* with a distilling column, separates into methylheptenone (five-sixths) and unaltered citral. The ketone is formed quantitatively, but the aldehyde is partially resinified; only traces of organic acids were left in the flask.

Methylheptenone prepared by this method is identical with that obtained by Wallach, by Tiemann and Semmler by the careful oxidation of citral, and with that extracted by Barbier and Bouveault from lemon-grass oil. The citral extracted from lemon-grass oil by means of sodium sulphite contains 10 per cent. of methylheptenone; this may be separated by fractionation in a vacuum with a distilling column, but has not the same odour or boiling point as that prepared by the above method; by transformation into the oxime, purification of this by distillation in *vacuo*, and subsequent decomposition, the methylheptenone is obtained quite pure and boiling at  $168^\circ$  C.—A. C. W.

*Anethol and its Homologues.* C. Moureu and A. Chauvet. Comptes Rend. 1897, 124, [8], 404—406.

THE authors describe a modification of Perkin's method of synthesising anethol, and the preparation of two homologues of the latter, *viz.*, parabutenylnisol and para-isopentenyl-anisol. The odour of aniseed is characteristic of all these compounds, and is also possessed by an isomer of butenyl-anisol obtained by Perkin; this property is attributed to the para position of the two side chains and to the peculiar unsaturated character of the hydrocarbon chain, —CH=CH—R.—A. K. M.

*Essences, Artificial, Ionone and Hawthorn.* Tiemaon.  
Le Goudron, 1, [2], 11.

1. *Ionone (Artificial Essence of Violets).*—Equal parts of citral and acetone are agitated with barium hydroxide solution for several days, the mass being then taken up by ether, which is afterwards decanted and the residue distilled, the fractions passing over between 138° and 155° (under 0.012 m. pressure) being collected. The unconverted acetone and citral are removed by steam and the remainder distilled under the same pressure, collecting the fractions boiling between 143° and 145°. 20 parts of this portion, *pseudo-ionone*, are heated to boiling, with 100 parts of water, 100 of glycerin, and 0.5 part of sulphuric acid. After cooling, agitating with ether, and evaporating the latter, the residue is distilled and the fractions boiling between 125° and 135° constitute *ionone* (sp. gr. 0.935).

2. *Artificial Essence of Hawthorn* is prepared by heating together, on the water-bath, paroxybenzoic aldehyde, methyl di-iodide, and a solution of potash in methyl alcohol. This essence boils at 218°, and its purity is best assured by the distillation test.—C. S.

*Basil, Essential Oil of, Its Chemical Composition.* Dupont and Guerlain. Comptes Rend. 1897, 124, [6], 300—302.

THIS oil is obtained by distillation from the leaves of *Ocimum basilicum* L., a plant of oriental origin, but which has been acclimatised in the South of France. The fresh leaves furnish about 0.04 per cent. of the essence, or when dried about 1.5 per cent. Essence of basil forms a slightly oily, yellowish liquid, possessing a strong characteristic odour. Its specific gravity at 15° C. is 0.9154. It is levorotatory ( $-7^{\circ}46'$  in 100 mm. tube). On distillation about four-fifths of the oil pass over between 190°—220° C., leaving behind a viscous brown substance which retains the odour of the original oil. The volatile portion on fractionation yielded two main fractions: one constituting about 60 per cent. of the essence (195°—200° C.), consisting of *l*-linalool ( $C_{10}H_{18}O$ , identical with the linalool obtained from oil of lavender, &c.); the second (205°—215° C.) possessed an odour resembling that of estragol (para-methoxy-allylbenzene), and was found to contain a large proportion of that body. The estragol, although not separable as such, was clearly identified by previous conversion into the isomeric anethol, and isolation of the latter.—H. T. P.

*Turpentine, The Rectification of; Oil of.* E. Kremers. Pharm. Rev. 1897, 15, 7.

FOR pharmaceutical purposes, oil of turpentine is usually required to be rectified. In a series of tables, the author reproduces the results of investigations dealing with this question. In some of the experiments, portions of crude oil (1,000 c.c.) of sp. gr. 0.872 at 20° C., and rotatory power ( $\alpha_D$ ) = + 11° 61' were agitated with an equal volume of milk of lime, and after an interval of at least 12 hours, distilled in a current of steam, 4 fractions of 200 c.c. each being collected, and the residual 200 c.c. rejected. The results obtained in one experiment are subjoined:—

Fraction.	Sp. Gr. at 20° C.	( $\alpha_D$ ).
1	0.864	+ 14° 18.0
2	0.866	+ 12° 29.7
3	0.8702	+ 11° 42.9
4	0.8722	+ 10° 7.00

The decrease in volatility is, therefore, accompanied by a diminution of rotatory power. In another similar experiment the whole (mixed) distillate was dried over anhydrous sodium sulphate. The oil possessed an agreeable odour, its sp. gr. was 0.864 at 20° C. ( $\alpha_D$ ) = + 12° 17'. Rectification over milk of lime, in the manner described, results, therefore, in the production of an oil of excellent quality. At the same time it is pointed out that the rectified oil when stored in the customary way is subject to rapid resinification.—H. T. P.

*Fennel, Commercial Varieties and their Essential Oils.*  
J. C. Umney. Pharm. J. 1897, 54, 225.

THE chief chemical and physical differences of the oils of various commercial varieties of fennel fruits are tabulated as follows:—

Source.	Percent- age Yield of Oil.	Optional Rotation 100 mm.	M. Pt. after Solidify- ing.	Sp. Gr.	Per Cent. of Fene- chone.
French sweet fennel	2.10	+ 16° 0	12° 5	0.976	None.
French bitter fennel	+	+ 16° 5	11° 7	0.980	+
Persian.....	1.70	+ 14° 0	11° 2	0.977	3.4
Indian.....	0.72	+ 21° 0	8° 2	0.968	6.7
Japanese.....	2.70	+ 15° 5	10° 0	0.975	10.2
Galician.....	4.40	+ 20° 0	6° 2	0.965	18.1
Russian.....	4.80	+ 23° 0	4° 4	0.967	18.2
Saxon.....	4.70	+ 22° 0	6° 1	0.974	22.5

The author finally giving it as his opinion that the Russian, Roumanian, Galician, Japanese, and Saxon varieties of the fruit, are best adapted for pharmaceutical use, with a preference for the last-named. The Indian fruits, which have been considerably used in this country, are thus shown to be of little value, owing to their richness in oil and the presence of fenchone in their oils.—J. O. B.

*Peppermint Oil, Occurrence of Sulphur Compounds in American.* C. Kleber. Pharm. Rev. 1896, 14, 269.

THE author conclusively proves that methyl sulphide is an ever-present constituent of American oil of peppermint. It may be detected by distilling about 50 c.c. of the oil, an efficient condenser being used, until a few drops have passed over. The distillate, when agitated with mercuric chloride solution, yields a white crystalline precipitate. Other sulphur compounds besides methyl sulphide are probably present; for during the rectification of crude peppermint oil, a penetrating disagreeable odour may, after a time, be noticed, resembling that produced when organic sulphur compounds are decomposed by heat.—H. T. P.

*Commarin, Purification of.* E. Claassen. Pharm. Rev. 15, 28; and Pharm. J. 1897, 58, 161.

CRUDE commarin is placed in a capacious copper distilling vessel or a good Bohemian flask, petroleum spirit of low specific gravity added, and the liquid boiled for 5 or 10 minutes, the still being fitted with a reflux condenser. The liquid is then poured into a warm bottle, and on cooling, crystals of commarin separate. The crude commarin is again treated with petroleum spirit, and the process repeated until it is exhausted. Any commarin remaining in the spirit may be removed by shaking out with 5 per cent. sodium hydrate solution, and subsequently precipitating with hydrochloric acid.—A. S.

*Bromphenacetine.* O. Hodurek. Ber. 1897, 477—480.

THE Fabrik vorm. Hofmann and Schoetensack prepare bromphenacetine in the following manner:—To a solution of 100 grms. of phenacetine in 1 litre of glacial acetic acid, 250 c.c. of strong hydrochloric acid are added, and then gradually a solution of bromine in hot caustic soda until a permanent bromine reaction is obtained. On dilution with an equal volume of water the greater part of the bromphenacetine separates. Heated with concentrated hydrochloric acid bromphenacetine is converted into the hydrochloride of *o*-brom-*p*-phenetidine—

Heated with acetic anhydride, it is converted into the diacetyl compound  $C_6H_3(OC_2H_5)_2.Br.N(C_2H_5O)_2$ —A. C. W.

*Guaiacum Resin.* J. Herzog and F. Schiff. Ber. 30, 378—380.

THE formula of the acid of this resin according to the authors, is  $C_{18}H_{18}(OCH_3)_2(OH)_2$ , whilst Doebner and Luecker only admit the presence of one hydroxyl group (Ber. 28, 866).—A. C. W.

*Spanish Lavender, Essence of.* E. Charbot. *Bull. Soc. Chim.* 1897, 17, [6], 378—380.

The following are the results of the examination of samples of essential oil of Spanish lavender prepared in 1895 and 1896:—

	1895.	1896.
Density at 15° C. ....	0.916	0.912
Rotation (100 mm.) ....	+ 16° 25'	+ 13° 20'
Esters, calculated as $C_{15}H_{17}O$ . CO. $C_{11}H_{15}$ .....	3.15 per cent.	3.4 per cent.
Free alcohol, calculated as $C_{10}H_{17}$ . OH .....	44.5 "	50.5 "

French oil of lavender is levorotatory and contains 35—40 per cent. of linalyl acetate.

After a series of fractionations, the author has separated borneol from the oil, this appears to be the principal alcoholic constituent.—A. C. W.

*Chloral, Industrial Preparation of.* A. Trillat. *J. Pharm. Chim.* 1897, 5, 218—222.

The process is divided into three stages—preparation of chloral alcoholate, conversion of this into chloral, and formation of the hydrate.

**Chloral Alcoholate.**—In a large glass balloon 60 kilos. of alcohol, as completely dehydrated as possible, are subjected to the action of a current of chlorine, the escaping hydrochloric acid being absorbed by water. The introduction of the chlorine lasts a considerable time—in some works 10—14 days. At first the flask must be cooled; if the temperature be not properly regulated the yield is much reduced. After a time the action becomes less violent; the mixture is then warmed to 60° C., and finally to 100° C. When the liquid is completely soluble in water, the current of chlorine is stopped, and, on cooling, a white mass of the alcoholate is obtained. In this operation, Springmühl recommends the use of 1 per cent. of iodine as a chlorine carrier; Page recommends an addition of crystallised ferrous chloride. In the former case the ethyl iodide formed is easily recovered.

**Chloral.**—In the ordinary process the chlorinated liquid is not allowed to cool, and is transferred to an enamelled still holding 150—200 kilos., where an equal volume of strong sulphuric acid is added in small quantities. The temperature is raised to boiling, the condensed vapours being returned to the still. During ebullition there is an evolution of hydrochloric acid gas, the cessation of which indicates the termination of the decomposition of the alcoholate. Fractional distillation follows, this ceasing when the thermometer has risen to 100° C. The distillate is again rectified, the portion coming over above 94° C. being pure chloral.

**Chloral Hydrate.**—The chloral is shaken with the theoretical quantity of water, and the product of the reaction at once poured over a smooth surface, when it solidifies; in this state it is sent into commerce.

To obtain crystals, the warm mass (heat is disengaged in the reaction) is mixed with one-third its volume of chloroform, and the mixture let cool in closed vessels; crystallisation is complete in a week. The mother-liquors serve for a second crystallisation. The crystals are dried at the ordinary temperature.

Flackings recommends crystallisation from warm carbon bisulphide; Martius uses benzene.

Other methods which have been described, differ from the preceding in that the chlorinated mixture, after solidification and pressure, is sublimed or distilled with calcium chloride. Chloral hydrate should be free from alcoholate, which has not the same physiological properties; and, warmed with twice its volume of water, it should give a clear solution, free from oily drops and not precipitated by silver nitrate. When carefully heated, it should volatilise completely, and the vapours should not be inflammable. Gently warmed with 3 vols. of strong sulphuric acid, the mixture should remain clear. On warming the hydrate of chloral with potash solution, turbidity is caused through

separation of chloroform; the clear portion is decanted and iodine dissolved in potassium iodide, added. So soon as the liquid begins to turn yellow, it is cooled, when the presence of alcohol, and consequently of chloral alcoholate, is indicated by the formation of a precipitate of iodoform. Chloral hydrate may be quantitatively analysed by determining the amount of soda required to convert it into chloroform.—A. C. W.

*Bismuth Iodogallate, Preparation of.* J. de Pharm. d'Anvers, 52, 326; and *Pharm. J.* 1897, 58, 167.

30.4 GRMS. of subnitrate of bismuth are dissolved in 100 grms. of nitric acid, and to the solution 500 c.c. of warm water are added. To this is added, with constant agitation, a clear solution of 16.6 grms. of potassium iodide and 18.8 grms. of gallic acid in 300 c.c. of distilled water. The precipitate is collected, washed with a saturated solution of gallic acid, and dried.—A. S.

*Hypo-iodous Acid and Hypo-iodites.* R. L. Taylor. *Chem. News*, 1897, 75, 97.

When a little alkali is added to an aqueous solution of iodine, there is practically no iodate formed, 90 to 95 per cent. of the iodine undergoing the reaction expressed by the equation  $2KOI + I_2 = H_2O + KI + KI$ .

The solution bleaches indigo much more rapidly than chlorine or hypochlorites, but does not bleach litmus. It gives a precipitate with cobalt nitrate, which blackens on standing, and an immediate brown precipitate with manganese salts and lead salts. Stronger solutions are obtained by using iodine water containing a little suspended iodine. All the solutions are decomposed completely by boiling for three or four minutes. It is stated that Lunge and Schoch obtained by the action of iodine upon lime in presence of comparatively little water, a bleaching liquid which resisted a boiling temperature for hours, but the author concludes that their observations were only correct so far as they agreed with those of Schönbein.

Free hypo-iodous acid is formed by the action of precipitated mercuric oxide upon iodine water. The filtered (colourless) solution possesses only the feeblest possible bleaching properties, but the addition of a little alkali changes it at once into as strong a bleaching solution as Schönbein's. It was found that 40 to 45 per cent. out of a possible 50 per cent. of the iodine used, existed in the solution as hypo-iodous acid. With iodine water containing a little suspended iodine, a stronger solution is obtained, which soon decomposes, turning brown, owing to the liberation of iodine.—A. S.

*Antipyrine (Dimethylphenylpyrazolone): Its Compounds with Phenols.* G. Patein. *Comptes Rend.* 1897, 124, [5], 233—235.

The conclusions arrived at are:—

1. Monomethylphenylpyrazolone does not combine with phenols or phenolic acids.

2. Since one of the two N atoms existing in the mono- and dimethylpyrazolones, is in each case linked in precisely the same way, the fixation of phenols by antipyrine must be a function of its second N atom.

3. For this reason, Meyer's view, according to which antipyrine is represented as a kind of betain, must be considered untenable, for a compound of this nature could not combine with phenols.—H. T. P.

*Citric Acid, A Synthesis of.* W. T. Laurence. *Proc. Chem. Soc.* 1897, [176], 65–66.

ETHYLIC citrate was obtained synthetically by the condensation of ethylic bromacetate with ethylic oxalylacetate in the presence of zinc, as indicated by the following equations, in which  $\text{Et} = \text{C}_2\text{H}_5$  :—

The yield of ethylic citrate is very poor, owing to other reactions proceeding simultaneously. To further confirm the formation of ethylic citrate, it was converted into the calcium salt of citric acid, and a substance obtained showing the characteristic properties of calcium citrate. The same salt was also obtained by heating the zinc compound formed in equation No. 1 with alcoholic potash and precipitating the calcium citrate from the hot solution.

The results were all confirmed by analysis. The above synthesis of citric acid seems to be of interest as being more direct and simple than the synthesis from sym. dichloroacetone or from ethyl- $\gamma$ -cyanaceto-acetate.

## PATENTS.

*Aceto-Derivatives of the Simpler Aromatic Amines, Process for the Manufacture of.* R. W. James, London. From W. J. Matheson and Co., Ltd., New York, U.S.A. Eng. Pat. 304, Jan. 5, 1897.

INSTEAD of obtaining the acetyl derivatives of aromatic amines, such as aniline, by heating these latter with acetic anhydride or acetic acid, the patentee proposes heating together a salt of the amine, such as the hydrochloride or sulphate, together with a salt of acetic acid. For instance, 129 kilos. of aniline hydrochloride and 82–84 kilos. of sodium acetate are heated for 12–24 hours to 125° C. under an inverted condenser in a vessel provided with an agitator. The melt is then poured into water, when the acetanilide separates out; or this product may be dissolved out by means of methyl alcohol or benzene, which leaves the inorganic salts behind. It is stated that it is desirable to recover by distillation the acetic acid and aniline which were not converted into acetanilide.—T. A. L.

*Hydrocarbons [Camphor Substitute], such as Turpentine or the like, for the Production of Crystalline Substances, and Apparatus for Treating and Manufacturing same; Impts. in the Treatment of.* H. B. McKenna, Stoke Newington, London. Eng. Pat. 3365, Feb. 14, 1896.

By the action of hydrochloric acid gas and air on American turpentine or other suitable hydrocarbon, crystalline substances are produced, which deposit in the apparatus described, and of which a drawing is appended. In order to purify the substance, it is distilled with steam and either pressed into cakes or sublimed like Japanese camphor. The crystals may also be placed in conical vessels, such as are used in sugar refining, and subjected to the operation known as claying, which consists in allowing a saturated solution of the camphor substitute to percolate through the crystals, by which means oil, moisture, or any soluble impurities are removed.—T. A. L.

*Oxygen Gas, Impts. in Apparatus for making.* A. Sweetser, West Dulwich. Eng. Pat. 6408, March 23, 1896 (see also this Journal, 1896, 213).

THE improvements claimed include the introduction of a filter between the generator and outlet pipe or jet, to

prevent clogging; the provision of automatic means for regulating the descent of the generator and the consequent exposure of fresh portions of the charge to the heat of the lamp. The generator and tubes are lined with non-oxidisable material or paint, and the charge may be coated with similar material or enclosed in a cover to ensure regularity of heating. Provision is also made for the sounding of an automatic signal when the charge is exhausted and the reservoir descends below a certain height; also for the opening of a safety valve when it is fully charged (to prevent excess pressure); and for lowering the flame, as the reservoir rises, and *vice versa*.—C. S.

*Amido-1-alkyl-2-alkyl-5-pyrazolones, Manufacture of New Derivatives of.* O. Imray, London. From "The Farbwerke vorm. Meister, Lucius, and Brüning," Höchst a/M., Germany. Eng. Pat. 7709, April 11, 1896.

HITHERTO the only derivative of amido-1-alkyl-2-alkyl-5-pyrazolone known, has been the 4-acetamido-1-phenyl-2-3-dimethylpyrazolone. New derivatives of 4-amido-1-alkyl-2-alkyl-3-methyl-5-pyrazolone and 1-p-amido-phenyl-2-alkyl-3-methyl-5-pyrazolone are obtained by the introduction of alcohol and acid radicles. Thus, 1-p-amido-phenyl-2-alkyl-3-methyl-5-pyrazolone or alkoyl derivatives thereof are obtained by treating the derivatives of 1-p-alkoyl-amidophenyl-3-methyl-5-pyrazolone having the general formula—

with alkyl iodides and subsequently with alkalis. The corresponding amido compounds are then obtained on hydrolysis with acids. All these new alkyl and alkoyl derivatives of amido-1-alkyl-2-alkylpyrazolone are basic compounds forming salts with acids. For example, 1-phenyl-2-3-dimethyl-4-dimethyl-amido-5-pyrazolone is obtained by heating 1 kilo. of 1-phenyl-2-3-dimethyl-4-amido-5-pyrazolone with an equal weight of methyl alcohol and 1.4 kilos. of methyl iodide for 1 hour to 90° C. After evaporating off the methyl alcohol, the base is liberated by an alkali, extracted with benzene, and crystallised from acetic ether and petroleum ether, and melts at 108° C. A number of other alkyl derivatives have been obtained from different 4-amido-1-alkyl-2-alkyl-3-methyl-5-pyrazolones, of which the melting points are given in the specification. By first methylating and subsequently benzoylating 1-phenyl-2-3-dimethyl-4-amido-5-pyrazolone, the 4-benzoyl-methylamido derivative is obtained (m.p. 137° C.). This, on hydrolysis, yields the 4-methylamido derivative, of which the picrate melts at 172° C. When p-acetylamidophenylhydrazine and ethylaceto-acetate (equimolecular weights) are heated in an alcoholic solution, evaporated, and heated to 140°–150° C., the product, on crystallisation from dilute alcohol, gives p-acetamidophenylmethyl pyrazolone melting at 197° C., which differs entirely from the product obtained according to Ger. Pat. 85,883, and has a different formula and constitution. The new product, when formed in an aqueous solution in presence of an acid, gives in addition the ethyl ether, which when anhydrous, melts at 132° C. The acetyl ether obtained by boiling with acetic anhydride or by shaking with acetic anhydride in presence of soda lye, crystallises in yellow laminae, and melts at 161° C. By heating the ethylacetyl ether of 1-p-acetamido-phenyl-3-methyl-5-pyrazolone with methyl iodide in benzene solution, iodides of ammonium bases are formed, which, by the action of acids or alkalis, yield 1-p-acetyl-amido-2-3-dimethyl-5-pyrazolone. This compound, when heated on the water-bath with an excess of concentrated hydrochloric acid, is hydrolysed, and on subsequent neutralisation gives p-amidophenyl-2-3-dimethyl-5-pyrazolone, which is easily soluble in water, alcohol, and chloroform, but sparingly soluble in benzene; it melts at 210° C. It differs from the similar acetyl derivative in not giving a green nitroso compound with nitrous acid. The dimethyl derivative melts at 135° C., the benzoyl compound at 225° C., and the urethane at 196° C.

—T. A. L.

*Oxy-phenoxacetic Acids, A New or Improved Process for Manufacturing.* L. Lederer, Munich, Germany. Eng. Pat. 28,968, Dec. 17, 1896.

THE method consists in reacting with hydrochloric or hydrobromic acid on alkoxylated phenoxacetic acids. Thus, 1 part of guaiacacetic acid is heated for several hours with 3 parts of concentrated hydrochloric acid, under pressure, to 100° C. On cooling, hydroxyphenoxacetic acid (pyrocatecholacetic acid) crystallises from the solution. It forms plates which melt at 139° C., and is converted on distillation into its anhydride, which melts at 58° C. The aqueous solution gives a dark blue colour with ferric chloride. The oxyphenoxacetic acids are said to possess "excellent curative properties."—T. A. L.

### PATENTS.

*Tetranitro Cellulose (Collodion Pyroxilin), Manufacture of Solutions of.* E. Bronaert and T. Schlumberger, Mulhouse, Alsatia. Eng. Pat. 1858, March 28, 1896.

ALTHOUGH tetranitro cellulose is insoluble in strong ethyl alcohol, it becomes soluble as shown by Eder (Ber. 1880, 13, 184) when small quantities of certain organic and inorganic acids and their ethers or salts are dissolved in the alcohol. The patentees prepare a solution of tetranitro cellulose by dissolving it in alcohol containing the following substances:—Free oxalic, citric, tartaric, lactic or levulinic acids; the salts of these acids, or of hydrochloric or alkylsulphuric acid with the alkalis, alkaline earths, &c.; also the ethers of these acids. The danger of drying tetranitrocellulose may be avoided by treating the wetted material with a solution of calcium chloride, followed by pressing and drying and solution in alcohol as above described.—J. L. B.

*Photographic Prints, Impts. in Chemical Compositions for Preparing the Surface of Suitable Material for.* E. P. Schoenfelder and E. Kehle, Newark, Essex, New Jersey, U.S.A. Eng. Pat. 15,852, July 17, 1896.

COLLODION is prepared by dissolving 300 grains of pyroxilin in 1 lb. of ether and 1 lb. of absolute alcohol. Of this collodion, 1½ oz. are thoroughly mixed with the following:—10 drops of a solution containing 15 grains of chloride of gold, platinum, or allied metal in 1½ oz. of alcohol (40 per cent.); 3 grains of an organic, e.g., citric, acid in 3 drops of alcohol; 15 grains of silver nitrate in 50 drops of alcohol; 1½ grains of a chloride, e.g., strontium chloride, in 3 drops of alcohol; 2 drops of a softening chemical, e.g., glycerin or castor oil; enough ammonia; 2 to 5 drops of gold bromide. This emulsion applied to the surface of any suitable material leaves a sensitive film, and photographs printed upon the film, when fixed with "hypo," do not require toning, as the latter effect is produced simultaneously with the printing.—L. A.

## XXII.—EXPLOSIVES, MATCHES, Etc.

### PATENT.

*Explosive Compounds, Impts. in.* A. V. Newton, London. From A. Nobel, Paris. Eng. Pat. 6431, March 23, 1896.

THE object of the invention is to produce an explosive compound which will not act too violently on coal to be blasted, but cause a rending instead of a shattering action. The new powder is a kind of gunpowder, in which charcoal is replaced by a combustible giving a greater body of gas on explosion, and at a lower temperature, so as to be less liable to ignite any firedamp that may be present. Dextrin may be used in the substitution, and inert substances may be added, such as alum or sodium bicarbonate; or combustibles or oxidisers, in excess of their "chemical combustion proportions." A powder may be made by

mixing and granulating 100 parts of potassium nitrate, 12 parts of sulphur, 75 parts of dextrin, and 40 parts of sodium bicarbonate. When a powder is wanted to be fired by detonative ignition, it may be made from 60 parts of potassium chlorate, 40 parts of dextrin, and 50 parts of sodium bicarbonate, granulated.

High explosives, such as picric acid or picrates, or ballistite, may also be incorporated with combustibles in excess, or with inert substances, and granulated.—E. S.

## XXIII.—ANALYTICAL CHEMISTRY.

### APPARATUS, ETC.

† *Filter Pump, A New.* J. Wetzel. Ber. 1897, 537.

In this pump the tube widens after the first constriction and then narrows, as is shown in Fig. 1. The water thus twice

Fig. 1.

Fig. 2.

exerts its action. The current must be so regulated that the bulb between the two constrictions does not become filled with water. Using water at 5° C., a vessel of 3 litre capacity was evacuated down to a pressure of 7 mm. of mercury, in about one-third of the time and with the use of about one-third of the water required to produce the same effect with a pump of the old form. Fig. 2 shows the pump as constructed for evacuation and delivery of compressed air.—A. C. W.

*Filter Paper, Acidity of.* Magnier de la Source. Ann. de Chim. Analyt. 1897, 2, 82.

ORDINARY white filter paper is found to be very faintly alkaline. A paper 12 cm. in diameter was found to neutralise 0.0015 grm. of H<sub>2</sub>SO<sub>4</sub>. This, however, is not due to the combination of the acid with the cellulose, as stated by Ganz (Zeits. für angew. Chem. 1889, 669), but to traces of earthy impurities. French Berzelius paper is perfectly neutral. The Berzelius paper of Schleicher and Schüll, which has been extracted by hydrochloric and hydrofluoric acid, has a distinct acid reaction, equivalent for a 12-cm. paper to 0.0014 grm. H<sub>2</sub>SO<sub>4</sub>. Some Swedish Berzelius paper, 50 years old, had an acidity equivalent to 0.0003 grm. The same paper washed with very dilute HCl, and then with distilled water until the apparent removal of all trace of acid, washing being continued for 25 days, and the washed paper being dried over caustic potash, gave a decided acid reaction, equivalent to 0.0008 grm. of H<sub>2</sub>SO<sub>4</sub> per filter; even after prolonged treatment with boiling water it gave an indication of acidity up to 0.0002 grm. It is thus evident that acid-washed paper always retains a trace of acid. The matter is of some importance in certain acidimetric operations, such as the determination of potassium bitartrate or other acid salts with a relatively high molecular weight.

—J. O. B.

*Steam-Distillation, Some Apparatus for.* F. E. Matthews.  
Proc. Chem. Soc. 1897, [174], 18—19.

In this paper several forms of apparatus for automatically distilling substances by steam are described.

Some solids of high melting point may be separated by boiling the substance mixed with water in a flask fitted

Fig. 1.

Fig. 2.

with a reflux condenser; the solid substance adheres to the inside of the condenser, whence it can be removed from time to time.

For liquids heavier than water, the flask in which the mixture is boiled is connected with the side tube of an ordinary distilling flask (see Fig. 1); this distilling flask, filled with water up to the side tube, serves as the receiver. Into the neck of the receiver, and passing below the surface of the water, a bent Liebig's condenser is fitted, which has the peculiarity of having a hole made in it a short distance above the level of the water in the receiver. On boiling the mixture in the flask, the vapours pass up the side tube of the receiver into the upper portion of its neck, and thence through the hole into the receiver, when condensation takes place. The condensed liquids run down the condenser to the water level in the receiver, where a drop of the heavy fluid sufficiently large to sink, is formed from time to time. The condensed liquids displace their own volume of water, which flows from the receiver through the side tube back again to the boiling-flask. In all cases in which vapour is passing in one direction in a tube, and water in the other, the advantage of perforating the tube near its lower end is pointed out.

For liquids lighter than water, the apparatus (see Fig. 2) consists of the boiling-flask, which is an ordinary distilling-flask; this is connected by the upper opening to an upright tube furnished with a T-piece. The top of the upright tube is connected to the condenser; the lower end dips two or three inches into a Woulff's bottle, containing water in sufficient quantity, which serves as the receiver. Through another neck of the Woulff's bottle, a second tube passes from the bottom of the bottle and is connected to the side tube of the boiling-flask. The mixed vapours pass from the boiling-flask into the upright T-tube, thence into the condenser; there becoming condensed, they fall down into the T-tube, producing a column of liquid which forces water from the bottom of the receiver back into the boiling-flask through its side tube.

Fig. 3.

A modification of this apparatus (see Fig. 3) dispenses with the necessity of having an india-rubber connection exposed to the hot vapour. In this modification the boiling flask is an ordinary plain flask. This is connected to the condenser by a side tube blown on to the upright tube. The water returns to the boiling flask through another T-tube, blown on to the side tube of the upright tube. For conveniently emptying the receiver without dismantling the apparatus, a separating funnel with two necks may replace the Woulff's bottle of the previous apparatus.

Many liquids bump badly when boiled with water; this can generally be avoided by introducing a zinc-platinum couple into the boiling-flask. The temperature of the water in the boiling-flask may be raised by dissolving suitable substances, such as sulphuric acid or calcium chloride in it, or liquids of higher boiling point may be used.

—A. S.

*Note on a Method for Determining Melting Points.*  
E. H. Cook. *Proc. Chem. Soc.* 1897, [177], 74-76.

NOTWITHSTANDING the theoretical simplicity of taking a melting point, it is surprising that in commercial work considerable differences frequently occur between analysts when reporting upon such a substance, for example, as paraffin scale. Probably most, if not all, of these differences are caused by the different methods employed. Thus it is well known that the "English test," which consists in allowing the wax to solidify in a test-tube in which the thermometer is placed, gives results from  $2\frac{1}{2}^{\circ}$  to  $3^{\circ}$  F. lower than the "American test," in which the wax is melted in an open dish. Both these methods again differ slightly from the capillary-tube plan, and in this process a different result is obtained when an open tube is used than when it is closed. There are, in fact, many precautions which are necessary to be observed if concordant results are to be obtained, and it is much to be desired that some distinct and definite regulations should be made with reference to the matter.

The apparatus employed is a beaker filled to the brim with water; inside this, and separated from it on all sides, is a smaller one. The smaller beaker is partly filled with mercury, in which is placed a thermometer. A stirrer is used to keep the water in the large beaker of uniform temperature. A cardboard or other disc, covers the smaller beaker when the operation is in progress. The whole is heated from below by means of a sand bath. When the melting point to be determined is under  $30^{\circ}$ , it is better to replace the sand bath by an evaporating dish containing water.

The process is conducted as follows:—The material the melting point of which is to be taken, is placed on three or four small pieces of thin ferrotype plate or other thin metallic sheet, or on the cover glasses which are used for microscope slides. If ferrotype or other metallic slips are used, care must be taken to remove the varnish or other coating in order that good metallic contact can be had with the mercury. The slips, with the substance on them, are now placed on the surface of the mercury and the heat applied until the substance melts. The solidifying point is obtained by raising the temperature above the melting point and allowing the beaker to cool, noting the thermometer when the first solidification takes place.

For temperatures between  $100^{\circ}$  and  $200^{\circ}$ , the larger beaker is filled with paraffin wax.

The following precautions have been found to be necessary:—(1.) The temperature must be made to rise very slowly. (2.) The liquid in the outer beaker must be frequently stirred. (3.) Not less than 2.5 cm. in depth of mercury must cover the inner beaker. (4.) Sufficient volume of water must be allowed between the two beakers. The minimum distances to give good results are 1 in. between them laterally and  $1\frac{1}{2}$  in. at the bottom. (5.) The inner beaker must be immersed a sufficient depth in the water. This point is of great importance, the least distance between the top of the mercury and the top of the water being 3 in. A greater distance is, however, to be preferred. (6.) The whole apparatus should be protected from draughts. (7.) The disc should be kept on the smaller beaker during the determination.

### INORGANIC CHEMISTRY.— QUANTITATIVE.

*Barium Thiosulphate for Standardising Solutions in Iodometry, Alkalimetry, and Acidimetry.* M. Mutnianski. *Zeits. anal. Chem.* 36, 220-221.

Barium thiosulphate is made by mixing hot highly concentrated solutions of 50 parts of sodium thiosulphate and 40 parts of barium chloride. The precipitate which forms is washed, first with lukewarm water, next with cold water, then with 95 per cent. alcohol, and finally with ether. It is then dried at the ordinary temperature on blotting-paper, and is ready for use; 266.7 parts of the salt are equivalent to 126.54 parts of iodine.

Its convenience for standardising iodine solutions depends upon the fact that an aqueous solution saturated at  $17.5^{\circ}$  C. forms a  $\frac{1}{100}$  normal solution exactly. Such a solution deposits

none of the salt on standing for some days at  $15^{\circ}$  C., although of course at lower temperatures its strength is altered. It is very quickly made by adding an excess of the barium thiosulphate to a quantity of water unaltered exactly at  $17.5^{\circ}$  C., shaking for a quarter of an hour, and then filtering from the undissolved excess of the salt. It may also be used to standardise normal acid solutions (hydrochloric and sulphuric), and hence also for controlling normal alkali solutions. The equations which indicate its application to this purpose are—

The liberated iodine is determined by titrating with the  $\frac{1}{100}$  normal solution of barium thiosulphate, using starch as indicator, and the strength of the acid is calculated therefrom.—H. S. P.

*Thoria in Thorite, Estimation of.* E. Hintz and H. Weber. *Zeits. Anal. Chem.* 36, [1], 27-31.

DECOMPOSE 1 grm. of the thorite with concentrated HCl, evaporate to dryness, take up with 2 c.c. of HCl and water, filter off silica, and pass  $\text{H}_2\text{S}$  to remove Cu and Pb. If any precipitate obtained will not filter off clear, add a few drops of copper chloride solution, when the increased precipitate will filter perfectly. Expel  $\text{H}_2\text{S}$  by boiling, dilute to 200 c.c., and precipitate hot with 1 grm. of oxalic acid in solution. After two days' standing, filter, wash with water, and digest the precipitate several hours on the water bath with 60 c.c. of cold saturated ammonium oxalate solution. Dilute to 300 c.c., allow to stand two days in the cold, filter, and wash with water containing a little oxalate; heat the filtrate and add 5 c.c. of concentrated HCl. The residue which was insoluble in the ammonium oxalate should be digested a second, third, and even a fourth time with 20 c.c. of that reagent; filtered, and the filtrate acidified as above. After two days, filter off the thorium oxalate precipitated by the HCl, wash with acidified water, ignite, and weigh. As the precipitate always contains some cerium and yttrium oxides, dissolve by boiling with HCl; or fuse with  $\text{KHSO}_4$ , dissolve, precipitate with ammonia, filter and dissolve the hydrate in HCl. Evaporate to dryness, dissolve in water and a drop or two of HCl, dilute to 300 c.c. and boil for a few minutes with 3 to 4 grms. of sodium thiosulphate. Cool, filter, and add ammonia; filter, dissolve hydrates in HCl, evaporate to dryness, take up with a little water and precipitate boiling with concentrated solution of ammonium oxalate. Dilute and allow to stand some time in the cold, filter off the cerium and yttrium oxalates, ignite, weigh, and deduct from the weight obtained above to find the weight of pure  $\text{ThO}_2$ .

When the thorite is very impure, the repeated extraction of the oxalate precipitate with ammonium oxalate solution is insufficient. In that case ignite the insoluble residue and dissolve with concentrated HCl; or fuse, precipitate hydrates and dissolve the washed precipitate in HCl. Evaporate to dryness, take up with a few drops of weak HCl, dilute to 100 c.c., and precipitate boiling with thiosulphate. Dissolve the precipitate in HCl, drive off excess of acid by evaporation, precipitate with oxalic acid, and add this precipitate to the main  $\text{ThO}_2$  precipitate. As the thiosulphate precipitation is not always complete, add ammonia to the filtrate obtained from it, dissolve the hydrates in HCl, evaporate to dryness, take up with water and precipitate boiling with concentrated ammonium oxalate. Dilute, allow to stand 24 hours, filter and precipitate the remainder of the  $\text{ThO}_2$  with ammonia, adding this also to the main thorium precipitate.

The authors have examined the reactions upon which the scheme is based. They find that the precipitation of thorium in slightly acid solution by oxalic acid is practically perfect, cerous salts behaving similarly. With regard to the solubility of thorium oxalate in ammonium oxalate, C. Glaser has stated (this Journal, 1896, 675) that "ammonium oxalate precipitates thorium, the precipitate is soluble in excess on boiling, but re-precipitates on cooling." The authors' experiments show (1) that precipitated thorium oxalate is perfectly soluble in hot concentrated ammonium oxalate, the solution remaining clear after dilution and two days' standing; (2) that addition of hot, concentrated ammonium oxalate solution to thorium solution containing a little free

acid gives a clear solution which remains so on dilution and cooling even after standing several days; (3) that if one neutralises considerably a thorium solution, containing free acid, by ammonia, on adding concentrated ammonium oxalate to the hot solution it remains clear, but on standing for 12 hours it becomes opalescent and deposits some precipitate; but the most of the thorium oxalate remains dissolved. Only conditions (1) and (2) arise in the above scheme. The authors find the precipitation of thorium from its ammonium oxalate solution by means of HCl or ammonia is practically complete, and is more convenient than the more correct method of evaporating, expelling the ammonium oxalate by ignition, &c.—H. B.

*Liquefied Ammonia, Testing Commercial.* H. Bunte and P. Eitner. J. für Gasbeleucht. 1897, 40, 174—175.

Owing to incorrect analyses, the impression has prevailed latterly that the liquefied ammonia sold in iron cylinders contains considerable quantities of water. Such could hardly be the case, as the gas, before compression, is thoroughly dried with caustic lime. The difficulties of testing liquefied ammonia were overcome in the following method:—A pipette of about 75 c.c. capacity, having a stop-cock on each stem, and at one end a smoothly-faced collar, was weighed. The cylinder containing the ammonia was placed valve lowermost, and to the outlet was attached by a union-joint a brass tube, the free end of which had a collar, on which was a leather washer, against which the collar of the pipette was firmly held by means of a detachable screw-clamp. Air was expelled from the pipette; the outer cock was then closed and the pipette two-thirds filled with the liquid ammonia, and the inner cock was then closed. The pipette was detached from the cylinder, and weighed, to ascertain the amount of ammonia taken. It was then placed upright, and the upper end connected to the first of a series of three weighed drying tubes packed with lumps of caustic potash. The outlet of the last drying tube dipped under mercury. By careful opening of the upper stop-cock of the pipette, the ammonia was allowed to slowly vaporise through the drying-tubes and mercury-seal. At the end of this evaporation, some drops of brown liquid remained in the pipette. The free end of the latter was attached to a caustic potash exsiccating apparatus, and when the coating of ice had gone from its exterior, the pipette was placed horizontally in an air-bath at 70°–80°, and a stream of dry air drawn through it for some time. Thus the volatile organic compounds and the water were collected in the weighed potash tubes, and a trace of brown organic substance, insoluble in ether and alcohol, but soluble in nitric acid and liquid ammonia, remained in the pipette. The impurities found in one analysis were:—

	Per Cent.
High-boiling organic substances left in the pipette...	0.08
Volatile substances resembling alcohol and water ...	0.41

—J. A. B.

*Perchlorate, Estimation of, in Saltpetre.* F. Winteler. Chem. Zeit. 21, (1897), 75. (See also this Journal, 1897, 163.)

THE methods for the estimation of perchlorate, which depend on the conversion of this, by heating, into chloride, are liable to error from three causes, and these errors may become serious when only small quantities of perchlorate are present. The errors which may be introduced are due, firstly, to volatilisation of unchanged perchlorate or of its resultant chloride; secondly, evolution of chlorine by the interaction of chloride and perchlorate; and thirdly, loss of chlorine due to the action of NO (arising when nitric acid is used to decompose accompanying chloride) on the perchlorate.

The author finds that the following method avoids these losses and leads to satisfactory results. The method, which depends on the observation that fuming nitric acid and its decomposition products quantitatively reduce perchlorates (and chlorates) by heating to a temperature of over 200° C. under pressure, is carried out by heating a given weight of the sample, together with an excess of silver nitrate and 10 c.c. of fuming nitric acid for 5 hours in a sealed tube at a temperature of 230° C., and weighing the resulting silver chloride. The author gives some analyses, made with

pure potassium chlorate and perchlorate, to show the accuracy of the method, and also an analysis of a sample of potassium nitrate. 10 grms. of this sample yielded 0.0282 gm. of AgCl, equivalent to 0.27 per cent. of KClO<sub>4</sub>. (The solution of this nitrate remained colourless after the addition of concentrated sulphuric acid and gave no precipitate with silver nitrate, i.e., all chlorine was present as perchlorate). Chlorides, if present, are decomposed, according to Erek, by boiling with nitric acid (sp. gr. 1.14) and alcohol, whilst chlorates may be removed from a mixture of chlorate and perchlorate by evaporation with concentrated hydrochloric acid.—J. T. C.

*Antimonio-Tungstates, and the Separation of Tungsten and Antimony.* L. A. Hallopeau. Bull. Soc. Chim. 1897, 17, 170—175.

ANTIMONIC hydrate, prepared by precipitating potassium bimetantimonate with hydrochloric acid, dissolves in a boiling solution of potassium paratungstate,

the filtered solution deposits potassium antimoniotungstate  $3K_2O \cdot 4WO_3 \cdot 3Sb_2O_5 \cdot 16H_2O$  or  $3KSbO_3 \cdot 2WO_3 \cdot 8H_2O$ .

The salt may be purified by recrystallisation, it is unaltered in air and loses 6H<sub>2</sub>O at 100° C., and calcination decomposes it into potassium tungstate, acid antimonate, and tungstic acid. The metallic salts give insoluble precipitates; from the silver salt by the action of hydrochloric acid and evaporation *in vacuo*, there is obtained a clear vitreous mass,  $4WO_3 \cdot 3Sb_2O_5 \cdot 3H_2O + 8H_2O$ , which does not lose water at 100° C.

The analysis of the compounds was effected by precipitating with mercurous nitrate, the mercury salt was filtered off, and the base determined as sulphate in the filtrate. The mixture of tungstic acid and antimony tetroxide formed by ignition of the mercury salt, was fused with a large excess of potassium cyanide (12 parts) in a porcelain crucible, according to the method given by Talbot (Chem. News, 22, 229) for the separation of tin and tungsten. The fused mass was taken up with water, the metallic antimony collected on a tared filter, washed with water, finally with weak alcohol, and dried at 100°. The sodium or potassium sulphate, after weighing, should be fused with potassium cyanide; a small quantity of antimony is sometimes thus recovered. If, after the fusion, a small quantity of antimony adheres to the crucible and cannot be removed, the crucible is washed, dried, and weighed, a small quantity of ammonium chloride added, and, by heating to redness, the antimony is completely volatilised; the loss in weight represents the adherent metal. Results by this process are said by the author to agree exactly with determinations by precipitating as sulphide and converting into the tetroxide. The conversion of the metallic antimony into tetroxide is tedious; even by repeated treatment with fuming nitric acid the filter paper is not completely destroyed; in order, then, to prevent loss of antimony on ignition, ammonium bisulphate is added and the crucible slowly raised to a red heat.

It was not found possible to separate antimonious oxide and tungstic acid by fusion with caustic soda in a silver dish, on taking up with weak alcohol a certain quantity of sodium antimoniate always dissolving in the alkaline tungstate solution.—A. C. W.

*Potassium, Estimation of: A Simplification of the Schweitzer-Lungwitz Method.* Adolf Mayer. Zeits. anal. Chem. 1897, 36, [3], 159—163.

IN the Schweitzer-Lungwitz method of determining potassium in manures, &c., the sulphates are precipitated by means of a solution of barium oxalate in hydrochloric acid, any iron present oxidised with hydrogen peroxide, and ammonia added to alkaline reaction, so as to simultaneously precipitate the alkaline earths as oxalates, and iron and aluminium as hydrates. The author's objection to this is, that owing to the small solubility of barium oxalate in hydrochloric acid in the cold (1.7 per cent.), more than 800 c.c. of the solution must be added when, as in the case of superphosphates, 15 grms. of barium oxalate are required.

In the following modification (which was taken into consideration and rejected by Schweitzer and Lungwitz), the hydrochloric acid solution of barium oxalate is replaced by

barium chloride and oxalic acid. Twenty grms. of the substance under examination are boiled for 30 minutes with water, cooled, made up to 500 c.c. and filtered. Fifty c.c. of the filtrate are warmed and normal solution of barium chloride added from a burette so long as a precipitate results.

An amount of normal oxalic acid equivalent to that of the barium chloride used is then added, the liquid boiled for 20 minutes, and made alkaline with ammonium. On cooling, it is made up to 100 c.c., allowed to settle, and filtered. Fifty c.c. of the filtrate are evaporated in a platinum basin and the residue ignited at as low a temperature as possible, in order to expel the ammoniacal salts. The ignited residue is dissolved in water, the solution filtered and the potassium precipitated by adding 10 c.c. of platinum chloride solution (containing 1 gm. of platinum and which is free from hydrochloric and nitric acids) and evaporating nearly to dryness; when cold, alcohol (80 per cent.) is added, and after standing for some time the precipitate is filtered off and dried at 120° C. The results obtained with this method agreed closely with those found by the ordinary method of estimating potassium. It is necessary, however, to boil the liquid for not less than 20 minutes after adding the oxalic acid, since with less boiling, the results are too low.

—C. A. M.

*Aluminium and its Alloys, Analysis of.* F. Jean. Rev. Chim. Industr. 8, 5—8.

The influence on the physical properties of aluminium, exerted by the presence of various metals and metalloids renders the careful analysis of this metal and its alloys a matter of importance, and though Moissan (this Journal, 1896, 136) and Gouthière (this Journal, 1896, 230) have published complete methods, the author considers the subject as by no means exhausted. The method pursued by him consists in the first place in carefully attacking 10 grms. of aluminium borings by 10 per cent. hydrochloric acid in a flask and absorbing the evolved gases by bromine water in a Will and Varrentrapp bulb tube. When reaction has finally ceased, the bromine liquor—containing the sulphur, phosphorus, and arsenic of the substance,—is evaporated to drive off the bromine, and the sulphur is determined from the precipitate produced by barium nitrate. Arsenic is thrown down from the filtrate by  $H_2S$ , and weighed as arsenic acid after drying, treating with fuming nitric acid, and calcining. The residue is taken up with water and any insoluble antimonious acid is calcined, weighed, and deducted from the weight previously obtained. This allows the arsenic and antimony to be calculated.

The filtrate from the arsenical precipitate is freed from hydrogen sulphide by heat and treated with 5 c.c. of nitric acid and 10 c.c. of concentrated ammonium nitrate, for the determination of phosphoric acid by the Pemberton method.

The hydrochloric acid solution of the metal is diluted and passed warm through a tared filter, and the residue, after washing with boiling water, is weighed and dried, the loss in weight on calcination indicating carbon. The remaining residue is fused with potassium and sodium carbonates and potassium nitrate; taken up with water; the solution acidified with HCl, and evaporated and calcined to estimate silica. The insoluble portion is calcined, dissolved in aq. regia and united to the original solution, which is then saturated with hydrogen sulphide to throw down the insoluble sulphides. In the absence of tin and antimony, the precipitate is dried, calcined, treated with nitric acid and a few drops of sulphuric acid and diluted with water and alcohol, the lead being determined as sulphate, and the copper thrown down by sodium hydroxide. When tin or antimony is present, yellow ammonium sulphide is added to the mixed sulphides and the soluble sulphides are determined in the ordinary way.

A colourless filtrate from the hydrogen sulphide reaction indicates absence of nickel and chromium, in which case the liquid is concentrated to 100 c.c. and silica estimated from one-half this quantity, by evaporation in presence of potassium chlorate. It is always advisable to fuse the silica with alkali carbonates, and separate anew, to ensure the absence of alumina. Iron is determined from the same solution, after the removal of silica, by adding 25 to 30 c.c. of HCl, and titrating with stannous chloride.

The second 50 c.c. are reserved for estimating zinc and manganose, to which end the liquid is made strongly alkaline with soda and boiled to dissolve the alumina, the manganese being thrown down by bromine, and the zinc titrated with sodium sulphide.

When chromium is present it is determined, in company with iron, in a separate portion of substance, 1 gm. of which is attacked by caustic soda assisted by heat until the evolution of hydrogen ceases. The liquid is then evaporated and fused with potassium nitrate and sodium bicarbonate, taken up with water and filtered, the insoluble oxides being dissolved in dilute sulphuric acid; and, after reduction of the solution by zinc, the iron is determined by titration. Chromium is then estimated colorimetrically from the same solution made up to 50 c.c., standard solutions of potassium chromate being employed for comparison.

Nitrogen, which is said to be present in some samples of the metal, is estimated by acting on 10 grms. with caustic soda solution of 36° B., passing the evolved hydrogen through 10 c.c. of decinormal acid in a Schloesing nitrogen apparatus, and determining the ammonia by titration with alkali of equal standard.

For sodium, Moissan's method is the most convenient, modified by converting the sodium nitrate formed into sulphate, digesting with concentrated ammonium carbonate, and, after calcination and treatment with 10 c.c. of barium hydrate solution, re-evaporating to dryness with more ammonium carbonate, and re-dissolving in boiling water—titrating the sodium as carbonate by the aid of decinormal acid. This modification prevents error arising from the incomplete insolubility of aluminium, &c. during the calcination of the nitrate. Any alkali contained in the barium hydroxide must be ascertained and deducted from the total obtained.—C. S.

*Copper; Analysis, Quantitative, of Commercial.*

E. Murman. Monatsh. f. Chem. 1896, 17, 697—731.

*Estimation of Copper as Sub-Sulphide.*—The introduction of a small proportion of hydrogen sulphide in the hydrogen used during the ignition of the copper sulphide was found to give more latitude both as to the time and temperature required. But in this case the crucible must be heated to a bright red throughout, or the results will be considerably too high; they will always be higher than those with pure hydrogen. The use of either pure hydrogen sulphide, carbon dioxide, or carbon monoxide, in place of hydrogen, also gives high results. It is therefore best to heat the sulphide in pure hydrogen for from 10 to 15 minutes in such a way that the crucible is surrounded by the flame, and to repeat the heating until the weight is constant, adding only a very small fragment of sulphur before re-igniting, and taking care that the mass is raised uniformly to a dull red-heat. Analyses made in this way gave numbers ranging from 99.996 to 100.023 per cent. The precipitated copper sulphide is apt to contain traces of alkali, lime, and silica, especially if it should have been treated with an alkaline sulphide to remove antimony and arsenic. 3 mgrms. of alkali have thus been separated from 2.5 grms. of sulphide. It may be completely removed by heating the sulphide precipitate in the funnel in an air-bath, and then washing it with hydrogen sulphide water, prior to drying and igniting as usual. The lime, which is derived from the containing vessel, is not so easily removed; but it causes only a very minute error. The silica must be separated, after weighing, by treating the precipitate with nitric acid. A little iron and nickel may also be present, and it is preferable to adopt Hampe's thiocyanate method for the separation of the bulk of the copper (see this Journal 1894, 13, 421).

*Estimation of Total Oxygen.*—The author prepares the sample, if of copper plate, by cutting it into pieces 6—8 mm. square, or if in fragments, by shearing it into pieces 4—6 mm. in diameter, and 10—20 mm. long. The sample is next treated with benzene or chloroform to remove fat, and dried on a towel, which is then sprinkled with sea-sand, and rubbed over the copper until the surface of the metal is perfectly bright (about 2—3 minutes). The sand is then thrown away, and a fresh quantity is

applied in the same way; this is finally removed and the copper is weighed immediately. Larger fragments may be cleaned by filing before applying the solvent for the grease. The pieces are then heated in hydrogen in a bulb tube, or preferably in a boat enclosed within a straight glass tube. A single wash-bottle, containing caustic potash and a little potassium permanganate, and a calcium chloride tube suffice for the purification of the hydrogen. A flask containing alkaline lead solution is unnecessary, as this reagent was found to be incapable of retaining such traces of hydrogen sulphide as may be present in the gas. If a bulb tube be employed, it should be 25 cm. long by 10–12 mm. wide (internal measurement), with a bulb 5 cm. in diameter, and should be fairly thick in the walls. The boat is preferable because a higher temperature may be applied and the operation may therefore be shortened. The best results are obtained by determining the loss of weight undergone by the copper; but for this purpose the bulb-tube, if used, should not be weighed with the specimen, because it is certain to lose weight on heating; copper filings, however, cannot be weighed separately, for some of them will fuse into the glass. It is preferable not to attempt to weigh the water produced by the action of the hydrogen, as this necessitates the use of a very elaborate purifying apparatus for the hydrogen, to ensure that it is entirely free from air. It is found that thick pieces of copper are practically as rapidly attacked by the hydrogen as thin fragments are; and as the errors of the method are mainly due to surface oxidation, it is desirable to employ pieces of appreciable size rather than sheet or filings. Thin sheet must be heated in the bulb tube for at least an hour to a clear red heat, and thick pieces for two hours, followed by a second heating for half an hour by way of control. A portion of the total oxygen, probably that which is not combined with copper, is removed with greater difficulty than the remainder. Reduction in carbon monoxide was found to be slower, but it failed to throw any light upon the difference in the condition of the different portions of the oxygen.

**Determination of the Cuprous Oxide.**—The silver nitrate method is found to give results which are so high that the process should never be employed, except in the treatment of crude copper containing much suboxide, in which case the error is relatively small.

**Estimation of Lead.**—Precipitation of lead as sulphate by evaporation with sulphuric acid and dilution, gives high results, owing to the presence of silica and bismuth in the precipitate. It is best to treat the cold nitrate or sulphate solution with sufficient hydrogen sulphide solution to precipitate a few centigrams of copper; the finely-divided precipitate is filtered off and will be found to contain the whole of the lead, which is estimated electrolytically, after filtering off the precipitate and (without washing) dissolving it in nitric acid. As little as 0.0003 per cent. of lead has thus been detected in a sample of copper, which gave no indication by the sulphate precipitation method. At least a part of the antimony and bismuth is thus concentrated with the lead.

**Estimation of Antimony and Arsenic.**—A large quantity of the copper is introduced into a bulb-tube, and is heated to clear redness for at least two hours in pure hydrogen, the bulb being covered with a hood of asbestos-card, and being turned round from time to time to prevent the deposition of antimony upon any part of the bulb itself. A portion of the antimony is deposited as a mirror in the straight part of the tube, and the escaping gases are passed through a Peligot tube containing hydrochloric acid and a little bromine. If the antimony be weighed as oxide, it is necessary, after once heating the precipitate, to treat it with cold water, which dissolves out fixed alkalis, and then to dry and re-ignite it before weighing. The tetroxide is not volatile at a red heat in the absence of reducing gases, and it is therefore recommended to pass air into the crucible during ignition. The method of weighing the tri-sulphide, after heating in carbon dioxide in a Gooch crucible, may give incorrect results owing to oxidation from access of air through the bottom of the crucible. The precipitate should, therefore, be heated in hydrogen sulphide gas after the carbon dioxide treatment.

**Determination of the Copper.**—From 1.2 to 1.5 gm. of the copper is dissolved in warm dilute nitric acid, one or two drops of hydrochloric acid and a distinct excess of sulphuric acid are added, and the solution is evaporated until all nitric acid is expelled. After dilution, the silver chloride and lead sulphate are filtered off, and washed with water containing sulphuric acid, and the copper is precipitated by hydrogen sulphide and weighed as cuprous sulphide. With the precautions named in the first section of this abstract, the result should be correct to within 0.03 per cent. The sulphide may be rapidly filtered by employing a filter paper 3 cm. wider than the bottom of the funnel, pressed on to a porcelain funnel with perforated bottom, with the aid of a truncated wooden cone; this is used in conjunction with a filter pump. Alcohol may be used for the last washing to expedite the drying.

The electrolytic estimation, as commonly used, is apt to give slightly incorrect results, partly owing to irregularities in the successive weighings of the platinum dish, which may show variations of 3 or 4 mgrms. A little water may also be retained in the deposited copper. Better results are obtained if the dish with its deposit be heated in hydrogen to a red heat; but trouble is thus given in the subsequent cleansing of the dish, owing to the superficial alloying of the copper and platinum.—W. G. M.

**Chromium, Determination of, in Ferrochrome and Chromium Steel.** Spüller and Brenner. Chem. Zeit. 1897, 21, [1], 3–4.

THE method of Spüller and Kalman (this Journal, 1894, 867, 950) has been modified as follows:—

1. To lessen the amount of sodium hydroxide needed (and the consequent inconvenience from its contained water) the substance to be fused is mixed with sodium hydroxide and a layer of sodium peroxide placed on the top. On fusion, the peroxide mixes gradually, and the action does not become violent. The rest of the peroxide is then added to the fused mass.

2. At the end of the fusion a further quantity of peroxide is mixed in, which greatly facilitates and quickens the solution of the cooled mass in water.

3. Chromium steels are dissolved in hydrochloric acid, and the chlorides converted by evaporation with sulphuric acid into sulphates. This gets over the difficulty of dissolving tungsten steels in sulphuric acid.

4. With chromium steels containing little chromium, the final titration is based on Zulkowsky's method (iodine and thiosulphate), not on Schwarz' method (permanganate).

—J. T. D.

**Phosphatic Slags, Mechanical Analysis of Basic.** H. W. Wiley. J. Amer. Chem. Soc. 1897, 19, 19–22.

EXPERIENCE has shown that the ammonium citrate method is of varying value, a lower solvent action of the acid ammonium citrate being noticed when the sample contains, in addition to tetracalcium phosphate, tricalcium phosphate, and particles of silicious slags and of iron and steel. It therefore seemed desirable to effect a mechanical separation, using sieves for particles  $\frac{1}{16}$  mm. in diameter and upwards, and separating smaller particles by levigation. As water cannot be used, from its solvent action on the free lime which the slag contains, 90 per cent. alcohol was used. Photographs are given showing the uniformity in size of the grains of the various separates. Analysis reveals a regular progression in the richness and availability of the sample from the coarsest to the finest parts. The data lead to the inference that it may be advantageous to the manufacturer of basic slags to secure a separation for the purpose of being able to place on the market a more concentrated and available fertilising material.—L. J. de W.

**Ozone, Atmospheric; Estimation of, on Mont Blanc.** M. de Thierry. Comptes Rend. 1897, 124, [9], 460–463.

AFTER having made qualitative tests with various ozone papers in 1894, 1895, and 1896, the author in 1896 made several quantitative analyses of the amount of ozone in the atmosphere about Mont Blanc. The method employed was that of Albert-Levy, in which the air is aspirated through three tubes containing 20 c.c. of a mixture of potassium

arsenite solution and potassium iodide solution free from iodate, the arsenite formed being determined by means of iodine, and the oxygen which has effected the change calculated from the result and multiplied by three.

The subjoined table gives the results obtained at Chamonix (altitude, 1,053 m.), and Grands-Mulets (altitude, 3,020 m.).

	Temp.	Barom.	Volume of Air corrected.	Ozone in 100 c.c.
	°	Mill.		Mmgrs.
Chamonix, August 23, 1896	20	680	586	375
" " " " " 24, " "	19	684	477	379
Grands-Mulets, September 4, 1896	21	539	315	974

The corresponding amount of ozone, as determined in the Montsouris observatory in Paris, was 2.0 mgrms. on August 23 and 1.9 mgrms. on September 1. From these figures the conclusion is arrived at that the amount of ozone in the air increases with the altitude.—C. A. M.

### ORGANIC CHEMISTRY.—QUALITATIVE.

*Magenta and Magenta S, Distinction between, by Schiff's Reaction.* P. Cazeneuve. *Bull. Soc. Chim.* 1897, **17**, 196.

A REPLY to Lefèvre (this Journal, 1896, 922), who maintains that Magenta and Acid Magenta, when decolorised by sulphurous acid, give similar colorations with aldehydes; this is also stated in Lefèvre's "Traité des Matières Colorantes," pp. 1063 and 1065. The author made similar solutions of 200 c.c. of water, 30 c.c. of magenta solution (1 in 1,000), 20 c.c. of sodium bisulphite of 34° B., and 3 c.c. of sulphuric acid of 66° B. 10 c.c. of this solution made with ordinary magenta give, rapidly, an intense violet coloration with one drop of formal or 15 per cent. acetic aldehyde; and much more dilute solutions give the same reaction. In the case of the solution made with Magenta S, no coloration was seen; and the same result was obtained with one drop of 40 per cent. aldehyde. The colour only appears on adding a large excess of aldehyde, but with pure alcohol the original rose tint reappears, and not the violet given by ordinary magenta with aldehydes. Moreover, a solution of 49 c.c. of 50 per cent. alcohol and 1 c.c. of 40 per cent. formal gives a less intense coloration with the Acid Magenta than is given by pure alcohol.

Acid Magenta is not a suitable reagent for the detection of aldehydes (see Paul, this Journal, 1897, 265).—A. C. W.

*Colour Reactions yielded by Tartaric and other Organic Acids.* E. Piñera. *Comptes Rend.* 1897, **124**, [6], 291—292.

THE reagent employed is a solution of  $\beta$ -naphthol in strong sulphuric acid (0.02 grm. in 1 c.c. of  $H_2SO_4$ ). About 0.05 grm. of the substance (dry) to be examined is treated in a porcelain dish with 10—15 drops of the solution. The following reactions are obtained:—

*Tartaric Acid.*—Coloration, blue, changing to an intense green on application of heat. When the mass is diluted with water (15—20 volumes), a permanently reddish-yellow solution results.

*Citric Acid.*—Coloration, blue, not affected by heat. On addition of water, a colourless, or slightly yellowish liquid is obtained. In presence of an admixture of tartaric acid, the green tint readily appears; and with 10—12 per cent. of the impurity, the coloration is dull blue-green.

*Malic Acid.*—Coloration, yellow-green, which becomes bright yellow on heating, and bright orange on dilution. This reaction is very delicate. Other organic acids yield similar reactions, but not sufficiently distinctive to be of value. With alkaline nitrites (2—3 drops of a solution), the reagent yields a very intense red coloration, which remains unchanged on addition of water. A solution of resorcinol (0.1 grm. in 1 c.c. of  $H_2SO_4$ ) may be similarly

employed to distinguish nitrates from chlorates. The former yield a red-brown product, which gradually assumes an intense violet tint, forming with water, an orange solution. With the latter, an intense green coloration is obtained, passing to brown on dilution.—H. T. P.

*Colza Oil, New Colour Reaction of.* Palas. *Ann. de Chim. Analyt.* **1**, 434; *Bull. Assoc. Belge des Chim.* **10**, [9], 358.

A ROSE coloration, gradually increasing in intensity, is produced when colza oil is agitated in the cold with an equal volume of rosaniline bisulphite (prepared by mixing, without heat, 30 c.c. of a 1 per cent. solution of magenta, 20 c.c. of 34° B. sodium bisulphite, 200 c.c. of water, and 5 c.c. of  $H_2SO_4$ ). The reaction is very delicate, sufficient for the detection of 2 per cent. of colza oil in olive oil. Linseed oil gives a bright yellow coloration, but no reaction occurs with olive, sesame, cotton, arachis, castor, rape, nut, or poppy oil, or with the fatty acids of colza oil.—C. S.

*White Wines, Testing for Coal-Tar Colours in, and the Difference between these Colours and Caramel.* A. d'Aguilar and W. da Silva. *Comptes Rend.* 1897, **124**, [8], 408—410.

THE authors do not agree with the results recently published by Megalhães (see this Journal, 1897, 156), and they find that caramel, when added to a wine, can be distinguished from the coal-tar colours. The wine is rendered alkaline by the addition of ammonia, and is then shaken up with amylalcohol. The colour taken up by the latter is noted, and also a dye trial is made with a little silk. The amyl alcohol becomes but faintly coloured if caramel only is present, and the fixation of the latter by silk is also very feeble. In the case of wines to which coal-tar colours have been added, the silk generally becomes distinctly dyed, and where this is not the case, the colouring matter (e.g., chrysoidine, amido-azobenzene) can be identified by other reactions.

—A. K. M.

*Vanillin, Test for.* *Pharm. J.* 1897, **58**, 167.

TO the solution under examination, add a few drops of a 1 per cent. solution of ferrous sulphate, and then bromine water, drop by drop. Vanillin gives a bluish-green colour, turning yellow after a time.—A. S.

*Legal's Reaction, The Generalisation of.* G. Denigès.

*Bull. Soc. Chim.* 1897, [6], 381.

THE author has shown in a former communication (*Bull. Soc. Chim.* **15**, 1058) that the coloration given by acetone with sodium nitroprusside on the subsequent addition of an alkali and acetic acid, is common to all compounds containing the acetyl group (substituted or not), if the carbonyl group be united to certain other groups. Von Bitó (*Annalen*, **267**, 372) had previously shown that the reaction does not affect the aldehyde or ketone groups, and he had attributed it to the presence of the groups  $CH_n.CO$  and  $CH_n.CO.H$ . The author's attention has now been drawn to this statement, which he considers too sweeping, since he has found that if the carbonyl be united to OH, OR, OM,  $NH_2$ , or Cl, the reaction does not take place.—A. C. W.

*Acetanilide, Exalgine, Phenacetine, and Methacetine; Separation of, by Micro-chemical Tests.* Schoepp. *Pharm. Zeit.* 1897, **42**, 106.

THE mixture is dissolved in the least possible quantity of concentrated hydrochloric acid and the analysis conducted in the following systematic manner:—

A. A little saturated solution of sodium bromide is added to a drop of the solution, and one crystal of potassium chlorate. An amorphous precipitate results after about a minute; one drop of 20 per cent. alcohol is added. Numerous needles separate = Acetanilide.

B.—1. Iodine, dissolved in potassium iodide, is added to a drop of the solution. An amorphous precipitate results, which should be treated immediately with a drop of water. The insoluble portion forms brown crystalline scales = Exalgine.

2. A small quantity of the dry mixture is placed in a drop of concentrated hydriodic acid. Brownish-red scales form immediately = Exalgine.

3. A small quantity of the dry mixture is placed in a drop of a mixture of saturated sodium iodide solution and gold chloride in hydrochloric acid. Brown four-cornered scales result = Exalgin.

C.—1. A drop of 20 per cent. alcohol and one crystal of potassium chlorate are added to a drop of the hydrochloric acid solution. After some minutes the mixture becomes somewhat turbid. Cry-stalline rosettes or stars separate = Phenacetine.

2. A little saturated solution of sodium iodide is added to a drop of the solution. Fine light yellow needles result after a few minutes = Phenacetine.

3. A little of the dry mixture is added to a drop of hydriodic acid. Light yellow needles form on the crystals which have not dissolved = Phenacetine.

D.—1. A little saturated potassium dichromate solution, or chromic acid, is added to a drop of the hydrochloric acid solution. Numerous cruciform crystals separate after a few minutes, sometimes only after heating = Methacetine.

2. A little concentrated ferricyanide of potassium solution is added to a drop of the solution and covered immediately with the cover glass. Yellow cubes separate = Methacetine.

3. A little saturated solution of sodium bromide and a crystal of potassium chlorate are treated with a drop of the solution, and the cover glass is placed on the micro-exsiccator. On evaporation of the drop, numerous cruciform crystals separate = Methacetine.—J. O. B.

## ORGANIC CHEMISTRY.—QUANTITATIVE.

*Paraffin in High-Boiling Distillates from Petroleum.*  
*Determination of.* Holde. Mitt. k. t. Versuchsanst. zu Berlin, 14, [1], 211—221.

AFTER testing the methods proposed by Pawlewski and Filemonowicz, Zaloziecki, Holland, Aisinmann, and Engler and Böhm, the author finds the latter, with certain modifications, is the most accurate, and therefore prescribes the following method of estimation:—10 to 20 c.c. of the oil, if poor in paraffin (such as Russian distillates, &c., setting below  $-5^{\circ}\text{C}$ .), or 5 grms. if rich in that constituent (American, Scotch, or Galician oils setting at or above  $0^{\circ}\text{C}$ .), are treated with a mixture of equal parts of 98.5 per cent. alcohol and ether in a 150 or 200 c.c. Erlenmeyer flask, at the ordinary temperature, until dissolved to a clear

the temperature being kept throughout as far below  $-15^{\circ}\text{C}$ . as possible, especially in the case of soft paraffin, when it should average  $-17^{\circ}\text{C}$ . at the highest. The washing is discontinued when the solvent is found to leave on evaporation a trace of fat or paraffin-like (but not oily) residue. Should the process of freeing the paraffin from oil take too long, the filter is transferred to another funnel and the paraffin removed, by the aid of hot benzene, into a basin, and, after evaporating the benzene, rinsed with 4 to 5 c.c. of warm ether into a test glass, where it is precipitated by stirring with a double volume of absolute alcohol at about  $-18^{\circ}\text{C}$ . This reprecipitation is also necessary for oils containing much soft paraffin, since, in the ordinary process, the large quantity of washing liquid required, redissolves an appreciable proportion of the precipitate. The purified paraffin is finally rinsed into a glass basin with hot benzene and heated on the water-bath until the odour of benzene disappears; after drying for  $\frac{1}{2}$  hour in the oven at  $105^{\circ}\text{C}$ . and cooling, it is weighed. Unnecessarily prolonged drying causes loss of paraffin by volatilisation.

The whole operation is complete in between an hour and an hour and a half, and the results—provided the prescribed temperatures, &c. be maintained—are regular to within 0.23 per cent. for hard paraffin and 0.33 per cent. for soft paraffin. For refrigerating the filter, the apparatus (Fig. 2)

Fig. 2.

devised by Normann, is considered suitable, since the paraffin can then be precipitated direct in the funnel a.—C. S.

*Mineral Oils, Dissociation of Petroleum Acid Salts and the Estimation of Free Acids in.* R. Zaloziecki. Chem. Rev. Fett-u. Harz ind. 4, [2] and [3], 25—27 and 36—38.

IN view of the converse dissociative reactions exerted by petroleum on the compounds of petroleum acids with alkalis, in aqueous and alcoholic solution respectively, the author proceeded to ascertain whether the one would counteract the other when both solvents were simultaneously present, and thereby enable an accurate titration of the free acids in the oil to be effected.

To this end experiments were instituted with  $\frac{1}{2}\text{N}$ ,  $\frac{1}{10}\text{N}$ , and  $\frac{1}{20}\text{N}$  aqueous caustic soda,  $\frac{1}{10}\text{N}$  alcoholic alkali, and mixtures of  $\frac{1}{10}\text{N}$  aqueous alcoholic alkali in the proportions of 1:1 and 1:2; 50 c.c. of the alkali being agitated with 100 grms. of oil in a separating funnel for one minute (or three to five minutes in the case of viscous oils, unless warmed to increase fluidity), and, after separation of the layers of oil and water, titrating back the excess of alkali in 10 c.c. of the latter, with normal acid. Tested in this way petroleum distillates, allowed to acidify by spontaneous oxidation, gave the following results, expressed in c.c. of  $\frac{1}{10}\text{N}$  acid per 100 grms. of oil;  $\frac{1}{10}\text{N}$  NaHO, 15.25;  $\frac{1}{10}\text{N}$  NaHO, 15.12;  $\frac{1}{10}\text{N}$  NaHO (1 aq. : 1 acoh.), 15.0;  $\frac{1}{10}\text{N}$  NaHO (1 aq. : 2 acoh.), 15.75.

Parallel experiments showed the correctness of the above-named assumption respecting the use of 1:1 aqueous-alcoholic alkali.

With regard to the preparation of neutral petroleum for mixing with known quantities of free acid, it was found that freshly prepared distillate from oil previously refined with alkali rapidly became acid, owing to the formation of oxidisable bodies during distillation, and it was therefore found preferable to employ a sample a year old, neutralising this with an excess of 1 per cent. of alkali without redistillation.

Fig. 1.

solution. The liquid is then cooled down to between  $-18^{\circ}$  and  $-20^{\circ}\text{C}$ ., and a further addition of the alcohol-ether stirred in until no oil drops, but only solid paraffin flakes, remain in suspension, whereupon it is passed through a 9 cm. filter, previously cooled in the apparatus shown in Fig. 1, and the precipitate rinsed with a little cold ( $-18^{\circ}$  to  $-25^{\circ}\text{C}$ .) alcohol-ether (1:1, or, for soft paraffin 2:1),

In nine other instances with oils, either with or without added petroleum acids, the results showed that an indirect titration with  $\frac{1}{10}$  N or  $\frac{1}{20}$  N alkali, effected by the aid of an excess of lye titrated back, is a sufficiently concordant and reliable method. For lubricating oils of high viscosity, it is advisable to use the decinormal alcoholic-amine-alkali, since alcoholic alkali gives results in excess of the truth, either on account of dissociation, the insufficiently accurate determination of the end point in the case of these highly coloured liquids, or by alterations in the amount of alkali due to the solvent action of the alcohol on the oil.

Experiment showed that though hydrolysis occurs when the salts of petroleum acids are boiled, or when they are shaken up with oils, either free or nearly free from acid; the decomposition is comparatively insignificant in amount, not exceeding 0.5 per cent. of the total acid in  $\frac{1}{10}$  N solutions.

Working on the same lines as Kraft (this Journal, 1894, 1207; 1896, 206 and 601), but substituting petroleum soaps for sodium palmitate and petroleum distillate for toluene, similar results were obtained; the dissociation ranging from 0.5 to 0.88 per cent. of the original acid, and being therefore negligible in acidimetric determinations.—C. S.

*Petroleum Oils, &c., Testing: Recent Experience in.* Holde, Mitt. K. t. Versuchsinst. zu Berlin, 14, [1], 229—237.

1. *Resinification of Mineral Oils.*—In continuation of the experiments on the behaviour of these oils when exposed in thin layers to the air (this Journal, 1895, 894), samples spread out thickly were heated to 100° C. for about 7 hours daily, with the following results:—Colourless, resin-free, "paraffin" oil (from the lowest lubricating oil fractions) gradually volatilised by the end of 15 months without leaving any trace of resinous residue; the thicker "motor" oil from the higher fractions left a small solid residue, consisting partly of original resin and partly of oxidised hydrocarbons; a very thick Russian oil volatilised only slightly and resinified but little, especially when previously extracted by 75 per cent. alcohol. On the other hand, lubricating oils (Russian and Oelheim) containing residuum, resinified considerably, and the first-named, which contained the larger proportion of low-boiling fractions, volatilised more rapidly and left a larger residue than the other Russian oil referred to above. In each case the residue was imperfectly soluble in petroleum spirit (although some of the original oils were completely so), but was almost totally dissolved by benzene. These results are parallel with those obtained in the previous series.

2. *Quantitative Estimation of Water in Fatty Oils.*—Experiments were made with various fatty oils, respecting the advantage of checking by a blank experiment, the loss of weight due to volatilisation of oil in determining the percentage of water by the evaporation test, though the figures obtained show that a fairly accurate estimate can be made without this check, still it is safer to make the parallel test in the case of all fatty oils and saponifiable fats. Where the amount of water is large, it is advisable to reduce the proportion by mixing with a known weight of oil perfectly free from water. To make the estimation, 10 to 20 grms. of oil are heated in a glass basin over a boiling water-bath, with continued stirring, until froth ceases to form on the surface, the ascending bubbles of steam being directed, by the aid of the stirrer, to the side of the basin and there dispersed. Another sample of the oil, previously freed from water, is heated concurrently, and the amount of water is determined by the difference between the losses of weight sustained by both.

3. *Vaseline Oil "Soluble in Water."*—A sample of this oil (an ammoniacal soap dissolved in mineral oil) was submitted to examination with regard to its property of protecting cast iron and steel against the action of water, and for comparison in this respect with the soft-soap solutions generally used for milling and cutting machinery. With this object small polished cast-iron and steel plates were immersed in water containing 2 and 5 per cent. of the oil, and also in 1 and 2 per cent. solutions of soft-soap, for three weeks. The effect of the oil was to preserve the steel from all corrosion, the surface being merely covered with

a faint black deposit, and the loss in weight restricted to 0.2 per cent., whereas with soap solutions the loss amounted to between 9.9 and 14½ per cent., and, on removal of the deposit, the surface was found to have become dulled. The cast iron was not so well preserved, having lost between 6.2 and 7.6 per cent. in weight, and parted with its lustre, in the oil and water mixtures, but was less corroded than in the soap solutions, where the loss in weight amounted to 13.8 and 17.5 per cent., and a copious brownish-yellow deposit was formed, especially at the points of contact between the plate and the vessel. The working tests on the machinery, were made with 2 and 4 per cent. emulsions of the oil in water and 1 to 2 per cent. solutions of soft-soap. Here also the superior protection afforded by the oil was manifested by iron and steel, the latter being free from corrosion and the former merely coated with easily removable brown flakes, whilst with soap the steel was slightly, and the cast-iron considerably, rusted.

It was also found that the presence of from 2 to 10 per cent. of this oil lowered the freezing point of water by 3 to 5° C., but no further reduction could be confirmed on the addition of 1 per cent. of glycerin to the 2 and 5 per cent. solutions, although with 0.1 to 0.5 per cent. of glycerin, they more frequently remained liquid at -5° C. than without this addition.—C. S.

*Lards, Determination of Solid Fats in Compound.* G. F. Tennille, J. Amer. Chem. Soc. 1897, 19, 51—54.

THE mechanical process adopted in the United States laboratory for the determination of the constituents of compound lards as described by Wainwright (this Journal, 1896, 620), cannot be relied upon under all conditions.

From a large number of tests of lards of known composition, 10 are selected containing cotton-seed oil of varying body, and both hard and soft stearin, but all having 20 per cent. of oleo-stearin to 80 per cent. of cotton-seed oil. Although some of the results are within 1½ units of the true percentage, others are 7 or 8 per cent. too high or low.—L. J. de W.

*Cocoa Butter, The Iodine Number of.* D. Holde, Zeits. anal. Chem. 1896, 36, [3], 163—164.

THE higher limit for the iodine value of cocoa butter has been given as 51, and this led Strohl to examine a large number of specimens of cocoa butter (this Journal, 1896, 362), and Strohl's figures were in turn criticised by Filsinger (this Journal, 1896, 747). The author now finds that de Negri and Fabris made a mistake in the transcription, the iodine value given by Huhl being 34.—C. A. M.

*Fatty Acids [Stearic Acid, &c.], Determination of Unsaponified Fat in Commercial.* F. and J. Jean, Rev. de Chim. Ind. 1896, 7, [83], 338—339.

THE following method is given:—The sample is melted, thoroughly washed with hot water, dried at 100° C., and titrated directly (5 grms.) with  $\frac{1}{2}$  N alcoholic potash and phenolphthalein. Another portion of the sample is completely saponified, the resulting soap decomposed by an acid, the fatty acids washed, dried, and a known weight titrated with standard alkali. The average equivalent of the mixed fatty acids is thus found, from which, and the results of the preceding titrations, the absolute composition of the sample may be deduced. For the examination of samples contaminated with tarry decomposition products, and containing fatty acids soluble in hot water, the following scheme is suggested:—10 grms. of the sample (dried at 100° C.) are washed with boiling water until the washings pass off perfectly neutral. From the wash-water the fatty acids are extracted by means of a mixture of ordinary and petroleum ethers, and weighed after evaporation of the solvents. The portion of sample insoluble in water is dissolved in alcohol, exactly neutralised with soda, and the solution evaporated to dryness. The residue is ground up with an excess of sand and fibrous asbestos, and extracted in a Soxhlet tube with ordinary and petroleum ether. The residue remaining when the ethereal solution is evaporated,

consists of tar and undecomposed fat. It is weighed, then saponified by soda, and again extracted (in aqueous solution) with the mixed ethers. The extract on evaporation leaves as residue the tar alone.—H. T. P.

*Shellac, Behaviour of the Resin Acids of, in Separating Fatty and Resin Acids by Gladding's and Twitchell's Processes.* F. I'izer and R. Defris. *Zeits. anal. Chem.* **36**, [1], 24—27.

THE resinous acids of shellac behave quite differently from colophony (resin) acids, in Gladding's process; thus a dark-coloured sample of shellac, containing 0.05 per cent. of unsaponifiable matter, gave only 13.76 per cent. of "resin acids" by this process. The silver salts of the acids differ from those of resin by being mainly insoluble in ether, resin silver salts being soluble. A mixture of 51 parts of colophony, containing 12.9 per cent. of unsaponifiable matter and 49 parts of the resin acids of the above-mentioned shellac, yielded 48.64 per cent. of "resin acids." The shellac used had an acid number of 65.43, and a saponification number of 204.78. A sample of commercial lac, composed of colophony and shellac, yielded only 63.7 per cent. of "resin acids" by Gladding's process.

Examined by Twitchell's process, the dark-coloured shellac gave 66.56 per cent. of "resin acids," the petroleum-ether layer containing an ester—a light yellow, transparent, resinous mass having the saponification number 199.5. A determination of its acid number gave a negative result. An orange-coloured sample of shellac, having an acid number of 53.05 and a saponification number of 201, gave by Twitchell's method, 72.89 per cent. of "resin acids." These results show that the shellac acids in part react as the fatty acids do, forming esters on treatment with HCl gas in alcoholic solution.

Samples of Angola-copal and Kauri-copal gave respectively 86.01 and 86.37 per cent. of "resin acids" by Twitchell's process. Gladding's process could not be used, as part of the soda-soap of the acid-separated out from the alcoholic solution on adding sodium hydrate solution, and the addition of the ether caused a further precipitation.

—H. B.

*Tannin, Estimation of. [The Tannoform Reaction.]*

E. Aweng. *Apoth. Zeit.* 1896, 831.

THE author has examined, as to its value for quantitative purposes, the well-known reaction between tannin and formaldehyde, whereby insoluble condensation products (tannoforms) are produced. Experiments were made with solutions of oak-bark tannin (1—25 per cent.) in water. He shows by a series of experiments that the tannoform reaction is unsuitable for quantitative work.—H. T. P.

*Gelatin, Volumetric Method for the Estimation of, in Glue and Glue Liquors.* F. Jean. *Rev. de Chim. Ind.* 1896, **7**, [83], 339—340.

ONE gram. of the sample is soaked in cold water, then dissolved by gently heating the liquid in a water-bath, and diluted to 100 c.c. at 35° C. To 10 c.c. of this solution are added 10 c.c. of a 1 per cent. solution of tannin, 5 grms. of salt, and 1 gram. of sodium bicarbonate, the mixture well shaken, rapidly filtered, and the precipitate washed with salt water (23° B.) until the filtrate measures 45 c.c. The excess of tannin is then determined by slowly adding to the filtrate a solution of iodine (4 grms. per litre) until a drop of the liquid yields with dry starch powder (thinly spread on filter paper) a blue stain. The liquid is now diluted to 60 c.c., and titration continued until a very faint end-reaction is obtained. The titre of the iodine solution being known (by titration against 0.01 gram. of tannin dissolved to 60 c.c.), the weight of tannin consumed in precipitating the gelatin is found by difference. According to the author, 100 parts of tannin = 88.5 of gelatin.

Since even the purest commercial tannin procurable, frequently contains impurities, the actual strength of the sample used must be found by the "hide" method; and the standard solution prepared so as to contain 1 gram. of real tannin per 100 c.c.—H. T. P.

*Beetroot, Method of Analysis of the.* L. Jesser. *Bull. de l'Assoc. des Chim. de Sucre.* 1897, **14**, 684—688.

IT is a well-known fact that the polarisation of the beetroots received is always higher than that of the fresh slices, and factories which pay for the beets on their sugar content are obliged to take this factor into account. The reason of the discrepancy is not yet very clear; the author, however, can personally confirm this difference, which reaches, one year with another, 1 per cent., notwithstanding conscientious sampling and every care in analysis. Attention is called to one source of error: the division of the beetroot, and, consequently, the apparatus for the division. The taking of the sample and rasping it are made after the two following principles:—(1.) The sugar content of the beetroot depends on its size. Roots of medium size are richest in sugar, the richness diminishing towards the two extremes. For this reason, samples are taken of every size to represent the lot. (2.) The sugar is not regularly distributed in the beetroot. The heart is richer in sugar than the periphery. For conversion into pulp the beetroot is cut lengthwise in half, and then into quarters, and rasped. In this way an equal portion of each root passes into the sample, and the average sugar content results very fairly. But experience has shown that the polarisation of the juice thus obtained gives erroneous results, and gradually the method has been arrived at of testing the sugar directly. For this purpose, machines are necessary by which it is possible to obtain a suitable pulp or cream. These machines may be classed in two groups: those which subdivide a part of the root prepared by hand, and those which remove a portion—of cylindrical form—in the form of cream. The only good ones are those which cut out segments, as then, from each root, great and small, a portion is obtained proportional to its size. A good machine ought to furnish only a small quantity of pulp, by taking from each root only a small segment, in order that a large number may be included in the sample. The cream should be tested without delay; a loss of 1 per cent. has been observed in a cream kept in a closed vessel for three hours. The sugar is tested by one of the methods of digestion, or by alcoholic extraction, the testing by the juice should be absolutely condemned. Digestion always gives higher results than polarisation of the juice. If pulp already pressed be subjected to a second subdivision and pressure, a juice of a richer quality and of higher quotient is obtained than at the first pressing.—L. J. de W.

*Beetroot, Determination of Sugar in the.* K. Kaiser. *Bull. de l'Assoc. des Chim. de Sucre.* 1897, **14**, 688—691.

THE difficulty of estimating the true sugar content of a lot of beetroots is attributed, not to the methods of analysis, but to the difficulty of sampling. Of 1,000 roots grown in proximity, the mean richness, 15.5 per cent., was shown by only 25, or one-fortieth of the lot; the others varying from 18.2 to 12 per cent.

In estimating the sugar in any sample of roots, it is important to take, as far as possible, a quantity of substance from each root proportional to its size. If the diameters of three beetroots are as 4:5:6, their volumes are as 64:125:216. To obtain equal proportions of pulp, the one of diameter 4 should be pierced once, the one of 5 twice, and the one of 6 three times. By a table the author has drawn up for beets of all sizes, and a scale placed near the perforator to show the number of perforations to be made, he obtains regularly 3 per cent. of pulp for analysis.—L. J. de W.

*Sugar in Beetroot, Comparison of Direct Methods of Estimating.* J. Graftian. *Bull. Assoc. Belge des Chim.* **10**, [9], 354—357.

ON comparing the de Molinari, Masson, cold digestion and alcohol-extraction methods with that of cold digestion of an arbitrary volume, the author finds that as a rule the latter gives results inferior to the other direct methods, the deficit decreasing, however, if the digestion be prolonged. Instantaneous digestion he characterises as chimerical, the results obtained in the cold depending for their approximate accuracy on the compensating effect of two errors: one an

excess, due to imprisoned air, and the other a deficit, caused by insufficient diffusion; but digestion in the warm tends to eradicate both. For cold digestion *in vacuo* a sufficient time for complete diffusion is necessary to ensure accuracy.—C. S.

*Betroot Juice, Estimation of Lime in, by Alcoholic Soap Solution.* N. Rydlewski. Bull. de l'Assoc. des Chim. de Suer. 1897. **14**, 696—699.

Is view of the importance of the organic lime salts present in betroot juice, and to obtain a quicker method of estimation than that of incinerating, dissolving the ash, and precipitating by ammonium oxalate, the author has prepared a soap solution on Müller's formula. It is standardised by barium chloride, of which 100 c.c. represent 0.0207 grm. of BaO or 0.0075 grm. of CaO. To carry out the test, 10 c.c. of juice or 5 c.c. of syrup are poured into a 300 c.c. flask, making up to the mark with distilled water. The soap solution is then run in drop by drop from a burette until a froth is obtained lasting five minutes. From the number of c.c. of soap solution used, the lime may be calculated. Tables are given of results obtained.—L. J. de W.

*Starch, Estimation of, in Frozen Potatoes.* D. Saare. Zeits. f. Spiritusind. 1897. **20**, 51—52.

THE estimation of starch in hard frozen potatoes is conveniently carried out by taking rather more than 5 kilos. of the sample and thawing in lukewarm water, continually replenishing the water until all the earthy particles have been removed. 5 kilos. of the drained potatoes are weighed, and the tare under water determined by a Keimann's balance. A deduction of 1 per cent. is made from the starch found, as a correction for errors of manipulation.—J. L. B.

*Liquorice Extract (Cakes, Pastilles, &c.), The Analysis and Composition of.* G. Py. J. de Pharm. et de Chim. 1897, [6], 280—284.

*Moisture.*—10 grms. of the sample are dried for 7 hours at 100° C.

*Ash.*—Total, and that soluble in water, determined in the 10 grms. that have served for the estimation of water.

*Alcoholic Extract.*—2 grms. are dissolved in about 30 c.c. of warm water, and to the solution, when cool, absolute alcohol is added until the mixture contains 75 per cent. of alcohol by volume. After 12 hours the precipitate is filtered off and washed with alcohol of 75 per cent. The filtrate is evaporated in a tared flask, the residue dried at 100° C., and weighed.

*Glycyrrhizin (Ammonium Glycyrrhizate).*—The alcoholic extract (from previous determination) is dissolved in warm water and precipitated by dilute sulphuric acid (1 in 10). The precipitate is washed with acidulated water, redissolved in strong ammonia, and the solution evaporated in a tared dish, dried at 100° C., and the residue (ammonium glycyrrhizate) weighed.

*Organic Matters Insoluble in Alcohol* are found by deducting the sum of the moisture, ash, and alcoholic extract percentages from 100.

The above determinations, as a rule, suffice to indicate the quality of commercial liquorice extracts. A more complete examination would include the determination of total nitrogen by Kjeldahl's process (the N derived from glycyrrhizin is found by multiplying the latter by 0.0593), and of reducing sugars. For the latter purpose the acid filtrate from the glycyrrhizin precipitate may be employed. Gelatin, being often added, either fraudulently, or to impart suppleness to liquorice sticks, &c., should always be looked for. To this end the portion of sample insoluble in 75 per cent. alcohol may be dissolved in water and tested with tannin, phosphomolybdic acid, picric acid, &c. Pure liquorice gives negative results with these reagents. The above liquid likewise serves for the detection of gum, the presence of which is indicated (1) by a white precipitate obtained on addition of three drops of copper sulphate (1 in 10) and 10 c.c. of potash solution (45° B.) to a little of the liquid, or (2) by the usual ferric chloride and chalk test. If desired, gelatin may be detected

in the original sample by dissolving 5 grms. in water and saturating the solution with ammonium sulphate. The precipitate of gelatin and glycyrrhizin is washed with ammonium sulphate solution; subsequently with 75 per cent. alcohol, which dissolves out the glycyrrhizin. The residue is dissolved in water and examined for gelatin. Admixtures of starch and lamp-black (frequently contained in liquorice pastilles) may be detected by microscopical examination.

The analyses of a number of extracts are given in a table. The author concludes that commercial liquorice extracts, whether containing gelatin or not, differ in a decided manner only in respect to the percentage of glycyrrhizin, and that the other constituents are subject to irregular variations. Samples containing less than 10 per cent. of glycyrrhizin, the author considers to have been produced, probably, from spent liquorice root.—H. T. P.

*Potassium Bitartrate, Estimation of the, contained in Wine.*

H. Gantier. Comptes Rend. 1897. **124**, [6], 298—300.

100 c.c. of the wine is concentrated by evaporation in a conical flask to about 15 c.c., and then set aside in a cool place, subject to as small fluctuations of temperature as possible, and alongside of it is placed a second flask, containing a saturated aqueous solution of potassium bitartrate. At the end of 2—3 days, the excess of tartar will have separated from the wine. (If crystallisation does not commence after about 12 hours, a minute crystal of tartar may be dropped into the liquid, and will induce the desired separation.) The mother-liquor is then decanted through a small filter, and its volume accurately ascertained. Subsequently, the crystals are washed with the aqueous tartar solution referred to above, the filter is returned to the flask, a volume of tartar solution, equal to that of the wine after concentration, added (to correct for the tartar retained by the mother-liquor), and then water, to dilute the whole to about 100 c.c. Finally, the liquid is heated, to facilitate solution of the crystals, and titrated with standard potassium hydrate and phenolphthalein in the usual way. The end-reaction, although somewhat obscured by the presence of colouring matters, is still sufficiently sharp. From the result obtained, 0.0015 grm. must be subtracted for each 1 c.c. of mother-liquor (*vide supra*), to allow for the slightly greater solubility of tartar in water as compared with wine extract. According to the author, this correction is practically constant for wines of different origin.—H. T. P.

*Tea, Analysis of.* Aglot. Rev. Chim. Industr. **8**, 17—20.

For the estimation of tannin, the author boils 1 grm. of powdered tea for 20 minutes with 50 c.c. of water, and repeats the operation several times with fresh water, finally making the volume up to 100 c.c., and determining the amount of tannin by the (Aglot) optical method, disregarding the turbidity due to albumin tannate.

From the examination of a number of teas, it appears that there is no definite relation between percentage of tannin and commercial value, the highest priced tea (Long-soo) containing 9.90, and the next highest (Loong-Tsing) 17.0 per cent., whereas another tea which contained the lowest of all (8.9 per cent.) was worth only one-tenth as much as the first-named. The theine, determined by the Domergue method—treatment with mercuric acetate and extraction by a mixture of equal parts of benzene and chloroform—ranged from 2.20 to 3.65 per cent.

In considering the question of detection of the adulteration of tea, it should be borne in mind that the most common practice consists in adding spent tea, and furthermore, that this spent tea still contains about one-half of its original tannin and theine. Now, since the percentage of tannin in sound tea ranges from 9 to 18 per cent., and the theine from 2 to 4 per cent., it is easy to make up an adulterated tea containing more than the minimum usually prescribed for either one of these bodies, but more difficult to prepare one having more than the minimum of both. It is therefore advisable to insert in hospital and similar contracts, a stipulation for a certain minimum percentage of tannin also, instead of theine alone, as at present. By this means,

assisted by the physical tests of flavour and odour, and by a knowledge of the original value of the reputed brand in the country of production, the difficulty of restricting such methods of adulteration would be lessened.—C. S.

*Fat in Milk, Estimation of.* H. Fresenius. Zeits. Anal. Chem. 36, [1], 31—32.

THE results obtained by the Babcock, Gerber, and gravimetric processes are compared. The gravimetric process used, consisted in evaporating the milk with quartz sand, and extracting the dry residue with ether in an extraction apparatus. The fat, after evaporation of the ether, was dried 1 hour at 100° and weighed. The results quoted show that only insignificant differences arise in the results obtained by the processes contrasted.—H. B.

*Cheese, Estimation of Nitrogen in.* B. A. van Ketel and A. C. Antusch. Nederl. Tijdschr. Pharm. 1897, 82—96.

THE authors, having analysed a number of cheeses, come to the conclusion that only about 80 per cent. of the nitrogen exists in the form of albuminoids, the remainder being due to ammonia and amido bodies. The nitrogen existing as ammonia is estimated by distilling the sample, previously powdered with the addition of sand, with water holding barium carbonate in suspension. The distillate is received into a measured quantity of standard sulphuric acid, and, after boiling, the excess of acid is neutralised with standard soda, using rosolic acid as indicator. The nitrogen existing as amido compound, is estimated by macerating the powdered cheese with water for 15 hours at the ordinary temperature. After adding a little dilute sulphuric acid (1—4), the albuminoids and peptones are precipitated by phospho-tungstic acid. The precipitate is filtered off, and then washed with water containing a little sulphuric acid. The filtrate is made up to a definite bulk, and the nitrogen is estimated in an aliquot part of the liquid by Kjeldahl's process, allowance being of course made for the nitrogen existing as ammonia. The peptones and albumoses are estimated jointly by boiling the powdered cheese (mixed with sand, as before) with water, and filtering off from the undissolved casein and albumin. In an aliquot part of the filtrate, the peptones and albumoses are precipitated by adding dilute sulphuric acid and phospho-tungstic acid. After washing with acid water, the precipitate is submitted to Kjeldahl's process. By the same process, the total nitrogen of the cheese is estimated, and, after allowing for the nitrogen existing in a different state, the balance is calculated as usual to casein. The amount of indigestible casein was found to be very trifling.—L. de K.

*Alkaloids, Determination of.* E. H. Farr and R. Wright. Pharm. J. [4], 4, 202.

THE present official process of the British Pharmacopœia was found, with slight modifications, to be well suited for the determination of morphine in opium. The authors confirm Dott's statement that morphine as ordinarily precipitated, does not become perfectly anhydrous at 160° C., but loses often 5 or 6 per cent. of water, on further drying at 110° C. The following details for the assay of tincture of opium were given:—80 c.c. of tincture is evaporated to about 20 c.c., mixed with 3 grms. of freshly slaked lime, and diluted with water to 85 c.c., stirring at intervals for 30 minutes. 50 c.c. of the filtrate are then filtered into a well-stoppered 4-oz. bottle, and 2 grms. of ammonium chloride, 30 c.c. of ether, and 5 c.c. of alcohol added. The whole is then shaken well at intervals for half an hour and set aside for 12 hours. The ethereal layer is removed with a pipette, filtered through counterpoised filters, and the contents of the bottle rotated with another 15 c.c. of ether, which is also passed through the filters. These are washed with a little ether, and the crystalline precipitate is collected on them, and washed with morphinated water till colourless. It is then dried at a gradually increased temperature, and finally at 110° for one hour. It is then weighed. 30 centigrms. of the crystals are now dissolved in a slight excess of  $\frac{1}{10}$ N. H<sub>2</sub>SO<sub>4</sub> solution, and then titrated back with  $\frac{1}{10}$ N. NaHO,

using litmus paper as indicator. To the amount of pure anhydrous morphine in the total amount of crystals, indicated by this titration, 0.05 grm. is added, as representing the average amount of loss in the process. This method gives results closely concordant with those obtained by Dott's and by Teschemacher and Smith's processes.

The authors found that quinine salts, and the cinchona alkaloids generally, may be obtained in a perfectly anhydrous condition in a water oven, provided time enough for complete drying be allowed. They recommend flat-bottom dishes to be used for drying alkaloidal residues, and quote figures proving that desiccation therein takes place much more rapidly than in the round-bottom capsules usually employed.—J. O. B.

*Kola, The Caffeine Compound in.* J. W. T. Knox and A. B. Prescott. J. Amer. Chem. Soc. 1897, 19, 63—90.

STRONG evidence is given that kolanin, the so-called glucoside of kola, is in reality a mixture of tannates of caffeine and theobromine, and that the glucose obtained on hydrolysis is obtained from the tannin. Both the free and combined tannins were separated by a method, taken in part from Allen, and were found to possess the appearance and properties of glucoside tannins. Artificial preparations of caffeine kola-tannin resembled kolanin, and gave similar reactions. Further work on its composition is contemplated.

When fresh kola seed is cut or bruised, a chemical change immediately takes place, as shown by the rapid change of colour of the cut surface from pink or cream-colour to red-brown. Various solvents were tried with the object of removing the active constituents without change, but without success. The coloration having been attributed to a diastatic ferment, sterilisation by heat was tried. A temperature of 45° C. is sufficient, when alcohol is employed, to coagulate the ferment—at least, to prevent the coloration afterwards.

For the assay of kola the process used was that given by Gomberg (this Journal, 1896, 384), based on the very complete precipitation of caffeine as periodide by Wagner's reagent from aqueous solutions acidulated with mineral acids, preferably hydrochloric, but avoiding excess. The precipitate formed, C<sub>8</sub>H<sub>16</sub>N<sub>4</sub>O<sub>2</sub>HI<sub>4</sub>, is constant under varying conditions of formation. The excess of iodine is measured, after filtering through a dry asbestos filter, by taking an aliquot part of the filtrate and titrating back with decinormal thiosulphate. 1 c.c. of Wagner's solution = 0.00485 grm. of caffeine, the proportion of theobromine (1.48 per cent. of the total alkaloids) not appreciably affecting the factor.

For the estimation of theobromine in presence of caffeine, the method of Kunze (this Journal, 1894, 178) was found very satisfactory: the alkaloid being precipitated as silver theobromine from an ammoniacal aqueous solution by nitrate of silver, and the precipitate converted into silver chloride on the filter.

The free alkaloid is extracted by chloroform, the combined by 90 per cent. alcohol. Dried kola contains half the alkaloid combined, fresh kola 60 per cent. Sterilising the kola, which checks the formation of the coloured body called kola-red, does not at the same time check the liberation of the alkaloid.—L. J. de W.

*Formaldehyde, Methods for the Estimation of.* G. Romijn. Zeits. anal. Chem. 36, [1], 18—24.

IN comparing four methods for estimating formaldehyde, the following aqueous solutions were used:—(1.) 2.075 grms. of pure "formaline." (2.) 2.075 grms. formaline + 1.3 grms. concentrated acetaldehyde. (3.) 2.075 grms. formaline + 0.353 grm. pure acetone. (4.) 2.075 grms. formaline + 1 grm. benzaldehyde,—these quantities being made up to 500 c.c. in each case. The first two methods are new.

(1.) *Iodometric Method*, based on the oxidation of formaldehyde in alkaline solution. 10 c.c. of solution "1" were mixed with 25 c.c. of tenth-normal iodine solution, and sodium hydrate solution dropped in till the liquid became clear yellow. After 10 minutes the reaction was complete; the excess of iodine was liberated with HCl, and

titrated with thiosulphate. Two atoms of I are equivalent to one molecule of formaldehyde. The results gave 37.38 and 37.40 per cent. of formaldehyde in the formaline. With solution "2," containing acetaldehyde, some iodoform was produced, and irregular, erroneous results were obtained. With solution "3" both the formaldehyde and the acetone were fully oxidised, the latter producing iodoform (as in Krämer's process). Solution "4," containing benzaldehyde, gave erroneous results, the benzaldehyde being considerably oxidised.

(2.) *Potassium Cyanide Method*, based on the property of formaldehyde of combining with KCN when solutions containing them are mixed. The addition-product can reduce alkaline silver nitrate solution in the cold, but if the solution be kept acid with  $\text{HNO}_3$ , then, when the aldehyde is in excess, no precipitate of silver cyanide appears, and when the KCN is in excess, one molecule of formaldehyde combines with one molecule of KCN, the excess of KCN precipitating  $\text{AgCN}$  from the  $\text{AgNO}_3$  present. The same formaline solutions as above were used for these tests. To 10 c.c. of tenth-normal silver nitrate, acidified with two drops of nitric acid, were added 10 c.c. of a 0.62 per cent. KCN solution, the whole diluted to 50 c.c., filtered, and an aliquot portion titrated by Volhard's process, 0.39 c.c. being consumed by the whole 50 c.c. When solution "1" (formaline alone) was mixed with the KCN solution before adding to the silver nitrate solution, good results—37.39 and 37.67 per cent. of formaldehyde—were obtained. Using solution "2," if the cyanide-aldehyde solution, immediately after mixing, was added to the silver nitrate, good results were obtained; but if the cyanide and aldehyde stood some time after mixing, the results were much too high. Solutions "3" and "4" gave correct results, even after the cyanide-aldehyde mixture stood for half an hour.

(3.) *Hydroxylamine Method* (Brochet and Cambier's, *Comptes Rend.* 120, 449).—This process gave good results with pure formaline, but the acetaldehyde, acetone, and benzaldehyde all vitiated the results.

(4.) *Legler's Method* (Ber. 16, 1335).—The author does not recommend this process.

In general, pure formaldehyde solutions are best analysed by the iodometric process, and where other aldehydes may be suspected, the KCN process should be used.—H. B.

*Acetone, Estimation of.* L. F. Kehler. *Amer. J. Pharm.* 69, 65; and *Pharm. J.* 1897, 58, 161.

PLACE 20 c.c. of Squibb's alkaline potassium iodide solution (this *Journal*, 1897, 168) in a flask, add 10 c.c. of 1 to 2 per cent. aqueous solution of acetone, and excess of sodium hypochlorite solution (about four-fifths normal), then close the flask and shake. Next acidify with hydrochloric acid, add excess of decinormal sodium thiosulphate solution, and, after allowing to stand for a few minutes, add starch indicator, and re-titrate the excess of sodium thiosulphate. The relation of the sodium hypochlorite solution to the sodium thiosulphate solution being known, the amount of iodine set free by the hypochlorite used, can readily be calculated, and this multiplied by 0.07642 gives the amount of acetone. The method is said to yield satisfactory results for ordinary work.—A. S.

*Guaiaicol, Determination of, by Demethylation.* M. Adrian. *Nouveaux Rem.* 13, 97.

THE process is a modification of that of Behal and Choay, compared with which the author claims that it gives more accurate results. 100 grms. of either commercial guaiaicol or of creosote are placed in a flask of 250 c.c. capacity, connected on the one hand with another flask which serves as a generator of gaseous  $\text{HBr}$ , and on the other with a reflux condenser. The exit tube from the condenser leads the gas through two wash-bottles containing water;  $\text{HBr}$  is generated by the action of water upon  $\text{PBr}_3$ . The delivery tube between the generator and the guaiaicol is furnished with a large bulb to prevent aspiration of the liquid when cooling. The gas is allowed to pass slowly through the guaiaicol, which is gently warmed after the process has

been in operation for half an hour, and is continued for 90 minutes. The liquid is then cooled, transferred to a large flask, diluted with 5 or 6 vols. of water, and all volatile bodies removed by steam distillation. When no more oily liquid comes over, the distillation is stopped, the pyrocatechol in the residual liquor is extracted, together with homopyrocatechol, by washing out with ether, the ether is cautiously distilled off, and the residue dried. This is then treated with benzene, which extracts the whole of the pyrocatechol, leaving the homopyrocatechol insoluble. From this last solvent pyrocatechol is crystallised out and weighed. Care must be taken at the end of the process to avoid the least trace of moisture either in the residue or in the solvent, or crystallisation will not take place.—J. O. B.

*Iodoform Gauze, Examination of.* G. Schaeferl. *Apoth. Zeit.* 1897, 12, 95.

FROM 1 to 1½ grms. of the gauze are heated under pressure in a strong flask on the water-bath for half an hour with 30 grms. of a solution of sodium ethylate, containing about 2 per cent. of sodium. After cooling, the solution is decanted, the residue thoroughly washed with water, and the alcohol driven off from the united liquids by evaporation. The liquid, after cooling, is then acidulated with dilute nitric acid, 30 c.c. of  $\frac{1}{10}$  N solution of silver nitrate added, and the whole made up to exactly 200 c.c. with distilled water. 100 c.c. are then filtered off, and in this liquid the uncombined silver is determined by means of  $\frac{1}{10}$  N solution of ammonium sulphocyanide with the customary iron alum indicator. Each c.c. of  $\frac{1}{10}$  N silver solution = 0.01309 grm. of iodoform. It is found that many commercial specimens of iodoform gauze fall far below their reputed strength, 14.9 and 6.1 per cent. of the antiseptic being found in samples which were said to contain 50 and 30 per cent. respectively.—J. O. B.

## XXIV.—SCIENTIFIC & TECHNICAL NOTES.

*Gallium, Occurrence of, in the Clay Ironstone of the Cleveland District of Yorkshire.* W. N. Hartley and H. Ramage. *Proc. Roy. Soc.* 1897, 60, 393.

THE authors found that the blast-furnace metal obtained from the Yorkshire ironstone, smelted at Middlesbrough-on-Tees, contained 0.00304 per cent. of gallium. It was found that the gallium is contained in the ore and is concentrated in the metal. The gallium was estimated by a method of fractional precipitations and spectrographic analysis of the precipitates, supplemented by gravimetric determinations of the purified gallium sesquioxide.—A. S.

*Crystalline Alumina, Synthesis by the Action of Chlorine on an Alkaline Aluminate.* H. Loyer. *Bull. Soc. Chim.* 1897, 17, [6], 345.

DEBRAY has prepared corundum by the action of hydrochloric acid on sodium aluminate at a red heat. The author finds that a similar result is obtained by the use of chlorine, a slow current of which gas was passed for 1–5 hours through a porcelain tube containing the aluminate mixed with 2 per cent. of potassium chromate. Oxygen is evolved, the reaction appearing to be—

The tube contains a rose-red crystalline mass, which, under the microscope, is seen to consist of small hexagonal tables, these are occasionally green and more rarely blue. The crystals are insoluble in hydrochloric and nitric acids and have a greater density than methylene iodide.

—A. C. W.

*Zircon in Tasmania, Discovery of.* U.S. Cons. Reps., March 1897, 364.

THE United States Consul-General at Melbourne reports that among the many valuable discoveries of late in the colony of Tasmania, one which has created much interest in mining circles has recently been partially developed. It consists of a deposit of zircons, allied with other gems and

rare earths. The gems found in this deposit are chiefly zircons, sapphires, and cinnamon rubies. The first-named are found in large quantities and in every variety of colour. Many of them have been cut and polished, with very gratifying results, being hard and of good lustre. The specific gravity of the zircon is 4.7, thus being heavier than the diamond, which is 3.75; its hardness, compared with the diamond, is 7, the latter being 10. It is of high commercial value for use in the manufacture of mantles for incandescent lights. The composition of the pure zircon is 64 per cent. of zirconia and 36 per cent. of silica. Analyses by Dr. W. H. Gaze, of Melbourne, of two samples of zircons from the above-mentioned deposit give 63 per cent. and 64 per cent. of zirconia, thereby testifying as to the purity of the gem. The rarer earths, *viz.*, lanthanum, thorium, didymium, niobium, erbium, yttrium, cerium, and chromium, are all more or less present.

The property which contains this deposit has been purchased by a Melbourne syndicate. It comprises an area of 105 acres, situated on the north-west coast of Tasmania, about midway between Emu Bay and Circular Head, and is easily accessible by road from either port. The property is heavily timbered, among which are trees of unusual height and girth. There is also permanent water on the ground. A large amount of work has been done in cutting races and forming dams for sluicing purposes, much labour being expended in removing the heavy timber from the creeks.

Associated with the zircon samples is a very rare mineral known as pyrochlore, of which there are several distinct varieties. They are, however, all composed of two rare metals—niobium and uranium—with some of the cerium metals. It may be described as niobate of uranium, with cerium, thorium, yttrium, didymium, and titanium. The percentage of each metal varies, and often some of them are absent. Thorium and yttrium are often present to the extent of 10 per cent. each. At present Dr. Gaze has only determined niobium, uranium, and titanium, and the residue contains the other rare earths. Uranium is contained in very considerable quantities.

Dr. Gaze reports as follows:—

"In the first place, the mineral varies much in composition. It is, therefore, impossible to get two results alike, especially when one has to pick out hundreds of little grains to obtain enough to operate on, and there is no certainty that all the grains are identical. The mineral is of very complex nature, as the analysis below demonstrates. In some instances, chromium has to a great extent replaced uranium; in others, lanthanum and didymium replace thorium and yttrium. With more compact and larger specimens better results should be obtained. In some instances only traces of the rare earths were obtained.

"Assay of Shekleton minerals, nitrate of uranium and chromium, a variety of pyrochlore:—Uranium, 5 to 0.5 per cent.; chromium, 10.5 to 12.5 per cent.; titanium, 12 to 13 per cent.; niobium, 1.5 to 2.5 per cent.; iron, 25.5 to 27.7 per cent.; magnesium, 2.2 to 0.5 per cent.; alumina, 7.3 to 6.2 per cent.; lime, 2.6 to 1.5 per cent.; silica, 15 to 12 per cent.; didymium, 7.5 to 0.5 per cent.; lanthanum, 6.2 to 2.2 per cent.; thorium, 1 per cent. to traces; yttrium, 1.5 per cent. to traces."

*Clevite.* Chem. and Druggist, April 17, 1897, 623.

From a mine recently discovered in Ryfylke, Norway, various minerals containing rare earths have been obtained. Clevite is amongst them, and it is now offered at 2*l.* per kilo., or, say, 1*s.* 4*d.* an ounce. It yields 1.5 to 2 c.c. of helium per gramme; therefore, an ounce-bottleful of helium is worth at least 8*s.*, and this does not include the cost of isolating it.

*Sugar Group, A New Synthesis in the.* H. J. H. Fenton. Proc. Chem. Soc. 1897, [176], 63.

In previous communications, it has been shown that the acid (dihydroxymaleic acid) obtained by oxidation of tar-

taric acid in presence of iron, decomposes, on heating with water, almost quantitatively into glycollic aldehyde and carbon dioxide. Also, that this aldehyde, when heated in a vacuum, undergoes condensation, yielding a sweet-tasting, solid gum which has the formula  $C_6H_{12}O_6$ .

The present paper describes an investigation which has been made upon the properties of this condensation product.

It is easily soluble in water, and its solution quickly reduces Fehling's solution and ammoniacal silver nitrate. It gives various colour reactions characteristic of "sugars," and, after purification with alcohol, yields, with phenylhydrazine, a normal hexosazone,  $C_{12}H_{22}N_4O_6$ , melting at  $168^\circ$ — $170^\circ$ . Heated with water to  $140^\circ$ , it yields furfural. It is optically inactive, and appears to be incapable of fermentation by yeast.

The purified "sugar," when further heated in a vacuum to  $100$ — $106^\circ$ , loses water and becomes hard and brittle. After 2—4 hours' heating it has the composition  $C_{12}H_{22}O_{11}$  and after 24 hours' heating the composition nearly approximates to  $C_6H_{11}O_5$ .

The conditions under which tartaric acid may be converted into dihydroxymaleic acid by atmospheric oxygen exhibit close analogies with some of the essential conditions of vegetable growth; and it is suggested that the direct production of a "sugar" in the manner above indicated may possibly help to throw light upon the natural formation of carbohydrates.

## PATENT.

*Type, and of Typographic Plates and Matrices, A New Paste [Lithographic] adaptable for the Manufacture of; designed as a Substitute for Lithographic Stones; and Process for the Preparation and Use of this New Paste.* Communicated by C. Delaze, Paris. Eng. Pat. 28,460, Dec. 12, 1896.

The basis of this paste is a limestone found in France near Vigan, in Hungary near Fünfkirchen, and in Bavaria near Munich. This is mixed with oleic acid, vaseline, or paraffin oil and with hydrochloric acid. For the preparation of typographic plates or matrices, silicate of potash is added. If required for lithographic purposes, carbonate of soda is also added. The composition, in the form of a paste, is then blown or cast through a pulveriser on to the surface destined to receive an impression.—V. C.

## New Books.

ENGINEERING CHEMISTRY, A Manual of Quantitative Chemical Analysis for the use of Students, Chemists, and Engineers. THOMAS B. STILLMAN, M.Sc., Ph.D. Professor of Analytical Chemistry in the Stevens Institute of Technology. Chemical Publishing Co., Easton, Pa., U.S. America. 1897. Price, 4.50 dols.

8vo volume containing preface, table of contents, and subject-matter, 505 pages, followed by an alphabetical index. The latter 18 pages of the work are devoted to tables. The text is illustrated with 154 engravings. The plan and scope of the work are given in the following summary of the contents:—Determination of Iron in Iron Wire; of Alumina in Potash Alum; of Copper in Copper Sulphate, &c., &c. Analysis of Limestone. Coal and Coke Analysis. Scheme for Analysis of Hematite, Limonite, and Sphatite Iron Ores. For Analysis of Blast-Furnace Slag. Analysis of Water for Scale-forming Ingredients. Sanitary Analysis of Water. Composition of Boiler Scale. Water for Locomotive Use. Feed-Water Heaters, &c. Determination of Heating Power of Coal and Coke. Calorimetry. Determination of Sulphur in Steel and Cast Iron; of Silicon in Iron and Steel; Aluminium in Iron and Steel, &c., &c. Determination of Sulphuric Acid and  $SO_3$  in fuming Nordhausen Acid; of Zinc in Zinc Ores, &c. Sodium Cyanide as a Component of Potassium Cyanide. The Chemical and Physical Examination of Portland Cement. Determination

of Nickel in Nickel Steel. Analysis of Chimney Gases for O, CO<sub>2</sub>, CO and N<sub>2</sub> of Flue Gases with the Orsat-Mueneke Apparatus; of Coal Gas, Water Gas, Producer Gas, &c. by the Hempel Apparatus, &c. Manufacture of Water Gas and Calculation of Heating Power of Various Illuminating Gases. Practical Potimetry, Calorimetry, Analysis of Clay, Kaolin, Fire Sand, Building Stones, &c. Physical Tests of Building Stones. Alloys. Chemical and Physical Examination of Paper. Soap Analysis. Technical Examination of Petroleum and Lubricating Oils. Oils used for Illumination. Analysis of Lubricating Oils; of Cylinder Deposits. Paint Analysis. Pyrometry. The Electrical Units. Energy Equivalents.

**PRINCIPLES AND PRACTICE OF AGRICULTURAL ANALYSIS.** A Manual for the Examination of Soils, Fertilisers, and Agricultural Products; for the use of Analysts, Teachers, and Students of Agricultural Chemistry. Vol. III. AGRICULTURAL PRODUCTS. By HARVEY WILEY, Chemist of the United States Department of Agriculture. Chemical Publishing Co., Easton, Pa. 1897. Price 3/75 dols.

VOLUME I. of this work has received notice (this Journal, 1895, 401). Vol. III. contains 644 pages of subject-matter, illustrated with 124 engravings, and followed by an alphabetical index. The subjects treated of are classified as follows:—Part I. Sampling, Drying, Incineration, and Extractions. II. Sugars and Starches. III. Separation and Determination of Carbohydrates in Crude and Manufactured Agricultural Products. IV. Fats and Oils. V. Separation and Estimation of Bodies containing Nitrogen. VI. Dairy Products. VII. Miscellaneous Agricultural Products.

**THE PRINTING OF TEXTILE FABRICS.** A Practical Manual on the Printing of Cotton, Woollen, Silk, and Half-Silk Fabrics. By C. F. SEYMOUR ROTHWELL, Lecturer on Calico and Delaine Printing at the Municipal Technical School, Manchester. Chas. Griffin and Co., Ltd., Exeter Street, Strand. 1897. Price 21s.

This work, it is stated, is intended to form a companion volume to Knecht Rawson, and Loewenthal's Manual of Dyeing (this Journal, 1897, 473). The volume is of similar size and appearance to the volume of the last-named work, and contains 302 pages of subject-matter and an alphabetical index, followed by 20 pages filled with printed and dyed patterns. The text is illustrated with 50 wood engravings, and is sub-divided into chapters treating of the following branches of the subject:—INTRODUCTION. Methods of Textile Printing. Styles. I. Machinery used in Textile Printing. II. Thickeners and Mordants. III. Printing of Cotton Goods. a. Bleaching of Cotton Piece Goods for Printing. b. The Steam Style. c. Colours produced directly on the fibre. d. Dyed Styles. e. Padding Style. f. Resist and Discharge Styles. g. Printing of Compound Colourings. IV. Printing of Woollen Goods. V. Printing of Silk Goods. VI. Practical Recipes for Printing. Appendix of Useful Tables.

**NOTES ON ASSAYING.** By P. DE PEYSER RICKETTS, E.M., Ph.D., Professor of Analytical Chemistry and Assaying, School of Mines, Columbia University, and Ed. H. MILLER, A.M., Ph.D. John Wiley and Sons, New York, U.S.A. Chapman and Hall, Ltd., London. 1897. Price 12s. 6d.

8vo volume containing preface, introduction, text filling 289 pages, and alphabetical index. The wood-cut illustrations are 39 in number, and at the close of the volume are given a collection of examples and problems, a list of suitable works of reference, &c. on assaying, and a list of articles for a laboratory outfit for ordinary fire assays, with the costs of these. The work is sub-divided as follows:—PART I. Apparatus. Reagents and Chemicals. Operations. II. Dry or Fire Assays. III. Wet Assays or Analyses. IV. Laboratory Tests for Ores. Assay, Blowpipe, and Qualitative Schemes. V. Tables, Examples, and References.

**THE ELEMENTS OF ELECTRO-CHEMISTRY, TREATED EXPERIMENTALLY.** By DR. ROBERT LUPKE, Lecturer in the Imperial School of Posts and Telegraphs, Berlin. Translated from the 2nd revised and enlarged Edition by M. M. PATTISON MUIR, M.A., Fellow and Lecturer of Gonville and Caius College, Cambridge. H. Grevel and Co., 33, King Street, Covent Garden, London, W.C. 1897. Price 7s. 6d.

"ALTHOUGH the main purpose of this book," as stated in the preface, "is to set forth the scientific aspects of Electro-Chemistry, the practical sides of the subject have not been left unnoticed." The work contains 218 pages of subject-matter, with 54 wood-cuts, and an alphabetical index. The matter is classified as follows:—PART I. Recent Theories of Electrolysis. (i.) Phenomena of Electrolysis. (ii.) Faraday's Law. (iii.) Hittorf's Transport Numbers. (iv.) Law of Kohlrausch. (v.) Dissociation Theory of Arrhenius. PART II. The Theory of Solutions of Van't Hoff. (i.) Osmotic Pressure. (ii.) The Vapour pressures of Solutions. (iii.) Boiling Points and Freezing-Points of Solutions. (iv.) Aqueous Solutions of Electrolytes. PART III. The Osmotic Theory of the Current of Galvanic Cells. (i.) Liquid Cells. (ii.) Concentration Cells. (iii.) Daniell Cells. (iv.) Reduction Cells and Oxidation Cells. (v.) Solution-pressures of the Metals. (vi.) Intensity of Fixation and Polarisation. (vii.) Irreversible Cells. (viii.) Accumulators. (ix.) The Energetics of Galvanic Elements.

**ENTWICKELUNG, BAU UND BETRIEB DER ELEKTRISCHEN OFEN ZUR GEWINNUNG VON METALLEN, CARBIDEN, UND ANDEREN METALLURGISCH-WICHTIGEN PRODUKTEN.** Von Dr. W. BORCHERS. Wilhelm Knapp, Halle a/S., Germany. H. Grevel and Co., 33, King Street, Covent Garden, London, W.C. 1897. Price M. 2/.

PAMPHLET containing 64 pages of subject-matter, illustrated with 42 illustrative engravings, and followed by an alphabetical index of names of authors, discoverers, or inventors. The contents of the little work are classified as follows:—DIE ERHITZUNGSARTEN. I. Widerstandserhitzung. II. Lichtbogenhitzung.

**LE FOUR ÉLECTRIQUE.** Par M. HENRI MOISSAN. G. Steinheil, 2, Rue Casimir-Delavigne, Paris. 1897. Price Fr. 15. H. Grevel and Co., 33, King Street, Covent Garden, London, W.C.

LARGE 8vo volume containing preface, 373 pages of subject-matter illustrated with 41 engravings, 3 pages of a classified Bibliographic index, and a table of contents. The matter is arranged as follows:—I. Description of various models of Electric Furnace. II. Researches on the different Varieties of Carbon. III. Preparation in the Electric Furnace of some Simple Substances. IV. Study of Carbides, Silicides, and Borides. A valuable feature of the work is the brief chapter devoted to "Conclusions" following each section of the subject.

## Trade Report.

### TARIFF CHANGES AND CUSTOMS REGULATIONS.

(From the Board of Trade Journal.)

#### ITALY.

##### Importation of Medicines.

The *Bollettino di Notizie Commerciali* publishes a decree of the Director-General of Taxes, according to which medicinal specialities which are not sold as patent medicines (*rimedi o specifici segreti*) must have a ticket printed with the formula of composition attached, either to the receptacle itself (i.e., the box or bottle in which the medicine is directly contained), or else on the outer wrapper in which the article is exposed for sale when the receptacle is wrapped in another wrapper or contained in a sealed packet or something similar.

March 18, 1897.

SCHOELLKOPF, HARTFORD, AND MACLAGAN, LTD.

## GENERAL TRADE NOTES.

## THE TECHNICAL MUSEUM AT HONG KONG.

*Bd. of Trade J., April 1897, 474.*

The *Manufacturer* (Philadelphia) states that attention has been called to the great success attending the "Technical Museum" in Hong Kong, which, about a year ago, was established by Tschingstschau missionaries. Beginning in a small way, it has been gradually extended, and has become very popular with the Chinese, 82,000 of whom visited it during the last year. The Chinese cannot be convinced or enlightened by circulars or pictures, and hold fast to the belief that the Celestials are vastly superior to the Western barbarians. But when they see, as in this Hong Kong museum, the wonderful achievements of electrical machines, little models of railroads in full operation, and other technical appliances, then they become interested, susceptible to conviction, and willing to have the thing introduced in their country or their houses.

## FRENCH SUGAR PRODUCTION.

*Bd. of Trade J., April 1897, 469.*

The French *Bulletin* of the Minister of Agriculture for March last, states that the sugar season of 1894-95 is characterised by two principal features, *viz.*, the marked increase in the output (a larger amount than has ever been produced in France), and the diminution in prices.

Sugars of 88° have fallen from 33·86 frs., the average price (per 100 kilos.) of 1893-94, to 26·50 frs., and No. 3 sugars from 35·65 frs. to 27·65 frs. This is a result of the general over-production, to which France, long the most important of producing countries, has only contributed in a slight degree.

Twenty years ago, in 1874-75, Germany produced 250,708 tons of raw sugar, Austria 106,312 tons, and France 450,711 tons. In 1894-95 the output of raw sugar has risen in Germany to 1,831,600 tons, in Austria to 1,044,500 tons; but in France to only 745,100 tons.

## THE INDIA-RUBBER TRADE OF LAGOS.

*Bd. of Trade J., April 1897, 181.*

The *Lagos Echo* states that, according to the returns to hand for the period July—December 1896, the total value of imports into the colony was 442,075*l.*, as against 459,302*l.* for the same period in 1895—a decrease of 17,227*l.* The total amount of exports for the same period in 1896 was 456,698*l.*, as against 568,423*l.* in 1895, showing the enormous decrease of 117,726*l.*

The decrease, particularly in the exports, is very marked and unusual, and speaks volumes for the retrogression of the trade of the colony. The item of export in which there is the greatest decrease is rubber, of which commodity there were exported, from July to December 1896, 3,541,287 lb., valued at 198,167*l.*, as against 4,480,871 lb., valued at 240,127*l.*, in 1895, a decrease of 939,584 lb., valued at 41,959*l.* A large portion of this decrease may be set down to the fact that the yield in the near districts has been about exhausted, the trees being nearly all destroyed by the reckless manner in which the bark is stripped; so that collectors have now to seek their supply further from home, where the difficulties of transportation and the additional expense have been such as to discourage many from pursuing the industry. Palm kernels also, however, and palm oil show—especially the former—if not such a large decrease, at any rate a sufficiently marked one.

## THE MINERAL PRODUCTION OF SPAIN IN 1896.

*Eng. and Mining J., April 17, 1897, 379.*

According to his usual custom, Señor Roman Oriol has prepared and published in the *Revista Minera* an interesting summary of the mineral production of Spain for the past year, from which the figures given below are obtained.

*Silver.*—The total production of silver in 1896 is estimated at 222,900 kilos., showing an increase over the preceding year. Of this total, 192,900 kilos. were obtained

from argentiferous lead. The only mines in which silver ores other than lead ores are found are in the province of Guadalajara: these mines produced last year 30,000 kilos. of silver.

**Lead.**—This is the most valuable mineral product of Spain, on account of the large quantity produced and the number of mines. A large part of the ores produced are exported as ores, but the amount of lead made in Spain is considerable. The total quantity of lead ores mined in 1896 was 320,000 metric tons, of which 162,600 tons were exported. The production of metallic lead, including the lead exported in ores, is estimated at 170,790 tons, an increase of 10,000 tons over the preceding year.

**Quicksilver.**—In the quicksilver mining industry, the most notable event in 1896 was the installation of compressed air rock drills in the twelfth level of the Almaden mines. These mines produced 22,100 tons of ore during the year under review. In Asturias, El Porvenir Mining Company raised 7,065 tons of ore; the Union Asturiana, 4,471 tons; and La Soterrana, 670 tons. In Granada, 800 tons were obtained. At Almaden, 16,076 tons were smelted, yielding 41,330 flasks of quicksilver. The total quicksilver production of Spain amounted to 43,884 flasks.

**Copper.**—The copper industry continued its prosperous career in Huelva in 1896. The Rio Tinto Company extracted 1,440,000 tons of cupriferous pyrites. Adding to this the output of other mines, the ore product of the province of Huelva amounted to 2,800,000 tons. The province of Seville produced from the mines of Aznalcollar some 25,000 tons of similar ore, and the mine Profunda, of Villamanin, in Leon, produced 1,050 tons of low-grade ore. The metallurgical treatment of the Spanish ores yielded 33,000 tons of precipitates with 75 per cent. of metal, and 23,000 tons of matte with 45 per cent. of metal. Besides these, 4,174 tons of sulphate of copper were produced by the Rio Tinto Company.

**Zinc.**—The centre of the zinc industry is the province of Santander, where the Royal Asturian Company raised 24,000 tons of crude calamine from the mines at Reocin, and 7,200 tons from the Udias and La Florida mines. From Reocin, also, 810 tons of blende were obtained. Zinc smelting is confined to the Arnao Works, in Asturias, where the out-turn amounted to 6,000 tons of spelter.

**Iron Ore and Iron.**—The production of iron ore in Spain for the year 1896 was 6,808,000 metric tons, an increase of 1,293,671 tons, or 23.5 per cent. over 1895. The exports were 6,253,473 tons, a gain of 1,005,281 tons, or 19.2 per cent. The production of pig-iron in Spain was 246,326 metric tons in 1896, of which 23,805 tons were exported. The production of steel ingots was 101,577 tons, 62,511 tons being made by the Bessemer and 42,066 by the open-hearth process. The total production of wrought iron and steel in bars, plates, and other finished forms was 137,809 tons. There were seven steel and iron works in operation during 1896.

**Coal.**—The production of coal in Spain for the year is given as follows, in metric tons:—

	1895.	1896.	Changes.
Coal .....	1,739,975	1,830,771	Increase, 91,696
Lignite .....	44,008	44,000	Decrease, 8
Total .....	1,783,983	1,874,771	Increase, 91,688

Of the coal in 1896, the Asturias produced 1,122,700 tons; Cordoba, 304,000 tons; Palencia, 132,000 tons; and Ciudad Real, 100,000 tons. Of lignite, Baleares produced 18,000 tons and Barcelona 15,000 tons.

**Other Minerals.**—Iron pyrites were mined and shipped by the Agnas Tenidas Company to the extent of 200,000 tons, a decrease of 40,000 tons from 1895. In manganese mining there was a remarkable gain, the production of manganese ores increasing from 10,162 metric tons in 1895 to 92,000 tons in 1896.

The production of salt amounted to 350,000 tons. The province of Gerona reports an output of 105 tons of barytes

and 592 tons of soapstone. The production of fluorspar in Barcelona has almost ceased, only three tons being reported last year.

#### AMENDMENTS TO THE UNITED STATES PATENT STATUTES.

*Scientific American*, March 20, 1897, 179.

##### The Old Statutes.

Sect. 4886.—Any person who has invented or discovered any new and useful art, machine, manufacture, or composition of matter, or any new and useful improvement thereof, not known or used by others in this country, and not patented or described in any printed publication in this or any foreign country, before his invention or discovery thereof, and not in public use or on sale for more than two years prior to his application, unless the same is proved to have been abandoned, may, upon payment of the fees required by law, and other due proceedings had, obtain a patent therefor.

Sect. 4920.—In any action for infringement the defendant may plead the general issue, and having given notice in writing to the plaintiff or his attorney 30 days before, may prove, on trial, any one or more of the special matters:

Third. That it had been patented or described in some printed publication prior to his supposed invention or discovery thereof; or,

Sect. 4887.—No person shall be debarred from receiving a patent for his invention or discovery, nor shall any patent be declared invalid, by reason of its having been first patented or caused to be patented in a foreign country, unless the same has been introduced into public use in the United States for more than two years prior to the application. But every patent granted for an invention which has been previously patented in a foreign country shall be so limited as to expire at the same time with the foreign patent, or, if there be more than one, at the same time with the one having the shortest term, and in no case shall it be in force more than 17 years.

##### The Amended Statutes.

Sect. 4886.—Any person who has invented or discovered any new and useful art, machine, manufacture, or composition of matter, or any new and useful improvements thereof, not known or used by others in this country before his invention or discovery thereof, and not patented or described in any printed publication in this or any foreign country, before his invention or discovery thereof, or more than two years prior to his application, and not in public use or on sale in this country for more than two years prior to his application, unless the same is proved to have been abandoned, may, upon payment of the fees required by law, and other due proceedings had, obtain a patent therefor.

Sect. 4920.—In any action for infringement the defendant may plead the general issue, and having given notice in writing to the plaintiff or his attorney 30 days before, may prove, on trial, any one or more of the following special matters:

Third. That it has been patented or described in some printed publication prior to his supposed invention or discovery thereof, or more than two years prior to his application for a patent therefor; or,

Sect. 4887.—No person otherwise entitled thereto shall be debarred from receiving a patent for his invention or discovery, nor shall any patent be declared invalid, by reason of its having been first patented or caused to be patented by the inventor or his legal representatives or assigns in a foreign country, unless the application for said foreign patent was filed more than seven months prior to the filing of the application in this country, in which case no patent shall be granted in this country.

AMENDMENTS TO THE U.S. PATENT STATUTES—*cont.**The Old Statutes.*

Sect. 4891.—All applications for patents shall be completed and prepared for examination within two years after the filing of the application, and in default thereof, or upon failure of the applicant to prosecute the same within two years after any action therein, of which notice shall have been given to the applicant, they shall be regarded as abandoned by the parties thereto, unless it be shown to the satisfaction of the Commissioner of Patents that such delay was unavoidable.

Sect. 4898.—Every patent or any interest therein shall be assignable in law by an instrument in writing; and the patentee or his assigns or legal representatives may, in like manner, grant and convey an exclusive right under his patent to the whole or any specified part of the United States. An assignment, grant, or conveyance shall be void as against any subsequent purchaser or mortgagee for a valuable consideration, without notice, unless it is recorded in the Patent Office within three months from the date thereof.

Sect. 4921.—The several courts vested with jurisdiction of cases arising under the patent laws shall have power to grant injunctions according to the course and principles of courts of equity, to prevent the violation of any right secured by patent, on such terms as the court may deem reasonable; and upon a decree being rendered in any such case for an infringement, the complainant shall be entitled to recover, in addition to the profits to be accounted for by the defendant, the damages the

*The Amended Statutes.*

Sect. 4894.—All applications for patents shall be completed and prepared for examination within *one year* after the filing of the application, and in default thereof or upon failure of the applicant to prosecute the same within *one year* after any action therein, of which notice shall have been given to the applicant, they shall be regarded as abandoned by the parties thereto, unless it be shown to the satisfaction of the Commissioner of Patents that such delay was unavoidable.

Sect. 4898.—Every patent or any interest therein shall be assignable in law by an instrument in writing; and the patentee or his assigns or legal representatives may in like manner grant and convey an exclusive right under his patent to the whole or any specified part of the United States. An assignment, grant, or conveyance shall be void as against any subsequent purchaser or mortgagee for a valuable consideration, without notice, unless it is recorded in the Patent Office within three months from the date thereof.

*If any such assignment, grant, or conveyance of any patent shall be acknowledged before any notary public of the several States or Territories or the district of Columbia, or any commissioner of the United States Circuit Court, or before any secretary of legation or consular officer authorised to administer oaths, or perform notarial acts under section 1750 of the Revised Statutes, the certificate of such acknowledgment, under the hand and official seal of such notary or other officer, shall be prima facie evidence of the execution of such assignment, grant, or conveyance.*

Sect. 4921.—The several courts vested with jurisdiction of cases arising under the patent laws shall have power to grant injunctions according to the course and principles of courts of equity, to prevent the violation of any right secured by patent, on such terms as the court may deem reasonable; and upon a decree being rendered in any such case for an infringement, the complainant shall be entitled to recover, in addition to the profits to be accounted for by the defendant, the damages the

AMENDMENTS TO THE U.S. PATENT STATUTES—*cont.**The Old Statutes.*

complainant has sustained thereby; and the court shall assess the same or cause the same to be assessed under its direction. And the court shall have the same power to increase the such damages, in its discretion, as is given to increase the damages found by verdicts in actions in the nature of actions of trespass upon the case.

*The Amended Statutes.*

complainant has sustained thereby; and the court shall assess the same or cause the same to be assessed under its direction. And the court shall have the same power to increase such damages, in its discretion, as is given to increase the damages found by verdicts in actions in the nature of actions of trespass upon the case.

*But in any suit or action brought for the infringement of any patent there shall be no recovery of profits or damages for any infringement committed more than six years before the filing of the bill of complaint or the issuing of the writ in such suit or action, and this provision shall apply to existing causes of action.*

Sect. 7.—*That in every case where the head of any Department of the Government shall request the Commissioner of Patents to expedite the consideration of an application for a patent, it shall be the duty of such head of a Department to be represented before the Commissioner in order to prevent the improper issue of a patent.*

Sect. 8.—*That this Act shall take effect January 1st, 1898, and sections 1, 2, 3, and 4, amending sections 4886, 4920, 4887, and 4894, of the Revised Statutes, shall not apply to any patent granted prior to said date, nor to any application filed prior to said date, nor to any patent granted on such an application.*

Approved, March 3, 1897.

This new law comes into operation on January 1st, 1898.

## THE PATENT LAW.

*Chem. and Druggist, April 17, 1897, 642.*

Sir Courtenay Boyle, Permanent Secretary to the Board of Trade, received, on April 8, a deputation of prominent British manufacturers, mostly from Lancashire, who had come to represent to him that great injury is inflicted upon British commerce by the ineffective character of the Patent and Trade Marks Act of 1883, especially that part of it (section 22) which enables foreigners to take out a patent in the United Kingdom for an invention for which patent rights have been refused them in their own country, or for one which is never worked in Britain at all. In almost every State, except Britain, the granting of patent rights is subject to the condition that the object patented shall be manufactured in the country within a certain time. But in this country the Board of Trade have, nominally, the power to grant licences to work a patent if the patentee "unreasonably" refuses such a licence. During the 14 years' existence of our patents law, however, only four applications for such licences have been made, and not one has been granted, the fact being that the Board of Trade considers itself prevented from exercising its power unless

the patentee absolutely refuses a licence. So long as he stops just short of a direct refusal, he may go on without hindrance making his patented article abroad, and dumping it down here in the finished state. This the deputation want remedied, either by a short Act of Parliament or by action by the Board of Trade. Mr. Ivan Levinstein, who was a member of the deputation, said that between 1891 and 1895 no fewer than 600 patents were granted in this country to foreigners, and in not a single instance of all the number were the goods patented made in this country. Sir Courtenay Boyle could not hold out much hope of alteration in this state of things. There would be no time this Session to pass such an Act as the deputation asked for, he said.

#### PROPOSED TAX ON CALCIUM ACETATE AND OTHER DISTILLATION PRODUCTS OF WOOD IN GERMANY.

*Chem. Ind.* 1897, 20, 133.

A group of forest proprietors in Germany is about to agitate for the imposition of a tax on the products of the dry distillation of wood, with the idea of increasing the market value of the raw material. In this connection it is pointed out that, so far as methyl alcohol is concerned, the only object effected would be to cripple the export colour and other industries employing this product (a good deal of which is imported). So, too, with acetic acid, which Germany is in a position to export in a manufactured condition as lead compounds, dyestuffs, &c.; and the present business done in the purchase of calcium acetate, and its conversion into more valuable products, would also suffer, owing to the difficulties in the way of arranging rebate of duty on re-export.

The case of Austria-Hungary is cited, where the import duty is prohibitive, without, however, increasing the price of wood.—C. S.

#### PRODUCTION OF CAMPHOR IN CHINA.

*A. Henry. Pharm. J.*, 4, 201.

The value of the secretion of *cinnamomum camphora* has only been known to the Chinese for 300 or 400 years, although the tree was valued for its timber from ancient times. The camphor first used in medicine was doubtless Malay camphor. Until recent years no camphor was produced on the mainland of China, but the industry has now been started, and promises to become important. This is the more noteworthy as Formosa has become Japanese territory, and it seemed likely at one time that the Japanese Government would establish a monopoly of the camphor trade. The increase of the camphor industry in China is shown from the fact that in 1885 only 25 piculs were exported from Ningpo, while in 1895 five ports of the Empire exported a total of 1,756 piculs. In Fukien the forests of indigenous camphor trees are considerable, but as yet this district has not furnished any material quantity to the above output, which is chiefly derived from Kwangsi, where it promises to develop in importance.—J. O. B.

Rosin..... Cwt.	116,723	63,387	30,969	18,239
Tallow and stearin "	239,034	182,533	289,638	175,747
Tar..... Barrels	739	752	274	157
Wood:—				
Hewn..... Loads	187,874	136,051	250,686	262,682
Sawn..... "	101,958	114,237	237,662	294,903
Staves..... "	5,886	7,816	29,346	43,818
Mahogany..... Tons	3,768	6,692	35,437	60,463
Other articles.... Value £	..	..	839,316	973,144
Total value .....	..	..	3,330,295	3,381,380

Besides the above, drugs to the value of 73,983*l.* were imported, as against 84,899*l.* in March 1896.

### EXPORTS OF METALS (OTHER THAN MACHINERY) FOR MONTH ENDING 31ST MARCH.

Articles.	Quantities.		Values.	
	1896.	1897.	1896.	1897.
Brass..... Cwt.	10,894	11,823	42,337	49,743
Copper:—				
Unwrought.... "	52,660	26,603	129,296	70,204
Wrought..... "	32,562	27,599	88,145	86,730
Mixed metal... "	21,197	17,649	51,018	44,261
Hardware..... Value £	..	..	180,256	198,265
Implements..... "	..	..	117,015	119,459
Iron and steel... Tons	263,341	351,144	1,862,060	2,290,506
Lead..... "	2,632	2,521	35,061	34,703
Plated wares.... Value £	..	..	30,901	32,926
Telegraph wires. "	..	..	21,238	139,642
Tin..... Cwt.	9,092	5,526	32,357	17,839
Zinc..... "	19,268	10,247	13,258	8,290
Other articles... Value £	..	..	80,014	77,376
Total value .....	..	..	2,684,456	3,169,955

### EXPORTS OF DRUGS AND CHEMICALS FOR MONTH ENDING 31ST MARCH.

Articles.	Quantities.		Values.	
	1896.	1897.	1896.	1897.
Alkali..... Cwt.	449,030	474,790	169,772	117,538
Bleaching materials "	97,878	87,479	34,872	28,532
Chemical manures Tons	40,893	45,561	235,875	240,321
Medicines..... Value £	..	..	98,885	166,137
Other articles.... "	..	..	388,190	437,568
Total value .....	..	..	867,574	930,096

### EXPORTS OF MISCELLANEOUS ARTICLES FOR MONTH ENDING 31ST MARCH.

Articles.	Quantities.		Values.	
	1896.	1897.	1896.	1897.
Gunpowder..... Lb.	680,440	565,700	18,673	13,589
Military stores.. Value £	..	..	126,533	91,213
Candles..... Lb.	1,756,000	2,284,500	28,527	34,548
Caoutchouc..... Value £	..	..	167,361	169,458
Cement..... Tons	30,552	40,733	59,563	67,113
Products of coal Value £	..	..	194,135	162,083
Earthenware..... "	..	..	150,115	167,294
Stoneware..... "	..	..	11,417	17,917
Glass:—				
Plate..... Sq. Ft.	188,940	82,964	8,282	5,749
Flint..... Cwt.	8,926	8,883	19,121	19,265
Bottles..... "	61,518	72,530	28,905	33,472
Other kinds.... "	14,230	18,006	11,534	14,039
Leather:—				
Unwrought.... "	12,030	13,593	113,716	128,327
Wrought..... Value £	..	..	34,224	32,696
Seed oil..... Tons	4,869	6,192	93,803	104,162
Floorcloth..... Sq. Yds.	2,163,300	2,623,500	82,189	104,869
Painters' materials Val. £	..	..	139,996	150,261
Paper..... Cwt.	95,246	99,639	146,478	140,417
Raxes..... Tons	5,147	4,637	27,192	25,961
Soap..... Cwt.	65,654	65,947	69,081	67,682
Total value .....	..	..	2,931,006	3,073,757

## Monthly Patent List.

\* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

### I.—PLANT, APPARATUS, AND MACHINERY.

#### APPLICATIONS.

6916. P. Jensen.—From G. Lunge and L. Rohrmann. Improvements in Glover towers, Gay-Lussac towers, and the like, used, for instance, in the manufacture of sulphuric, muriatic, and nitric acids. March 16.

7071. C. W. Ingraham and P. B. McSwords. Carbureter. March 18.

7108. W. P. Thompson.—From A. Testelin. Improved process and apparatus for spraying, distilling, evaporating, or concentrating liquids. Complete Specification. March 18.

7127. P. Jensen.—From L. Rohrmann and H. H. Niefenfuhr. Improvements in Glover towers and the like. Complete Specification. March 18.

7133. J. Gwynne. Improved method and machinery or apparatus for cooling liquids. March 18.

7331. J. A. Smith.—From B. L. Ryder. Improvements in apparatus for drying fruit and other organic matter. March 20.

7534. H. A. Wheeler. A smokeless furnace. Complete Specification. March 23.

7547. H. H. Schou. Improvements in refrigerating apparatus. March 23.

7664. H. Higgins. Improvements in or relating to drying and sterilising. March 24.

7667. H. Higgins. Improvements in and relating to sterilising apparatus. March 24.

7668. H. Higgins. Improvements in or relating to sterilising apparatus. March 24.

7888. E. Fournier. Improvements in or relating to apparatus for use in sterilising, disinfecting, and similar purposes. Complete Specification. March 26.

8018. J. Grossmann. See Class IV.

8234. T. S. C. Lowe and J. Haug. Improvements in coke, gas, and metallurgical furnaces, and processes connected therewith. Complete Specification. March 30.

8247. J. Laidlaw and J. W. Macfarlane. Improvements in centrifugal machines. March 31.  
 8393. W. McG. Greaves. Improvements in water-heaters and superheaters. April 1.  
 8414. A. H. Crockford and A. S. Vose. Improvements in pressure and vacuum gauges. April 1.  
 8456. J. Muir, E. A. Morse, and F. O. Pierson. Refrigerating apparatus. Complete Specification. April 2.  
 8482. W. Tattersall. Improvements in heating or cooling apparatus. Complete Specification. April 2.  
 8506. F. Wippermann. Improvements in drying apparatus. April 2.  
 8596. T. C. Palmer. Improvements in and connected with condensers. April 3.  
 8775. N. S. Jenkins. Improvements in melting apparatus. April 6.  
 8976. L. Couher. Improved means applicable for use in storing sulphuric acid and facilitating its transport. April 8.  
 9042. T. Fletcher and Fletcher, Russell, and Co., Ltd. Improvements in furnaces for use with light hydrocarbons as fuel. Complete Specification. April 9.  
 9212. M. Graham. Improvements in or relating to apparatus for charging gas and other retorts. April 10.

#### COMPLETE SPECIFICATIONS ACCEPTED.\*

##### 1896.

6377. D. Adorjan. Apparatus for producing highly overheated steam and vapour. March 31.  
 7868. T. C. Sanderson. Apparatus for drying white lead, colours, and other powdery, granular, and nodular substances. March 31.  
 7997. W. Shedlock. Evaporating apparatus, chiefly designed for obtaining salt from brine. March 24.  
 12,557. S. J. Norton and H. A. Stenning. Apparatus for compressing air and other gases. April 14.  
 16,196. J. G. Chamberlain and J. Weddell. Evaporative surface condensers. April 7.  
 19,290. A. J. Boulton.—From O. Patin. Electrical furnaces. April 14.  
 29,587. E. Gauhe and Goekel. Mixing drums. April 7.

##### 1897.

189. W. L. Gilder. Furnaces. March 31.  
 1580. J. Thomas and L. P. Thomas. Presses suitable for the treatment of oil-cake and other materials. March 31.  
 4249. J. Bryson. See Class III.

## II.—FUEL, GAS, AND LIGHT.

#### APPLICATIONS.

6779. M. A. A. E. Boukaine. Process of manufacturing a material suitable for production of acetylene. March 15.  
 6797. A. Ehrenwerth. Process for the manufacture of incandescent light. March 15.  
 6940. H. A. Kent. Improvements in inverted incandescent gas lights, and attachment of incandescing material to same. March 17.  
 6997. G. Pereira, E. Sorel, and B. Cruvellier. Improvements in the manufacture of acetylene gas, and in apparatus therefor. Complete Specification. Filed March 17. Date applied for Nov. 5, 1896, being date of application in France.  
 7013. L. L. Merrifield. Improvements in apparatus for the manufacture of carburetted water-gas. March 17.  
 7043. T. Lyons, J. Lyons, and J. Pearson. Improvements in acetylene gas generators. March 18.  
 7168. F. S. Thorn and C. Hoddle. Improvements in acetylene gas generators. March 19.

7172. Comte Albert Dillon de Micheroux. New process to desulphurate coals, to destroy their smoke and bad smell, to increase the number of their calories, &c. March 19.  
 7177. E. Bohm. Improvements in and in means for the production of ozone. March 19.  
 7295. P. L. Caron. Improved apparatus for producing acetylene gas. March 20.  
 7296. P. Guerard. Apparatus for the automatic production of acetylene gas. March 20.  
 7330. R. Schoder. A process for stiffening incandescence mantles. March 20.  
 7435. C. Billington, jun. An improved method of and means for removing "scum" or retort carbon from gas retorts. March 23.  
 7651. A. Arter. Improvements in apparatus for the treatment of gas for illuminating and other purposes. March 24.  
 7744. E. G. Brewer.—From The Gesellschaft für Acetylen-Gaslicht Basel. Improvements in apparatus for generating acetylene gas. Complete Specification. March 25.  
 7782. H. H. Lake.—From F. Ferracini. Improvements in apparatus for automatically generating acetylene gas. Complete Specification. March 25.  
 7858. E. S. Higgins, H. A. Bessemer, and W. B. Nicholson. Improvements relating to the production of gas and its utilisation for the generation of steam and for other purposes, and to apparatus therefor. March 26.  
 7918. J. G. A. Kitchen. Improvements in or relating to acetylene generators. March 27.  
 7920. J. B. de Lery. Improvements in the method of and apparatus for effecting illumination partly by flame and partly by incandescence. Complete Specification. March 27.  
 7921. J. B. de Lery. Improvements in and connected with burners for incandescence gas lighting. Complete Specification. March 27.  
 7929. F. H. Smith. An acetylene gas lamp or generator. March 27.  
 7956. W. B. Hartridge. Improvements in the manufacture of artificial fuel blocks, and apparatus for that purpose. March 27.  
 7991. A. A. Stephenson. An improved composition and apparatus for enriching gas. March 29.  
 8007. R. Dixon. Improvements in or relating to the manufacture of coke. March 29.  
 8108. J. G. A. Kitchen. Improvements in or relating to acetylene generators. March 30.  
 8270. J. G. A. Kitchen. Improvements in and relating to acetylene generators. March 31.  
 8332. A. E. Yeadon and S. N. Yeadon. Improvements in the manufacture of briquettes or compressed blocks for fuel smelting or other analogous purposes. April 1.  
 8359. C. W. Kemp. Improvements in or relating to incandescent gas lighting. April 1.  
 8363. W. C. Perrins. Improvements in gas lighting. April 1.  
 8485. E. Bouchaud-Praceiq. Improvements in apparatus for carburising air. April 2.  
 8513. J. A. Bellon-Lencanhez. Improvements relating to the production and purification of gas, and apparatus therefor. April 2.  
 8551. J. H. Exley. Improvements in apparatus for manufacturing acetylene gas. April 3.  
 8552. H. Cousin. Improvements in apparatus for manufacturing acetylene. Complete Specification. April 3.  
 8583. W. Blackie. Improvements in the manufacture of oxygen gas, and apparatus therefor. April 3.  
 8721. V. Meune. Improved acetylene gas generator. April 6.  
 8759. D. Meyer. Improvements in incandescent gas burners. Complete Specification. April 6.  
 8793. W. P. Barltrop. An improved apparatus for the production of acetylene gas. April 6.

\* See Note (\*) on previous page.

8989. J. G. Kerr and C. Fry. Improved apparatus for the production and storage of acetylene gas. Complete Specification. April 8.

9019. D. A. Casalonga. Improved method and plant or apparatus for the treatment of wood for the manufacture of charcoal. April 8.

9045. C. O. Rusling. Improvements in protecting and sustaining the mantles of "Welsbach" and similar lights. April 9.

9126. C. H. Stearn. Improvements in the manufacture of filaments for incandescence lamps. April 9.

9175. F. Wilkins. Improved apparatus and fittings for impregnating atmospheric air with pure volatile hydrocarbon in substitution of gas for producing light, heat, or power. April 10.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

6349. H. Hart. Illuminating apparatus. March 31.

6852. H. C. B. Forester. Apparatus for pressing artificial or patent fuel or the like into solid form. March 31.

6853. H. C. B. Forester. Manufacturing artificial or patent fuel. March 31.

6922. V. B. Lewes. Manufacture or production of illuminating gas. March 31.

9244. W. Nicholls. Manufacture of incandescence bodies for illuminating purposes. April 14.

9316. C. E. Botley and C. F. Botley, jun. Treatment of gas for illuminating and other purposes. March 31.

11,737. E. Clausolles. Apparatus for the production and storage of acetylene gas for illuminating purposes. March 31.

12,788. R. R. Gibbs. Generation and storage of acetylene. March 31.

15,654. D. Whalley and J. Hacking. Acetylene gas store generators. March 24.

16,277. L. V. Pratis and P. Marengo. Production of pure hydrogen gas and the application of hydrogen to the obtaining of light, heat, and power. March 31.

16,277A. L. V. Pratis and P. Marengo. The utilisation of hydrogen gas for the obtaining of light, heat, and power. April 14.

20,529. G. S. T. Gastine. Apparatus for the production of acetylene. March 24.

23,592. G. Trouve. An acetylene lamp. March 24.

24,558. H. H. Lake.—From V. Hanotier and G. Hostelet. Lamps adapted for producing and burning acetylene gas. March 31.

26,261. J. C. Mewburn.—From F. G. Bates. Manufacture of combustible gas, including illuminating gas in motor engines driven by such gas and in steam generators. March 24.

29,202. D. Nagy. Process for making brown coal and lignite coke. March 24.

29,863. C. Dellwik. Production of water-gas and apparatus therefor. March 24.

1897.

911. V. Daix. Production of acetylene gas. April 14.

1153. E. H. F. des Essards. An improved generator for acetylene and certain other gases. April 14.

1440. A. J. Boulton.—From H. F. Fuller. Apparatus for the generation of gas. March 31.

2284. R. E. Carter. Apparatus for the production and storage of acetylene gas. April 7.

#### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

##### APPLICATIONS.

7233. G. W. Jobson.—From Kalle and Co. Improvements in the manufacture of guaiacol. March 19.

9019. D. A. Casalonga. See Class II.

#### COMPLETE SPECIFICATION ACCEPTED.

1897.

4219. J. Bryson. Retorts for the distillation of shale and other bituminous substances, or for the calcining of ironstone, lime, and other substances. March 31.

#### IV.—COLOURING MATTERS AND DYES.

##### APPLICATIONS.

6913. H. R. Vidal. An improved manufacture of colouring matters. Filed March 16. Date applied for March 11, 1897, being date of application in France.

7213. H. H. Lake.—From The Farbwerk Muhlheim vormals A. Leonhardt and Co. Improvements in the manufacture of sulpho acids of the naphthalene series and of colouring matters derived therefrom. March 19.

7329. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of new safranine derivatives. March 20.

7337. S. Pitt.—From L. Cassella and Co. Improvements in the production of azosafarine derivatives. March 20.

7341. J. Y. Johnson.—From C. F. Boehringer and Soehne. Improvements in the preparation of alkylated uric acids. March 20.

7701. W. H. Claus and A. Rec. Manufacture of brown colouring matters containing sulphur. March 25.

8018. J. Grossmann. Apparatus for testing indigos and other dyes and colours. March 29.

8175. G. B. Ellis.—From La Société Chimique des Usines du Rhone, anciennement G. P. Mounet et Cartier. Improvements in the manufacture of colouring matters. March 30.

8188. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. Improvements in the manufacture or production of colouring matters. March 30.

8235. G. W. Johnson.—From Kalle and Co. Improvements in the manufacture and production of azo dyestuffs or colouring matters suitable for dyeing cotton. March 30.

8353. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of new safranine derivatives. April 1.

8569. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. Improvements in the manufacture or production of colouring matters. April 3.

8994. A. M. Clark.—From Kullmann and Rapp. A process for the production of new tetra-azo compounds. April 8.

9092. M. N. J. Rigby. An instantly drying ink. April 9.

9213. H. R. Vidal. Improvements in the preparation of diphenyl, dinaphthyl, and their derivatives. April 10.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

7596. Levinstein, Ltd., and I. Levinstein. Manufacture or production of new colouring matters. April 14.

8860. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Process for discharging para-nitro-aniline red fabrics, white and coloured, and manufacture of a discharging colour therefor. March 31.

9343. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of basic disazo dyestuffs. March 24.

11,309. Read, Holliday, and Sons, Ltd., and H. Dean. Manufacture of basic colouring matters. April 14.

18,489. H. R. Vidal. Manufacture of sulphuretted colouring matters. March 24.

20,250. B. Willcox.—From The Badische Anilin and Soda Fabrik. The manufacture and production of colouring matters from dinitronaphthalenes. April 14.

1897.

1145. H. Inray.—From F. Peterson and Co. Manufacture of new colouring matters from benzidin sulpho acids. March 31.

## V.—TEXTILES, COTTON, WOOL, SILK, Etc.

### APPLICATIONS.

6768. O. Inray.—From The Farbwerke vormals Meister, Lucius, and Brüning. A method of improving cotton fibre. March 15.

7093. C. D. Abel.—From J. Kleinewefers Sohn. Process and apparatus for mercerising cotton in the form of hanks. March 18.

8460. K. T. Sutherland. Improvements connected with the removal of gum and such like from fibres. April 2.

9056. E. Crepy. Improvements in the method of and means for "mercerising" vegetable fibres, fabrics, and the like. April 9.

### COMPLETE SPECIFICATION ACCEPTED.

1896.

12,897. L. Frankenstein. Finishing or ornamenting the surface of waterproof fabrics. April 7.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

### APPLICATIONS.

7622. J. Tait. See Class XIX.

7821. S. Schwabe and Co., Ltd., A. Binz, and R. Boral. Improvements in printing textile fabrics which may be subsequently dyed. March 26.

8033. W. Watson and E. Bentz. Improvements in the production of coloured discharge patterns on indigo-dyed cotton fabrics in calico-printing. March 29.

8114. O. H. Stone. A new or improved process of colouring papers. March 30.

9011. L. Koenig, jun. Improved appliance for dyeing and bleaching textile staples, filaments, or fibres, on tubes and bobbins. April 8.

### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

7977. H. W. V. Wilson and W. Brown. Apparatus for varnishing or otherwise coating paper, cardboard, or other material. April 7.

8311. L. C. G. Lesage. Process and apparatus for use in colour printing. April 7.

## VII.—ACIDS, ALKALIS, AND SALTS.

### APPLICATIONS.

6916. P. Jensen.—From G. Lunge and L. Rohrmann. See Class I.

7066. W. Garroway. Improvements in the manufacture of ammonium nitrate and other salts. March 18.

7192. A. Schmidt. Process and apparatus for the production of the acetates of lead, copper, and the like. Complete Specification. March 19.

7715. J. McGougan and A. McGougan. Improved process for the production of nitrites of the alkali or alkaline earth metals. March 25.

8094. B. C. Hinman. A new manufacture of a salt or compound containing bromine. March 29.

8220. S. Bourgeois, A. Leneauchez, L. Hoche, and E. Isidor. Improvements in or relating to apparatus for the recovery of ammonia and other products from gases. March 30.

8335. W. Wyld and J. H. Cox. Improvements in the means or method of manufacturing ferric sulphate. April 1.

8671. B. C. Hinman. A new manufacture of a salt or compound containing bromine. April 5.

8976. L. Couher. See Class I.

9099. T. Savage. Improvements in the production of nickel sulphate. April 9.

9161. A. J. Bambridge and G. Weddell. Improvements in the manufacture of bicarbonate of soda and of carbonate and bicarbonate of ammonia. April 10.

9215. H. R. Vidal. An improved process for manufacturing alkaline cyanides and other cyanated products. April 10.

### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

10,252. D. A. Peniakoff. A process for obtaining and extracting caustic alkalis from alkaline aluminates, and hydrates of barium and alumina from barium aluminate. April 14.

15,834. A. J. Outhenin-Chalandre. Electrolysis of soluble salts, especially applicable for the production of chlorine. April 7.

## VIII.—GLASS, POTTERY, AND ENAMELS.

### APPLICATIONS.

6840. A. D. Brogan, A. M. Malloch, and J. Craig. Improvements in and relating to leers or kilns for annealing glass. March 16.

8494. L. Mondron. Improvements in the manufacture of plates of glass designed for covering walls, ceilings, and other surfaces. Complete Specification. April 2.

### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

7899. R. Stanley. Ovens for drying and burning tiles, pottery, and other plastic or semi-dry ware. April 14.

8148. The Coalport China Co., Ltd., and T. J. Bott. Ornamentation or decoration of china, earthenware, glass, and like ware. March 31.

10,471. W. West. Apparatus for the manufacture of moulded clay, earthenware, and ceramic articles. April 14.

15,804. J. Davis and A. J. Davis. Method of producing coloured glass lights for lenses, also applicable for other suitable purposes. April 7.

17,391. P. T. Sievert. Manufacture of sheets, cylinders, and other forms of glass. April 14.

1897.

334. G. G. M. Hardingham.—From G. W. Blair. Manufacture of glass articles. March 24.

1432. A. J. Boulton.—From P. A. J. Gasse. Decoration of earthenware, china, glass tiles, bricks, and the like. April 7.

3376. E. W. Brock. New or improved process for transferring printed matter from paper to glass, earthenware, and other enamelled surfaces. April 7.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

### APPLICATIONS.

7798. T. Parker.—From G. W. Parker. Improvements in the art, method, or process of treating gypsum rock for the production of artificial marble and the like. March 25.

8261. J. Howden. Improvements in fireproof floors. Complete Specification. March 31.

8268. J. Sayers. Improvements in the manufacture of artificial stone and the like. March 31.

9030. T. C. Hutchinson. An improved treatment of blast-furnace slag or scoria for the manufacture therefrom of hydraulic or similar cement, or for other purposes requiring use of dry granulated slag. April 9.

9072. D. Wilson. An improved cement or concrete. April 9.

9073. D. Wilson. Improvements in the manufacture of slabs for the beds of billiard tables and other purposes, steps and blocks for building and other purposes, pillars, columns, posts, poles, chimney pots, pipes, or tubes, baths, sinks, tanks, buckets, casks, drums, or barrels, and other hollow articles and vessels. April 9.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

9100. J. C. Nichol. Material to be used as a substitute for wood, and to be known as "fabricoid." April 14.

11,182. W. P. Thompson. Method of preparing or treating wood. March 31.

11,682. J. Dixon and A. Reynolds. Manufacture of silica bricks or other highly refractory bricks. April 14.

26,847. J. J. Moffat. Fireproof floors, ceilings, walls, and partitions. Nov. 26.

29,654. O. Kraner. Process for the production of a material for making floors, plasterings, ceilings, walls, roofs, and the like without joints or chinks. April 7.

1897.

2085. C. A. Allison.—From E. P. Stone. Process of solidifying wood. April 7.

2402. W. D. Cliff. Glazed bricks, and manufacture of the same. April 7.

2791. F. S. Wisner. Method of manufacturing stone-ware and the like. April 7.

3345. C. Lucke. Presses for forming artificial stones, slabs, tiles, and the like. April 7.

4048. W. S. Robinson and S. M. Brookfield. Cement and concrete. March 31.

#### X.—METALLURGY, MINING, Etc.

##### APPLICATIONS.

6881. H. R. Cassel and B. C. Hinman. An improved process of and apparatus for extracting gold from its ores and compounds. March 16.

6890. W. H. Stallard.—From J. H. R. Whinfield. Improved method for treating iron and steel and other metals. March 16.

6991. H. Griffith, jun.—From V. Coppee and A. E. Kemplen. Improvements relating to aluminium. March 17.

6992. H. Griffith, jun.—From V. Coppee and A. E. Kemplen. Improvements relating to the casting of aluminium and other metals. March 17.

6993. H. Griffith, jun.—From V. Coppee and A. E. Kemplen. Improvements relating to the brazing of aluminium. March 17.

7021. La Société des Cuivres de France. Process and apparatus for obtaining pure copper in a single operation. Filed March 17. Date applied for Aug. 26, 1896, being date of application in France.

7198. J. Cope. Improvements in and relating to nickel or nickel-alloy castings. March 19.

7218. B. Becker. Improvements in extracting precious metals from minerals containing them, and apparatus therefor. March 19.

7234. S. O. Cower-Coles. Improvements in or connected with means for separating metals from cyanide solutions. March 19.

7532. E. A. Ashcroft. Improvements in the combined electrolytic and leaching treatment of zinc-bearing ores and zinc-bearing products. March 23.

7555. H. R. Cassel and B. C. Hinman. An improved process of and apparatus for extracting gold from its ores and compounds. March 23.

7756. W. J. May. Improvements in potassium fluxes for use in the manufacture and casting of iron or steel. March 25.

7757. W. J. May. Improvements in fluxes for use in the manufacture and casting of steel. March 25.

7758. W. J. May. Improvements in metallic sodium fluxes for use in the melting or working of metals. March 25.

7988. H. M. Martin. Improvements in the production of castings. March 29.

8040. A. Gilbertson and D. Jenkins. A new or improved method or process for the manufacture of sheets of iron, steel, or other material. March 29.

8273. J. Nicholas. Improvements in the recovery of metals contained in ores or other compounds. March 31.

8376. G. Kentler and F. Steinert. Process and apparatus for recovering iron from slag-heaps. Complete Specification. April 1.

8577. B. K. Jamison. Improvements in the manufacture or treatment of armour plates and in apparatus employed therein. April 3.

8578. B. K. Jamison. Improvements in the manufacture or treatment of steel or nickel steel, and of articles made from steel, and in apparatus employed therein. April 3.

8626. F. Moss and S. J. Davis. A new process for staining and colouring metals and for other suitable purposes. April 5.

8763. C. H. Foote, W. R. Walker, and E. A. S. Clarke. Improvements in the manufacture of steel by the Bessemer or open-hearth process. Complete Specification. April 6.

8873. W. Noad and W. Agate. An improvement in the obtainment of copper from ores and other copper-bearing substances. Complete Specification. April 7.

8887. O. Imray.—From The Pennsylvania Salt Manufacturing Co. Improvements in apparatus and appliances for casting metals. April 7.

8990. G. H. Blenkinsop. Improvements in or relating to the smelting of mixed minerals, ores, and the like containing lead and zinc. April 8.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

7315. J. E. Preston. Amalgamating apparatus. April 6.

7422. R. A. Hadfield. Manufacture of steel or alloy of iron. April 7.

7436. W. Gibbings. Blast furnaces. April 14.

8967. S. Vivian. Recovery of gold, silver, and other precious metals. March 24.

10,494. J. R. Wylde, J. W. Kynaston, and J. Brock. Extraction of zinc from ferruginous liquors, specially applicable to the treatment of the spent liquors of copper works. April 7.

10,864. B. Politzer. A process for protecting metallic surfaces against chemical and atmospherical action. March 24.

11,555. D. A. Peniakoff. A process of manufacture of sulphate of aluminium, which may or may not be combined with other sulphides. April 7.

12,782. A. Wilson and F. Stobbs. Carbonising iron and steel. April 14.

23,817. B. Meyer. Treatment of weldable iron. March 31.

30,144. A. F. Cothias. Process of casting for reducing the density of cast articles. March 31.

1897.

2789. H. S. Lloyd. Storage batteries. March 31.

4136. W. B. Johnson.—From The Pennsylvania Salt Manufacturing Co. Apparatus for casting metals. March 31.

4309. S. Neffgen. Process of treating granular or pulverulent iron ores and slag, or other residues containing iron, to facilitate the extraction of the same. March 24.

## XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

### APPLICATIONS.

6818. J. Entwisle.—From C. T. Barret. An improved storage battery. Complete Specification. March 16.

6929. F. Taylor, A. Cooke, and B. W. D. Montgomery. An improved diaphragm for separating the gases in electrolysis of sodium chloride and other salts, and other improvements. March 17.

7024. G. W. de Tonzelmann and C. W. Baker. Improvements in electric welding. March 17.

7027. A. J. Marquand. Improvements in and relating to secondary batteries or accumulators, and the manufacture thereof. March 17.

7113. F. H. Perry. Improvements in primary batteries. March 18.

7314. F. E. Everard. Improvements in or relating to accumulator plates or electrodes for secondary batteries. March 20.

7775. W. J. S. Barber-Starkey. Improvements in or relating to electrodes for secondary batteries. March 25.

7958. E. A. Jahneke. Improvements in and connected with electric batteries. March 27.

8059. D. G. Fitz-Gerald. Improvements in elements for secondary batteries and electrodes for electrolysis. March 29.

8131. S. V. B. Essick. Improvements in primary electric batteries or generators. Complete Specification. March 30.

8231. G. F. Redfern.—From C. Riordon. Improvements in storage batteries. Complete Specification. March 30.

8537. H. Stanhope. Improvements in or connected with electric batteries. April 3.

8696. A. P. Laurie. Improvements in secondary batteries or storage cells. April 6.

9118. L. Epstein. Improvements in secondary voltaic batteries. April 9.

### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

8080. E. Commelin and R. Vian. An improved electrical accumulator under pressure. April 14.

10,472. G. A. Grindle. An improvement in active material for secondary voltaic batteries. March 31.

10,718. H. O. Tador. Manufacture of positive lead electrodes for electrical accumulators. April 7.

11,212. T. Clark. Dry cells for galvanic batteries. April 7.

11,730. W. P. Thompson.—From The Elektra Galvano-plastische Anstalt, H. Teich, and A. Floeck. Apparatus for producing galvanic or electrolytic depositions. April 14.

11,732. E. Grunwald. Plate for storage batteries. April 14.

19,218. E. J. Constan and A. von Hansen. Manufacture or production of chemical products by electrolysis. April 14.

25,360. F. H. Snyder. Improvements relating to the coating, covering, or amalgamating of metals with metals, and of other substances with metals and other materials, by the aid of electricity, and to apparatus therefor. March 24.

27,262. O. Rothmund, E. von Burgwall, and L. Ofenschussl. An improved primary element with interchangeable electrodes and regenerable positive electrodes. March 31.

29,306. A. Heil. Secondary batteries. March 24.

1897.

859. Aschermann. Process for the extraction of metallic alloys and pure metals by electric heat. March 31.

995. W. S. Doe. Galvanic batteries. March 31.

## XII.—FATS, OILS, AND SOAP.

### APPLICATIONS.

7228. P. Villain. Improvements in the manufacture of scented antiseptic, medicinal, or multi-coloured or variegated soap, and in machinery or apparatus therefor. March 19.

8560. T. McKinnon. Improvements in or relating to soaps or other like preparations. April 3.

8796. E. G. Scott. Improvements in and connected with the saponification of fatty matters and in the manufacture of glycerine. April 6.

## XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, Etc.

### APPLICATIONS.

7014. N. W. Meadows. A process for reclaiming india-rubber from fabrics coated on both surfaces. March 17.

7399. E. O. S. Gentile and H. R. Gentile. Improvements in and in the manufacture of pigments, printing inks, or paint mixtures. Complete Specification. March 22.

8479. J. F. Spong. Improvements in compounds of india-rubber. April 2.

8510. C. A. Hakanson, J. H. Hakanson, and A. R. Hakanson. Paint or composition to be used as a coating, more especially in the manufacture of artificial slates and for coating tiles, plates, and other articles. April 2.

8811. R. Hingston and J. C. Rankin. An improved anti-fouling and anti-corrosive paint. Complete Specification. April 6.

### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

12,451. E. Cadoret. Plastic and incombustible material—textiloid—to be used as a substitute for india-rubber, celluloid, leather, oil-cloth, linoleum, mother-of-pearl, tortoise-shell, amber, ivory, and the like, and capable of being moulded, drawn or made into threads, and in the form of plates, tubes, cylinders, or soft or silky threads resembling silk in appearance. April 7.

26,548. F. Fenton. Production of artificial gutta-percha and caoutchouc-like substances. March 31.

## XIV.—TANNING, LEATHER, GLUE, AND SIZE.

### APPLICATIONS.

6769. O. Imray.—From The Farwerke vormals Meister, Lucius, and Brüning. See Class XXI.

7270. E. White. Improvements in apparatus for tanning hides and skins. March 19.

8042. A. Mitscherlich. Process for the manufacture of glutinous substances. March 29.

8391. A. Zimmermann. Improvements in the treatment of gelatinous substances, skins, and the like. April 1.

8632. G. Honeyman, S. Honeyman, and R. Arneil. An improved method for the manufacture of chrome-tanned leather. April 5.

9106. E. O. Daniel. Improvements in the preparation for and tanning of hides and skins. April 9.

### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

13,686. H. Schmidt and J. Landini. Arrangement for performing a continuous work of tanning. April 14.

1897.

5762. A. J. Boulton.—From G. L. Lippold. Improved substitute for leather or like material, and the method of manufacturing the same. April 14.

## XV.—AGRICULTURE AND MANURES, Etc.

### COMPLETE SPECIFICATION ACCEPTED.

1895.

9789. F. M. Mooney and A. Dickson. Manufacture and storing of superphosphates and the like. April 14.

## XVI.—SUGARS, STARCHES, GUMS, Etc.

### APPLICATIONS.

7861. M. Sachs. Processes for separating impure sugar at one operation into crystallised sugar and molasses. March 26.

9108. A. J. Boulton.—From C. M. Higgins. Improvements in or relating to adhesive compounds. Complete Specification. April 9.

### COMPLETE SPECIFICATION ACCEPTED.

1897.

1144. A. Classeu. Manufacture of chemical compounds of starch and dextrine, or equivalent bodies, with formaldehyde or its equivalents. March 24.

## XVII.—BREWING, WINES, SPIRITS, Etc.

### APPLICATIONS.

8080. B. J. B. Mills.—From A. Dalmote. An improved diastasic preparation to be employed in the manufacture of bread and other foods and beverages, and to be used as an aid to digestion. March 29.

8223. J. G. Hathaway. An improved method of and apparatus for purifying and maturing alcoholic liquors. March 30.

9018. O. Trachmann. Process and product for the preparation of certain kinds of beer. April 8.

### COMPLETE SPECIFICATIONS ACCEPTED.

1896.

13,262. B. W. Valentin. Manufacture of material for use in brewing or priming ales and beers. April 7.

29,965. J. Y. Johnson.—From The Electric Rectifying and Refining Co. Apparatus for treating or purifying, rectifying, ageing, deodorising, and decolorising alcoholic and other liquids or liquefied matter. March 31.

1897.

2434. J. Sinclair. Improved valve fittings for use in fermenting vats or stone squares. April 14.

## XVIII.—FOODS, SANITATION, Etc., AND DISINFECTANTS.

### APPLICATIONS.

#### A.—Foods.

6915. K. I. O'Doherty. An improved method of preventing the decomposition of animal, vegetable, or other alimentary substances or products. Complete Specification. Filed March 16. Date applied for Aug. 27, 1896, being date of application in Queensland.

7220. A. S. Peyser. A method of treating milk and obtaining therefrom a gelatinous proteid substance and thus forming a nourishing food for invalids and others. March 19.

7649. K. Franz. A new or improved food preparation and process for the manufacture thereof. Complete Specification. March 24.

8052. W. P. Thompson.—From E. O. Taffin. Improved substitute for coffee and process of making the same. March 29.

8080. B. J. B. Mills.—From A. Dalmote. See Class XVII.

8586. T. Hyatt. Improvements in the treatment and utilisation of chicory. Complete Specification. April 3.

#### B.—Sanitation.

7436. E. Phillips. Improvements in the disposal of sewage, and in the collection and storage of gas given off in such process. March 23.

8281. G. A. de Katow.—From Riensch and Co. A new or improved process and apparatus for purifying and utilising town sewerage. March 31.

8375. P. J. Fröh. Process and apparatus for removing all dirtying ingredients in the chimney smoke. April 1.

8500. W. M. Ducat. An improvement in or connected with the purification of water sewage and other foul liquids. April 2.

#### C.—Disinfectants.

6823. J. L. Mortimer and J. H. Williams. A new and improved disinfecting and antiseptic block. March 16.

### COMPLETE SPECIFICATIONS ACCEPTED.

#### A.—Foods.

1896.

7042. H. Higgins. Preservation of foods and other perishable goods. March 31.

7880. R. Haddan.—From Kathrein's Malzkaffee Fab. mit beschränkter Haftung. Process for producing coffee substitutes for grain. April 7.

11,060. J. Davidson. Manufacture of products from tea. March 24.

23,400. H. H. Lake.—From A. Astolfi and E. Brugnattelli. Improved alimentary substance. April 7.

25,295. H. D. Perky. Method and means for the reduction of grain to thread-like or shredded form, and for the disposition of the same in the manufacture of biscuit and other forms of bread. March 24.

27,114. S. P. Sorenson and A. P. Heyman. Manufacture of artificial food for swine, cattle, and the like. March 24.

#### B.—Sanitation.

1896.

11,243. E. W. T. Jones and J. Garfield. Purification of sewage and other liquids. April 7.

15,208. H. W. Kearns. Apparatus or means for treating the sludge or deposit from foul waters and the like. March 24.

23,676. S. de Petroff. A new or improved method for the treatment of town sewage, refuse, and the like, for the destruction of animalculæ and the production of a fertilising compound. April 7.

#### C.—Disinfectants.

1896.

1978. S. Wohle and A. C. Irwin. Manufacture of detergent. April 7.

## XIX.—PAPER, PASTEBOARD, Etc.

### APPLICATION.

7622. J. Tait. Improvements in bleaching and purifying paper pulp. March 24.

## COMPLETE SPECIFICATIONS ACCEPTED.

1896.

210. H. H. Lake. — From E. Berland and J. Girard. Manufacture of paper pulp from the broom plant. April 7.  
 9100. J. C. Nichol. See Class IX. April 14.  
 12,682. W. A. Kershaw and The Medway Paper Mills Co., Ltd. Manufacture of multiple-pulp papers. April 14.

1897.

1550. P. H. Hansen and J. K. Westengaard. Manufacture of artificial horn and the like. March 24.  
 4099. A. A. Hunting and E. A. Leigh. Method and apparatus for drying paper and similar materials. April 7.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

## APPLICATIONS.

6790. E. H. C. Durkopf. Improvements in the manufacture of products of condensation from formaldehyde and tannin. March 15.

7341. J. Y. Johnson. — From C. F. Boehringer and Soehne. See Class IV.

8026. C. Castel. Improvements in the manufacturing of acid ethyl-sulphuric and the production of alcohol. March 29.

8308. F. Richard. Improvements in vaporising apparatus suitable for converting methyl alcohol into formic aldehyde. March 31.

8387. H. Mack. Method of producing highly concentrated fat solutions of fragrant substances. Complete Specification. April 1.

8671. B. C. Hinman. See Class VII.

8915. J. Y. Johnson. — From C. F. Boehringer and Soehne. Method of preparing alkylated dichloroxypurines. April 7.

## COMPLETE SPECIFICATIONS ACCEPTED.

1896.

7712. A. Classen. Production of formaldehyde compounds of the albumen and protein bodies. March 3.

9576. H. E. Newton. — From The Farbenfabriken vormals F. Bayer and Co. Manufacture of a pharmaceutical substance. March 31.

- 10,003. J. Y. Johnson. — From C. Boehringer and Soehne. Manufacture or production of cionamic aldehyde. March 31.

- 10,005. E. Fischer. A method of preparing alkylated uric acids. April 14.

- 11,061. J. Turner and Co., Ltd., and P. Schidrowitz and O. Rosenheim. Manufacture of derivatives from piperidine, tetra-hydro-quinoline, and their homologues. April 7.

- 24,568. A. Blaile. Process for the manufacture of artificial musk. April 14.

1897.

1164. W. L. Wise. — From The Chemische Fabrik von Heyden Gesellschaft mit beschränkter Haftung. Manufacture of

ture of *o*-sulphamin benzoic acid alkylesters and of anhydro-*o*-sulphamin benzoic acid. March 31.

## XXI.—PHOTOGRAPHY.

## APPLICATIONS.

6704. J. Joly. Improvement in or relating to photography in colours. March 15.

6769. O. Imray. — From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of prepared sensitised leather for photographic purposes. March 15.

## COMPLETE SPECIFICATIONS ACCEPTED.

1896.

- 18,131. J. A. Michel-Dausac and L. Chassagne. Means for reproducing the colours in photography, suitable also for dyeing and printing. March 31.

1897.

5026. A. Rateau. Chromo-photographic apparatus. April 7.

## XXII.—EXPLOSIVES, MATCHES, Etc.

## APPLICATIONS.

6772. F. Müller, S. Oberlander, V. H. Fuchs, and S. Gomperz. Improved blasting compound, and process for its manufacture. March 15.

6995. B. E. Dickinson and Kynoch, Ltd. Improvements in fog signals. March 17.

8555. J. Nicholas. Improvement in explosive compounds. April 3.

9111. W. Greaves and E. M. Hann. Improvements in or relating to explosives. April 9.

## COMPLETE SPECIFICATIONS ACCEPTED.

1896.

- 14,007. F. M. Hale and J. B. Reavil. Percussion fuses for explosive projectiles or shells. April 14.

1897.

1154. F. W. Jones. Manufacture of explosives. March 24.

## XXIII.—ANALYTICAL CHEMISTRY.

## COMPLETE SPECIFICATION ACCEPTED.

1896.

- 10,627. R. Wells. Apparatus for testing butter, margarine, and the like, and method of employing such apparatus. March 31.

## PATENT UNCLASSIFIABLE.

## APPLICATION.

8227. G. L. Schaefer. Improvements in chemical compounds. Complete Specification. March 30.

# THE JOURNAL OF THE Society of Chemical Industry.

Single Copies (Members only) 2 6.]

## The Society of Chemical Industry.

### Past Presidents:

Sir Henry E. Roscoe, B.A., D.C.L., LL.D., Ph.D., F.R.S.	1881—1882.
Sir Frederick A. Abel, Bart., K.C.B., D.C.L., D.Sc., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, LL.D., Ph.D., F.R.S.	1884—1885.
E. K. Mnspratt	1885—1886.
David Howard	1886—1887.
James Dewar, M.A., LL.D., F.R.S.	1887—1888.
Ludwig Mond, Ph.D., F.R.S.	1888—1889.
Sir Lowthian Bell, Bart., F.R.S.	1889—1890.
E. Rider Cook	1890—1891.
J. Emerson Reynolds, M.D., F.R.S.	1891—1892.
Sir John Evans, K.C.B., D.C.L., LL.D., Sc.D., F.R.S.	1892—1893.
E. C. C. Stanford	1893—1894.
T. E. Thorpe, LL.D., Sc.D., Ph.D., F.R.S.	1894—1895.
Thomas Tyrer	1895—1896.

## COUNCIL FOR YEAR ENDING JULY, 1897.

President: Dr. Edward Schunck, F.R.S.

### Vice-Presidents:

Chas. Dreyfus.	Dr. W. Jay Schieffelin.
Dr. A. Dupré, F.R.S.	E. C. C. Stanford.
Prof. A. K. Huntington.	G. N. Stoker.
Beverton Redwood.	Dr. T. E. Thorpe, F.R.S.
Sir H. E. Roscoe, F.R.S.	Prof. W. A. Tilden, F.R.S.
A. Gordon Salamon.	Thomas Tyrer.

### Ordinary Members of Council:

George Beilby.	C. C. Hutchinson.
R. Forbes Carpenter.	Jean Levinstein.
R. Le Neve Foster.	J. S. McArthur.
Oscar Guttman.	B. E. R. Newlands.
Douglas Herman.	Sir Robert Pullar.
David Howard.	Wm. Thorp, B.Sc.

With the Chairmen and Secretaries of Sections.

### Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

### Honorary Foreign Secretary:

Dr. Ludwig Mond, F.R.S.

General Secretary: Charles G. Cresswell.

Offices: Palace Chambers, 9, Bridge Street, Westminster, S.W.

## THE JOURNAL.

### Publication Committee:

#### The President.

A. H. Allen.	C. Clarke Hutchinson.
G. H. Bailey, D.Sc., Ph.D.	Wm. Kellner, Ph.D.
Joseph Bernays, M.I.C.E.	J. Lewkowsitch, Ph.D.
H. Brunner.	A. R. Ling.
A. C. Claudet.	Ludwig Mond, F.R.S.
E. Rider Cook.	B. E. R. Newlands.
Chas. Dreyfus.	John Pattinson.
Sir John Evans, K.C.B., F.R.S.	W. H. Perkin, Ph.D., F.R.S.
G. G. Henderson, D.Sc.	H. R. Procter.
John Heron.	Beverton Redwood.
D. B. Hewitt, M.D.	Walter F. Reid.
David Howard.	John Spiller.
Prof. J. J. Hummel.	William Thorp.
Prof. A. K. Huntington.	Thomas Tyrer.
F. Hurter, Ph.D.	

### Editor:

Watson Smith, 31, Upper Park Road, Haverstock Hill, N.W.

## NOTICES.

### ANNUAL GENERAL MEETING.

The Annual General Meeting will be held in Manchester on the 14th, 15th, and 16th July next. The programme and application form for tickets will be found in this number. Tickets of Membership will be issued in time for the Meeting, and will form, as heretofore, vouchers for visits to works and excursions.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those Members whose names are placed in italics in the list of Council will retire from their respective offices at the forthcoming Annual General Meeting.

Prof. F. Clowes, D.Sc., has been nominated to the office of President; Dr. Edward Schunck, F.R.S., has been nominated Vice-President under Rule 11; Mr. A. Gordon Salamon and Dr. Wm. Jay Schieffelin have been nominated Vice-Presidents under Rule 24; and Mr. D. Howard, Mr.

Ivan Levinstein, and Mr. Wm. Thorp have been nominated Vice-Presidents under Rule 8.

The Hon. Treasurer and Hon. Foreign Secretary have been nominated for re-election to their respective offices.

Members are hereby invited to nominate fit and proper persons to fill four vacancies among the Ordinary Members of Council under Rule 18. Nomination forms for this purpose can be obtained from the General Secretary upon application.

*Extract from Rule 18:*—"No such nomination shall be valid unless it be signed by at least ten Members of the Society who are not in arrear with their subscriptions, nor unless it be received by the General Secretary, at the Society's Office, at least one month before the date of the Annual General Meeting, to the election to take place at which it refers. Nor shall any such nomination be valid if the person nominated be ineligible for election under Rules 12 or 15. No member shall sign more than one nomination form."

An international congress on technical education will be held in London during the month of June. The congress will be opened on June 15th, and will close on Friday, June 18th. The congress has been invited by the Society of Arts to meet in this country, and the meetings will be held in the Society's large hall. The Companies of the Drapers, Fishmongers, Goldsmiths, Merchant Taylors, and Clothworkers are associated with the Society of Arts in the invitation issued to members of the Congress, and the Right Hon. the Lord Mayor has invited members to an evening reception at the Mansion House on June 17th. The congress will be opened at 11 a.m. on Tuesday, June 15th, by an address from the President, the Duke of Devonshire, K.G., and from the President of the last congress, M. le Professeur Leo Saignat. The subjects for discussion at the congress will include—

- (1.) Advanced technical education.
- (2.) Secondary technical education.
- (3.) Advanced commercial education.
- (4.) Secondary commercial education.

The subscription to the congress will be 5s. Applications for membership should be accompanied by the amount of the subscription, and be addressed to the Secretary, Society of Arts, John Street, Adelphi, W.C.

#### COLLECTIVE INDEX.

In reply to numerous inquiries, the compilation of the Collective Index is in active progress, part of the work being already in the printers' hands. The labour of revision and correction must, however, of necessity, take time; and it is hoped that those members who have already subscribed will extend their indulgence to the Indexer, who is making every effort to complete this vast work.

The prices are as follows:—

To Members (see Rules 25 and 27) and Past Members (see Rule 30); Libraries, Corporations, and Exchanges on the Society's List	Each copy 10s.
To Subscribers .....	„ 12s. 6d.
To others .....	„ 15s.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SPOTTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed. The circulation of the Journal is now more than 3,000 per month.

#### LIST OF MEMBERS ELECTED 24th MAY 1897.

- Badcock, Stanley H., 9, Buckingham Vale, Clifton, Bristol, Smelter.
- Bird, Fred. J., 52, Cambridge Gardens, Netting Hill, W., Chemist.
- Burrell, Loomis, Little Falls, Herkimer Co., N.Y., U.S.A., Manufacturer.

- Butler, David B., 41, Old Queen Street, Westminster, S.W., Cement Expert.
- Cairns, Wm., 5, Carlton Place, Glasgow, Plumber.
- Caldwell, Jas., c/o Mexican Gold and Silver Recovery Co., Hermosillo, Sonora, Mexico, Chemist and Assayer.
- Crawford, Walter W., Imperial Chambers, 91, Pitt Street, Sydney, N.S.W., Mechanical Engineer.
- Durkee, Frank W., Tufts College, Mass., U.S.A., Assistant Professor of Chemistry.
- Fitzgerald, Francis A. J., c/o The Carborundum Co., Niagara Falls, N.Y., U.S.A., Chemical Engineer.
- Goldschmidt, Dr. Guido, Laboratory, Salzgasse 1, Prag, Austria, Professor in Imperial German University.
- Hartmann, Ernest E., c/o Onomea Sugar Co., Papaikou, Hawaii, Chemist.
- Harvey, Jas., Love Clough, near Rawtenstall, Lancashire, Technical Chemist.
- Hunter, Prof. A. G. Kidston, (subs.) c/o John Hunter, 81, Great Clyde Street, Glasgow; and (Journals) P.O. Box 164, Dunedin, N.Z., Professor of Chemistry.
- Huntington, Dr. Harwood, 159, Front Street, New York, U.S.A., Consulting Chemist.
- Jones, Fred. W., Barwick, near Ware, Herts, Explosives Works Manager and Chemist.
- Kerr, Wm. M., 131, South 3rd Street, Philadelphia, Pa., U.S.A., Manufacturing Chemist.
- McFarland, B. W., 420, Temple Street, New Haven, Conn., U.S.A., Chemist.
- Nelson, Walter, Messrs. Geo. Nelson, Dale, and Co., Ltd., Embsay Mills, Warwick, Gelatine Manufacturer.
- Patchett, James, Oakworth, Hadley, Wellington, Salop, Ironmaster.
- Prochazka, John, 15, East 12th Street, New York, U.S.A., Coal-Tar Colour Chemist.
- Schoder, Dr. Robt., The Incandescent Gas Light Co., 14, Palmer Street, Westminster, S.W., Chemist.
- Smith, Theophilus R., c/o Brotherton and Co., Haigh Park Chemical Works, Stourton, near Leeds, Chemist.
- Van Gelder, Arthur P., Columbia University, New York City, U.S.A., Instructor in Chemistry.
- Wallace, Robt. A., Dorset Hall, Merton, Surrey, Chemical Manufacturer.

#### CHANGES OF ADDRESS.

- Akitt, Thos., c/o Hermosillo; Mina Cerro Colorado, Altar, Sonora, Mexico; Journals as before.
- Beckett, G. H., c/o San Remo; Bofors, Vermland, Sweden.
- Bradburn, J. A., c/o 1816; 1709, West Genesee Street, Syracuse, N.Y., U.S.A.
- Burrough, H., jun., c/o Lafayette Avenue; c/o Burrough Bros. Manufacturing Co., Baltimore, Md., U.S.A.
- De Lessing, G. C., c/o Lexington Avenue; 145, East 29th Street, New York, U.S.A.
- Dickinson, F. M.; Journals to c/o Broken Hill Proprietary Co., 3, Great Winchester Street, E.C.
- Fanta, F., c/o Arundel Street; 97, Queen Victoria Street, E.C.
- Graham, C. C., c/o Hull; Highmoor, Benrhydding Road, Ilkley, Yorks.
- Heal, Carlton, c/o Finchley; Chapel Road, Penketh, near Warrington.
- Heriot, T. H. P., c/o Trinidad; Pin. Albion, Barbice, British Guiana.
- Holden, G. H., c/o Victoria Park; Mendip Mount, Heaton Mersey, near Manchester.
- Hopkins, Erasmus, c/o Worcester; 207, State Street, Boston, Mass., U.S.A., Port Examiner.
- Howard, A. G., c/o Woodford; Burnt House, Chigwell, Essex.
- Kawakita, M., c/o London; Imperial Engineering College, Tokio, Japan.
- Langer, Dr. C., c/o London; Hampton House, Milverton Terrace, Leamington.

- Lucas, B. R., 1/o Middlesbro'; Moss Villa, Elworth Road, Sandbach, Cheshire.
- McLellan, J. Y., 1/o Bernburg; Fabriche Unite di Bicchieri Colori, Cogoletta, near Genoa, Italy.
- Matsui, G., 1/o Gower Street; 31, Nicholas Street, St. Peter's Road, Mile End, E.
- Meggitt, H. A., 1/o Mansfield; Laboratory, Sutton-in-Ashfield, Notts.
- Meggitt, Loxley, 1/o Mansfield; Laboratory, Sutton-in-Ashfield, Notts.
- Messel, Dr. R., 1/o 53; 30, Ebury Street, S.W.
- Miles, G. Wellington, jun., 1/o Milk Street; 7, Exchange Place, Boston, Mass., U.S.A.
- Patterson, T. L., 1/o Sugar Refinery; Maybank, Fimart Street, Greenock, N.B.
- Preston, Alf., 1/o Market Street; Park Hill View, Bury, Lancashire.
- Rademacher, H. A., 1/o Lee Street; P.O. Box 243, Lawrence, Mass., U.S.A.
- Redwood, I. L., 1/o Bayonne; Bantry House, Picardy Hill, Belvedere, Kent.
- Royal-Dawson, H., 1/o Cockle Creek; Retain Journals until further notice.
- Schuppings, Dr. R. C., 1/o Brooklyn; c/o G. H. Graham, 66, Broadway, New York, U.S.A.
- Scrymgeour, Wm., 1/o South Africa; Australian Gold Recovery Co., Kalgoorlie, West Australia.
- Segner, P., 1/o Princess Street; 8, Dickinson Street, Manchester.
- Smith, Allan, 1/o Bury Road; Bolton Road, Edentfield, near Bury, Lancashire.
- Thorp, Wm., 1/o Crouch End; 22, Sinclair Gardens, West Kensington, W.
- Tipler, F. C., 1/o Richard Street; 48, Brooklyn Street, Crewe.
- Wilson, Ellwood, 1/o East Orange; 10, Belsize Avenue, Hampstead, N.W.
- Wyatt, Dr. Francis, 1/o Old Slip; 39, William Street, and 29, Stone Street, New York, U.S.A.

## Death.

Cunliffe, Jos., Kern Mill, Whittle-le-Woods.

## London Section.

THE CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE, W.

Chairman: R. Messel.

Vice-Chairman: Boverton Redwood.

Committee:

B. Blount.	H. de Mosenthal.
C. F. Cross.	B. E. R. Newlands.
W. J. Dibdin.	S. Rideal.
R. J. Friswell.	F. G. Adair Roberts.
S. Hall.	F. Napier Sutton.
D. Howard.	Wm. Thorp.
E. Grant Hooper.	T. Tyrer.

Hon. Local Secretary:

John Heron, 110, Fenchurch Street, E.C.

The names in italics are those of Members of Committee who retire at the end of the current session.

The following have been elected to fill the vacancies, and will take office in July next:—Committee: E. J. Boyan, Otto Hehner, J. B. Knight, A. R. Ling, and Lewis T. Wright.

### SESSION 1896-97.

June 14, 1897:—

Dr. A. Dupré, F.R.S. "Note on a possible Danger from Fire involved in the Transport of Barium Peroxide in Wooden Barrels."

Dr. Pauli (Farbwerke, Hoechst a. Main). "On the Valuation of Commercial Nitrate of Soda."

Mr. Hudson Maxim. "Recent Improvements in Smokeless Powder Compounds and in Processes of Manufacture."

Mr. Alex. Cameron. "Comparative Experiments on the Estimation of Phosphoric Acid."

Mr. William A. Davis. "The Strength of Commercial Formaldehyde Solutions."

Meeting held on Monday, May 3rd, 1897.

DR. R. MESSEL IN THE CHAIR.

## ON A SLOW COMBUSTION ARC LAMP SUITABLE FOR FACTORIES AND STREET LIGHTING.

BY W. S. SQUIRE, PH.D., F.R.S.

ACCORDING to Mr. W. H. Preece, one-half of the cost of arc lighting is due to the consumption and replacement of the carbons. If in respect of this expense an economy of 50 per cent. could be realized an important step in advance would be made, still more so, if an economy of 75 per cent. could be obtained. The lamp I am about to introduce to your notice goes much further than that, as you will see presently.

In an ordinary arc lamp the consumption of carbons is usually at the rate of about  $1\frac{1}{2}$  ins. per hour—1 in. for the positive or upper carbon, and  $\frac{1}{2}$  in. for the negative or lower carbon, or, say, 40 mm. per hour, both carbons included. This, of course, will vary somewhat according to the amount of the current. The consumption of carbons in the new lamp (varying also with the strength of the current) and consuming the same amount of electrical energy as the ordinary arc lamp will be from 1.20 to 2 mm. That is to say, only 5 per cent. of the consumption of the ordinary lamp—an economy of 95 per cent. As this result has been attained by means—partly of a mechanical, partly of a chemical character, I thought it a fit subject to bring before a society occupied to a great extent with questions of chemical engineering.

The lamp was invented by an American named Jandus, born at Wisconsin, of Hungarian parents.

I propose in the first place to describe the mechanical construction of the lamp, giving you an opportunity of handling and examining the various parts. I will then have the parts put together so that you may see the same lamp in action. While this is being done we can consider the chemical side of the question.

Fig. 1 represents the lamp in section. The current enters the lamp by the negative terminal, and then passes through a resistance which has the effect of reducing the voltage (which is in this room 108) down to 81. This is about double the voltage usual for arc lamps. It then passes by the insulated screw shown on the right hand to the lower carbon holder, and so to the lower carbon. It crosses the arc to the upper carbon. It leaves the carbon by the brush rings, and then goes through the magnet coil to the positive terminal.

The magnet coil encloses two cast-iron magnets, which I may call the male and female magnets. The female magnet is fixed, but the male is free to move up and down. These will have a tendency to attract one another, and when the current in the coil is strong enough to enable the induced magnetism to overcome the weight of the lower magnet this will rise carrying with it the upper carbon. The effect of this will be to lengthen the arc, and by increasing the resistance, to diminish the current through the coil, and so arrest the further rise of the magnet. Matters thus remain in equilibrium until, by consumption of the carbon, the arc becomes longer, and the current thereby diminished. The lower magnet then begins to descend. It will be seen that both the fixed and the movable magnet are hollow, and that the upper carbon is not attached to either of them. How then does the movable magnet carry the carbon with it? This is one of the most ingenious contrivances in the lamp. There are three equidistant slots in the lower magnet. In each slot a brass ring is inserted, the rings being prevented from falling out by a wire passing round the magnet. The tendency of these rings is to fall together and clip anything passing in a downward direction, but they will allow anything to pass in an upward direction. By this means the carbon is firmly attached to the lower magnet.

If, however, the magnet drops so far that the rings come in contact with a brass plate cut out so as to fit into the

slots in the magnet, they are lifted and rolled back so as to allow the carbon to slide down by its own weight between the rings; the moment the normal current is re-established

Fig. 1.

the magnet rises, the rings clutch the carbon, and its further movement is arrested. It is in this way that the upper carbon is gradually fed forward.

A somewhat similar device is employed to make an electrical contact with the upper carbon by means of the brush rings. These do not clutch the carbon at all, but rest gently against it, and being hung in such a way that they are free to turn, they make electrical contact without opposing any sensible resistance to the movements of the carbon. Moreover, they are so placed that the electrical contact is at no great distance from the arc, so that the carbon offers a minimum of resistance, and it is also an unvarying resistance—a point of some importance.

As shown in the drawing, the arc is produced inside a small glass cup, which is closed at the top by the so-called "gas cap." This cap has a double duty to perform. In the first place it prevents to a considerable extent the escape of the gases resulting from the combustion of the carbons inside the cup. In the second place it provides for automatically extinguishing the lamp when the upper carbon is nearly exhausted.

The carbon passes freely through the aperture in the centre of the cap, but the brass carbon holder cannot pass. As soon as this arrives at the cap the movement is arrested, the feed is stopped, the lamp is extinguished, and no harm can happen to the metal work.

Besides the small glass cup in which the arc is produced there is also an outer globe, which is so fastened by packing to the body of the lamp as to be quite air-tight. In this way a layer of highly heated gases is caused to float in the upper part of the outer globe upon the colder gases beneath. This tends to assist the action of the gas cap in keeping the air from the arc. Lastly, the outer globe is closed at the bottom by an escape valve, which opens to let out the gases when expanded by the heat of the arc. Of course this valve is removed when the carbons are renewed.

It is evident that the arc is produced in a small chamber, to which the possible access of air is reduced to a minimum. Consequently, very little combustion of the carbons takes place. After the lamp has been at work for a short time, almost all the oxygen present in the glass cup has been consumed, and the gases in the cup are found to have the following composition:—

Carbon dioxide .....	1.4
Carbon monoxide .....	23.6
Oxygen .....	2.7
Nitrogen .....	72.3
	<hr/> 100.0

The interior chamber is not, however, perfectly air-tight, and diffusion will occur between the gases in the interior chamber and those in the globe outside. Consequently, a very slow combustion of the carbons will go on, while, on the other hand, the gases produced in the interior chamber will diffuse into the outer globe. After some hours burning the gases in the outer globe are found to have the following composition:—

Carbon dioxide .....	0.8
Carbon monoxide .....	12.2
Oxygen .....	12.9
Nitrogen .....	74.1
	<hr/> 100.0

It is obvious that, in order to produce this effect, the tube in which the upper carbon, with its holder, slides must be perfectly air-tight, and the joint between the glass globe and the lamp must also be air-tight.

The result of this arrangement is that the carbons burn away very slowly, the consumption never exceeding 2 mm. an hour.

Using carbons of 13 mm. diameter, the upper one having a length of 270 mm., or, say, 10½ ins., and the lower one a length of 150 mm., or, say, 6 ins., the lamp is found to burn—

	Hours.
With a current of 4 amperes .....	220
" " 6 " .....	160
" " 7 " .....	120

Consider what this means! When the ordinary arc lamps are used, a man must go up the post every morning

and put in fresh carbons. In the case of a lamp burning 220 hours it will be necessary to renew the carbons, on an average, only once in three weeks, say, once a fortnight in winter, and once a month in summer. This is not only a great saving in carbons but in wages as well.

The lamp which we have put together has now been burning for about 10 minutes, and the gases in the interior chamber or cup should have the composition I have indicated. I will quickly remove the lower carbon and cup. At the moment that I do so, the highly heated upper carbon as it passes out should set fire to the gases in the cup (*experiment performed*). You see the carbon monoxide burning with the characteristic blue flame.

I wish to direct your attention to the way in which these carbons burn. In the case of the ordinary arc lamp burning in air, the consumption of the positive carbon, as compared with the negative carbon, is as two to one. In the case of the Jandus lamp it is as four to one, so that the consumption of the lower carbon is practically a negligible quantity. Owing to the lower carbon, in the case of an arc produced in air, burning away at about half the rate of the upper carbon, which is in all lamps fed up to the arc, the point of light is gradually lowered in the globe, so that any devices, such as reflectors, or holophane globes, soon cease to act properly unless there is a special compensating mechanism, usually both complicated and costly. Owing to the very small consumption of the lower carbon in this lamp, the luminous point is practically fixed without any compensating mechanism whatever.

There is also a considerable difference between the shape of the ends of the carbons burning in air and those burning in the Jandus lamp (see Fig. 2). In the Jandus lamp they

Fig. 2.

**ENCLOSED  
ARC.**

**OPEN  
ARC.**

remain very nearly flat, slightly convex on the negative, slightly concave on the positive. When the carbons burn in air the negative is very distinctly pointed, while there is a sort of crater formed on the positive. This is generally attributed to a transfer of the particles of carbon from one pole to another, but, of course, the forms produced in this way must be perpetually broken down and obliterated by the burning away of the carbons. When there is little or no burning away, as is the case with the Jandus lamp, we should expect to find this production of a point and a crater greatly accentuated, and in an exaggerated form. Nothing of the kind however happens; both the carbons remain practically flat without point or crater. Perhaps we shall have to modify our previous conceptions in regard to this matter.

We have still to consider the distribution of the light over a considerable space of ground. You will say perhaps that the light diminishes according to the square of the distance. Yes, that is quite true of a white hot ball, like the sun, but it is very far from true of the light of the electric arc. The light emitted in one direction is very much greater than

that in another direction, and it depends very much what that direction is. Mr. Hesketh, of Blackpool, has been experimenting, both with the Jandus lamp and with an arc lamp burning in air. Figs. 3 and 4 give his results in a graphic form. You will notice that an arc lamp, burning in air, shoots down its rays in such a way that the maximum is attained at an angle of 15° from the perpendicular, while the Jandus lamp attains its maximum at about 75°, that is to say, only 15° from the horizontal. Consequently, while the ordinary arc lamp brilliantly illuminates objects almost immediately underneath it, and objects at a distance only slightly, the Jandus rays are better distributed over distant objects. Fig. 5 shows the amount of illumination on the ground at different distances. Assuming the lamps to be placed at a height of 20 ft., the ordinary arc lamp produces a prodigious illumination up to 20 ft. or thereabouts, but then it rapidly falls off. At 34 ft. it is less than the light of the Jandus, and then it dies away almost to nothing. The Jandus, on the contrary, starts low, owing to the partial shadow of the lower carbon. As soon as we get out of the shadow of the corner of the lower carbon the light increases, and then, owing to the nearly horizontal direction of its maximum, it diffuses its light very equally, and as you see it illuminates objects at 140 ft. quite as much as the ordinary arc does at half that distance.

The advantages presented by the Jandus lamp may be summed up as follows:—

It will burn on the public mains which have usually a voltage of about 110 without any accessories whatever.

The ordinary arc lamps must either be placed in series or must be furnished with a comparatively high resistance so as to reduce the voltage to about 40. This means conversion of a good deal of electricity into heat which does nothing but keep the wire of the resistance warm.

The lamp is very economical, the consumption of carbon being insignificant.

The distribution of light is very equable, far more so than in the case of the ordinary arc lamp.

The construction of the lamp is extremely robust. There is no clockwork or delicate mechanism. Probably it might fall from a considerable height without sustaining any other injury than the smashing of the glass.

It is eminently suited for illumination of chemical and other works. It is an essential part of the construction of the lamp that it should be practically air-tight, the working parts therefore would not be liable to be injured by gases or dust flying about in the factory.

I may mention that any further particulars about the lamp may be obtained from Messrs. Drake and Gorham, 65, Victoria Street, Westminster.

#### DISCUSSION.

Mr. J. A. Hicks inquired what was the ampère consumption as compared with ordinary arc lamps.

Mr. H. BALLANTYNE was in a position to corroborate most of Dr. Squire's statements as to the advantages of the Jandus lamp. He would like further information, however, as to the consumption of the carbons and the gases produced in the outer envelope. Bearing in mind the materials of which the lamp was composed it was practically impossible to obtain absolutely air-tight joints, and one would expect, therefore, that when the lamp was switched off a certain amount of air would find its way in, and that after a few hours a diminution of the carbonic oxide would have taken place. He gathered that that was the case, and would like to know if the rate of consumption quoted by the author referred to a continuous run without switching off or to an intermittent run as in ordinary circumstances. He would also like to know whether the composition of the gases in the outer envelope also referred to their state after a continuous run or after intermittent switching off.

Dr. LUDWIG MOND remarked that Dr. Squire had laid some stress on the remarkable saving in carbon effected by this lamp. He did not profess to be an expert on the subject, but he believed it was generally considered that in the ordinary arc lamp the rapid consumption of carbon

Fig. 3.

Fig. 4.

Fig. 5.

was not altogether wasteful, since such lamps gave more powerful illumination. He would therefore like to know what was the efficiency of the Jandus lamp as compared with the ordinary arc lamp, and to what extent the economy in carbon was counterbalanced by a loss of lighting power.

Mr. R. J. FRIWELL enquired whether there was anything like a plus pressure in the envelopes around the carbons, as, if so, the lamp might possibly be used in

explosive atmospheres, since a continuous small current of carbonic oxide from the inner envelope would prevent the access of explosive gases to it. The lamp might thus be available for use in factories where the ordinary arc lamp was inadmissible on account of the explosive nature of the atmosphere.

Dr. S. RIDEAL pointed out that from the analyses given an explosive combination of carbon monoxide and oxygen

was found between the outer and inner envelopes, seeing that in the inner globe the monoxide was in excess whilst oxygen was in excess in the outer globe.

Mr. LEON GASTER asked for further information as to the light efficiency of the lamp as compared with ordinary arc lights. Prof. S. Thompson, in a recent course of lectures, had pointed out that in lamps with enclosed arc a brown deposit was found inside the globe, which obscured the green rays. That was an undesirable result, since green and yellow rays were what one wished to have as being the essential ones for light. Moreover, the accumulation of products of combustion, using impure carbons, must in time result in a loss of light. The author had stated that the lamp required 81 volts and 6.5 amperes, which meant an energy of over 500 watts to consume per hour. In a circuit of 110 volts an energy of 30 volts  $\times$  6.5 amperes, = 195 watts, would be wasted in heating the resistance put in series with the arc lamp. Would not the large amount of energy used in this lamp be in the long run dearer than the saving in the carbons? Experiments made by Prof. Ayrton showed how greatly the results of arc lamps varied according to the current employed, and that only certain current intensities and lengths of arc yielded good results. As the arc used in the Jandus lamp was a rather long one, he would like to know whether the arc could be kept steady and work satisfactorily with alternate currents, especially those of slow frequency.

Dr. W. S. SQUIRE, in reply to Mr. Mond's remarks, said that the economy claimed for the Jandus lamp was not only in respect of the saving in the carbons, but also in the attention required to replace the carbons, which were so quickly consumed in the ordinary lamps. There was not any greater waste of current in this lamp than in the ordinary lamps, indeed not nearly so much if the ordinary lamps were used singly or in parallel with the current as usually supplied by the street mains, for in that case the ordinary lamp required a resistance involving a considerable loss of heating. The Jandus lamp being run with a high voltage and a low amperage, required therefore a long arc, while with the ordinary lamps the reverse was the case, and the arc was therefore a short one. In both cases the watts, i.e., the amount of electric energy consumed in the lamp, would be practically the same. The proportion of gases produced would vary according to the time the lamp was burnt. The table before the meeting represented the composition of the gases in the outer envelope after the lamp had been burning for three or four hours. He did not make the analysis himself, and therefore could not vouch for its correctness, it being obvious that the exact proportion of the gases must depend to some extent on the particular part of the envelope from which they were taken. At any rate, the analysis proved that diffusion had taken place from the inner to the outer envelope. He did not claim that the escape valve was absolutely air-tight in the chemist's sense of the term. Unless it were very carefully made and tested, he would not consider it suitable for use in an explosive atmosphere, though as a general rule it might be fairly safe. Why, he asked, should one take an arc lamp into an explosive atmosphere at all, when a glow lamp answered all purposes and was infinitely more suitable.

Dr. Mond remarked that he understood the author to claim an economy in the working of the lamp, due to the dispositions of the carbons. But the question was what was the candle power produced for a given consumption of current.

Dr. SQUIRE replied that the lamp gave an illuminating power of about 1,200 candle power per half a Board of Trade unit. But the power was not all in the same direction. Most of it was at an angle of 75, and the rest at various angles. The light produced in an arc was to a certain extent a measure of the resistance of that arc. With a greater resistance the energy was converted into heat, and that heat was realised upon the points of the carbons. Therefore if the arc were increased in length, the temperature of the carbon would be increased, because the resistance was greatest there. An ordinary arc lamp upon the usual circuit of 100 volts required a resistance interposed in order to get the arc of such a length as to bring down the

voltage to about 40. This reduction involved considerable loss. It did not follow that a larger arc would produce more light, because the light came from the carbon, and only to a small extent from the arc itself. The longer arc, that is to say, the greater resistance, enabled a current of less amperage to heat the carbons to the required temperature.

Mr. GASTER said that his experience of such lamps was that over 85 per cent. of the current went away, and he did not see any advantage in the larger arc. With a greater surface of carbon they would have not more light but heat, and that was just what was not wanted.

Dr. SQUIRE, interposing, said that was just what was wanted, as it was because of the high temperature of the upper carbon that the light was evolved. Electricity as electricity could not be used as a source of light. It must first be converted into heat in such a way that some substance, usually carbon, as in both the arc and glow lamps, was heated to incandescence. All bodies, without exception, offered at ordinary temperatures more or less resistance to the electric current, and were therefore more or less heated. Quite as much heat as was developed in the electric arc would be developed in a long wire offering the same amount of resistance, but as the heat was in that case spread over a long resistance, the temperature developed would be low. In the case of the arc, the resistance, and therefore the heat, being all at one point, a very high temperature was attained. The higher the temperature the greater the amount of light.

Mr. GASTER, resuming, said that what was wanted was the largest possible amount of light from the smallest possible surface. He would like to know at what intervals the results shown on the diagram before them had been taken, and if they had been checked at various times to ascertain if they agreed.

Dr. Mond said that it might interest members to know that he had accidentally learnt a fact that day which corroborated Dr. Squire's statement that the light of the arc increased with the resistance between the carbons. It had been generally supposed that the heat of an arc could not be carried beyond the volatilising point of carbon, which was estimated at 3,500° C., but M. Moissan had, in the course of his experiments on the melting of titanium, attained temperatures in the arc which he estimated at between 4,000 and 5,000° C.

A MEMBER inquired if there was a deposit of carbon in the inner envelope sufficient to interfere with the emission of light.

Dr. SQUIRE replied that a slight deposit did occur upon the inner glass, but the matters forming this deposit when given off from the arc would be, and in fact were, carried by convection to the upper part of the glass and there deposited, so that the deposit was invariably above the line of light, and in no way interfered with the illuminating power. It was easily removed by the attendant when changing the carbons.

The CHAIRMAN thought that the lamp, owing to its great power of diffusion, was likely to be of considerable advantage in illuminating large spaces. The theoretical points raised during the discussion were of great interest and deserved further consideration. It was obvious that in a lamp of this nature the light produced must be at least equal to that of an ordinary arc light, but from the fact that practically no crater was formed in the carbons, the consumption of carbon must be much less.

## ON ATTEMPTS TO CONVERT OLEIC ACID INTO CANDLE MATERIAL.—I.

BY DR. J. LEWKOWITSCH.

ONE of the most fascinating technical problems in the fat industry, is the conversion of oleic acid into solid fatty acids or, at all events, into solid substances which we comprise under the name "Candle Material."

Several years ago I was led to attack this problem from a technical point of view, and I set myself the task of examining the various processes proposed hitherto in the

hope that a thorough and methodical investigation might lead to some practically feasible method.

The great commercial importance of this subject becomes at once apparent if we consider the difference in the prices of "stearine" (commercial stearic acid) and "oleine" (commercial oleic acid)—round about 15*l.* per ton at present prices—bearing in mind that the candlemaker obtains, even by the best methods known, 30 per cent. of oleic acid. This acid must rank in the candle works as a by-product, the sale of which for soapmaking becomes more and more difficult the greater the pressure of cottonseed oil and other cheap oils is on the market.

At the first glance the problem seems to resolve itself into the simple addition of two hydrogen atoms to oleic acid with formation of stearic acid, the most desirable candle material. But whereas the lower members of the acrylic or oleic series are readily converted into saturated acids, oleic acid itself resists all attempts at hydrogenisation. I have carried out a large number of experiments in this direction under most varied conditions, but hitherto all of these gave negative results. It has been tried to act with hydrogen *in statu nascendi*—evolved by electricity—on oleic acid under pressure, but the process has not proved a commercial success.

The remarkable power of resistance oleic acid offers to the assimilation of hydrogen becomes also apparent, if hydrogenisation is attempted in a roundabout fashion, *viz.*, by first converting it into the dibromo-addition product, and then reducing the latter by hydrogen. Dibromo-stearic acid is readily formed, but on attempting to reduce the latter, I always obtained the original oleic acid.

It is true that reduction can be effected by means of phosphorus and hydriodic acid, but the palpable hopelessness of such a process, from a commercial point of view, has not even elicited an attempt to try this process on a semi-large scale. By heating oleic acid with 1 per cent. of iodine to 270—280 C. P. de Wilde and Reychler succeeded in obtaining about 70 per cent. of stearic acid. But as only one-third of the iodine could be recovered, the process had to be abandoned. Even when for part or the whole of the iodine the cheaper bromine or chlorine was substituted, commercial failure resulted. The process had a fair trial on the large scale in a Belgian candle works, but the large amount of valueless by-products, coupled with the fact that no autoclave could resist the corrosive effect of the halogens, showed once more that beautiful laboratory experiments but too often lead to disastrous results in the works.

The action of chlorine on oleic acid and the reduction of the chloro-derivatives under pressure by means of zinc, or iron powder, &c. has been made the subject of a German patent by Zürrer, who claims to have obtained solid saturated fatty acids. I have not finished yet the examination of this process, and am, therefore, not in a position to offer any remarks, but I may say that as far as I am aware, it has not been tried yet on the large scale.

The conversion of oleic acid into its solid isomeric elaidic acid has figured of long in text books, and has been propounded as a commercial process as often as it has been shown to be a valueless process to the candlemaker. To the reagents effecting this change, *viz.*, nitrous acid and sulphurous acid, there has been added lately sodium bisulphite, which Saytzeff allows to act on oleic acid under pressure at a temperature of 175—180 C.

At this juncture I may mention that about two years ago Lidoff made the statement that by the action of nitrous oxides at 80—85 C. on oleic acid, an increase of weight of the material takes place, and that the resulting product absorbs 9 per cent. only of iodine, whereas oleic acid assimilates 90 per cent. My own experiments, however, showed me that elaidic acid is formed and the apparent low iodine value is due to the action on potassium iodide of nitrous acid not washed out completely from the product.

Great hopes were at one time entertained of the application of Varentzapp's reaction, *viz.*, the conversion of oleic acid into palmitic and acetic acids by means of caustic potash. The process has been described and its commercial results stated in two papers read before this Section by the late Lant Carpenter (this Journal, 1883, 98; 1884, 200). It is true large quantities have been worked by Mr. Radisson

in Fournier's works at Marseilles, and the candles made from the artificial palmitic acid created some sensation in technical circles at the Paris Exhibition of 1878. But on account of their rank odour and their greasy touch the candles found no buyers, and although further improvements were heralded, the process seems to have or has died a premature death. At the last Paris Exhibition I vainly looked (Lewkowitsch, Technical Report on the Paris Exhibition, *Chemiker Zeitung*, 1889, 1190) for the candles made with Radisson's artificial palmitic acid, and on enquiry I elicited the fact that the process had been abandoned, not only for the reasons stated above, but also on account of the high cost and the great danger attending its working in consequence of the concomitant evolution of hydrogen.

Another promising process, *viz.*, M. v. Schmidt's zinc chloride process has met with no better fate. The process and its products have been examined on a laboratory scale by the late R. Benedikt and his paper (*cf.* Chemical Analysis of Oils, Fats, Waxes, &c. by J. Lewkowitsch, p. 664), well repays perusal on account of the beautiful illustration it affords of the capabilities of the modern processes of fat analysis as a means of research. I have examined the process myself, and, as a matter of course, I could but confirm Benedikt's statement with that exception, however, that I found no solid saturated acids other than hydroxy acids. The temperature at which the interaction of oleic acid and zinc chloride is to take place must be kept at exactly 185° C. as the inventor directs. Deviation from this point leads to an increase of liquid substances. Unfortunately the solid candle material must be distilled and the considerable proportion of  $\beta$ -hydroxystearic acid (melting point 82° C.) in the crude product is seriously diminished by the partial conversion of this acid into oleic and iso-oleic acids. Thus, from a candlemaker's point of view, a substance of high melting point is rendered practically valueless. Schmidt's process was tried on the large scale in an Austrian candle works. The quantity of liquid unsaponifiable substances obtained was, however, so large that commercial success was out of the question. It only remains to be added that the inventor has allowed his patent to lapse.

The action of concentrated sulphuric acid on oleic acid is well known in candle works, and practical application of it is made in the partial conversion of oleic acid into solid substances. I say partial, as out of the 47 per cent. of oleic acid with, *e.g.*, tallow, would yield only 17 per cent. are converted into candle material. As stated already, 30 per cent. of oleic acid still result as a by-product.

The sulphuric acid process seemed to offer the greatest hope of success, and I have devoted considerable attention to it.

I have also examined and have still under examination several other reactions not mentioned above, and I hope to lay the results of this research at some future time before this Society.

My reason for bringing some of my results regarding the action of sulphuric acid on oleic acid before the Society, incomplete though they are, is that David has recently taken out a patent for a process which to some extent covers results I have obtained some time ago. Whilst preparing these notes I find that there has also appeared a paper by the same chemist in the *Comptes Rendus*, an abstract of which is published in last month's issue of our Journal.

It is not my intention to criticise David's paper, but I must remark that his "stearolactone," the proportion of which is stated by him to be 18—20 per cent. of the crude product, is practically nothing but  $\beta$ -hydroxystearic acid. At any rate, in my own experiments I obtained chiefly  $\beta$ -hydroxystearic acid, even when closely following his direction. The impure substance had an acid value of 189.12 and an ether value of 14.29 only, so that the amount of lactone was insignificant. Besides, the melting point of the crystals obtained by the first crystallisation from alcohol, and therefore still very impure, was 60°—60.5° C., whereas stearolactone melts at 47°—45° C. The melting point of  $\beta$ -hydroxystearic acid is 81 C. Experiments made with

mixtures of concentrated and fuming acids (see below) gave  $\beta$ -hydroxystearic acid and not the lactone.

### I. Action of Sulphuric Acid on Oleic Acid.

The action of sulphuric acid on oleic acid is a very complicated one, and although a number of papers have been published by different authors a satisfactory explanation of the reactions taking place is still a desideratum.

No doubt this is chiefly due to a formula satisfactorily expressing the chemical constitution of oleic acid not having been established yet. We shall perhaps best get an insight into the difficulties besetting this subject by briefly examining its theoretical aspect.

At present we know four fatty acids of the empirical formula  $C_{18}H_{34}O_2$ , *viz.*, oleic acid, elaidic acid, iso-oleic or solid oleic acid, and rapic acid.

The last-mentioned acid, rapic acid, is certainly not identical with any of the other three acids, for it does not solidify on cooling; nor does it give the elaidin reaction. Being but little studied the acid need not engage our further attention.

Elaidic acid is undoubtedly the stereometrical isomeride of oleic acid, and its formula will be readily derived from that of oleic acid.

On attempting to arrive at a rational formula of oleic and iso-oleic acids, the safest plan will be to try the inductive way by building upon well ascertained facts. Oleic acid, on being heated with melted caustic potash, yields palmitic and acetic acids. This reaction would appear to be in favour of the simplest expression, *viz.*,  $C_{15}H_{31}CH=CH-COOH$ . But as iso-oleic gives the same products, it tells us no more than that under the influence of caustic potash an intramolecular change takes place, one acid being converted into its isomeride before being finally broken up. We might, therefore, assign to oleic acid and iso-oleic acid the formulae  $C_{15}H_{31}-CH_2-CH_2-CH=CH-COOH$  and  $C_{15}H_{31}-CH_2-CH=CH-CH_2COOH$  respectively, or *vice versa*.

A more definite answer is supplied by the sulphuric acid reaction. On treating oleic acid with this acid at a low temperature and boiling the product with water, one obtains, amongst other substances, (1) a solid anhydride, the corresponding acid of which does not exist in its free acid, and (2) a hydroxystearic acid.

The solid anhydride  $C_{18}H_{34}O_2$  (having the same empirical formula as oleic acid, but differing from it by its physical state and by not absorbing halogens) must be considered as the inner lactone of a hydroxy acid,  $C_{17}H_{36}O_3$ , and reasoning from analogy, its stability would lead us to look upon it as a  $\gamma$ -lactone, so that its formula would be expressed by—

and its corresponding acid thus—

This would fix the  $\gamma$ -carbon atom as one of the doubly-linked carbon atoms in oleic acid, and it would only remain to choose between the formulae of a  $\gamma$ - $\delta$  or a  $\beta$ - $\gamma$  unsaturated acid, thus—

or—

The hydroxystearic formed besides the lactone just described yields, on being subjected to distillation *in vacuo*, two unsaturated acids, *viz.*, oleic and iso-oleic acids, a portion of the original acid passing over unchanged at the same time.

This behaviour of the hydroxystearic acid is completely analogous to that of all known  $\beta$ -hydroxy acids derived

from lower fatty acids of the acrylic series, and analogy thus speaks for the formula—

On treating *iso-oleic acid* with concentrated sulphuric acid and boiling the product with water, two hydroxystearic acids are formed, one of which is identical with the hydroxy acid yielded by oleic acid. The proportions of the two hydroxy acids vary according to the temperature employed during the interaction, the yield of the second hydroxy acid decreasing as the temperature rises. This second hydroxystearic acid distils without decomposition *in vacuo*, it yields no lactone and cannot therefore be a  $\gamma$ -hydroxystearic acid. Reasoning again from analogy this behaviour of the acid would correspond to that of an  $\alpha$ -hydroxy acid, thus—

Since both oleic and iso-oleic acids lead to the same hydroxystearic acid it is evident that both acids must have, in common, one carbon atom which is linked by a double bond to its neighbour; and as we fixed the  $\gamma$ -carbon atom as one of these for oleic acid, the carbon atom common to both acids must be either the  $\beta$  or the  $\delta$  carbon atom, so that we would have to adopt for iso-oleic as formula, either a  $\delta$ - $\epsilon$  or an  $\alpha$ - $\beta$  unsaturated acid.

The above-mentioned analogies render it more likely that oleic and iso-oleic acid have the  $\beta$ -carbon in common as one of the doubly linked carbon atoms, so that we should have as the likeliest formulae for oleic and iso-oleic acids the following:—

I have avoided adducing the formation of palmitic acid as an additional proof, for the conclusion derived from the behaviour of an unsaturated acid with melting caustic potash—formerly held as conclusive—has lost much of its force, and one might, therefore, rule out of court whatever evidence is afforded by the formation of palmitic and acetic acids. But I would think the reasoning given above speaks in favour of the formulae as stated, and I may therefore omit discussing the formula—

and proposed by Barnet (Berichte, 1894, 173).

I have dwelt at some length at these theoretical speculations as they are of the utmost importance for the solution of our problem. I merely will remark by the way that the same reactions, *mutatis mutandis*, occur in the case of erucic, brassidic, and iso-erucic acids.

From the candlemaker's point of view the conversion of oleic acid into iso-oleic would be an important step, for the latter acid melts at  $47^\circ \text{C}$ , and does not share the fate of elaidic acid when worked into candles, for commercial distilled stearine does contain considerable quantities of iso-oleic acid.

I have made some experiments with oleic acid and sulphuric acid diluted with an equal volume of water (*cf.* Fittig, Liebig's Annalen, 283, 51), but no practical result was obtained. As the conversion into iso-oleic acid by means of iodostearic acid and alcoholic potash had to be left out of the question for obvious reasons, I was forced to fall back upon the known interaction of concentrated sulphuric acid on oleic acid.

The products of this reaction at a low temperature are chiefly  $\beta$ -hydroxystearic acid, sulphostearic acid, and stearylactone.

Adopting the formula  $C_{13}H_{27} - CH=CH-CH-COOH$  for oleic acid, we may explain the interaction by the simple addition of  $SO_3H.OH$  to oleic acid, much as hydrobromic acid is assimilated.

According as the  $SO_3H$  group is assimilated by the  $\gamma$  or the  $\beta$  carbon atom, two different sulphostearic acids will be formed, and, as there is no reason why one acid should be formed in preference to the other, it is reasonable to assume that both acids are formed, say, in equal proportions, and that we thus obtain the two sulphostearic acids—

(One might as well write the formulæ of these acids—

but the mode of expression adopted renders the chemical changes more conspicuous to the eye.)

These acids are not very stable, and, by merely allowing the crude product to stand, they absorb moisture enough to be partially split up into  $SO_3H_2$  and hydroxy acids, *viz.*,  $\beta$  and  $\gamma$  hydroxy acids—

the latter of which immediately undergoes dehydration, forming  $\gamma$ -stearolactone. Another portion of the sulphostearic acids will remain unchanged.

On boiling the resulting mass with water, the sulphostearic acid is further converted into hydroxystearic acids. Thus a suitable candle material would be obtained, if subsequent distillation could be avoided, whereby, as explained already,  $\beta$ -hydroxystearic acid is changed into oleic and iso-oleic acids. (I purposely omit here following up the possibility of  $\beta$ -hydroxystearic acid forming products of condensation, *viz.*, hydroxystearohydroxystearic acid  $OH.C_{17}H_{33}.COO.C_{17}H_{33}.COOH$  and the dibasic anhydride—

as suggested by Jaillard.)

In the first instance it seemed necessary to direct efforts to the production of a crude material containing the smallest amount of unsaturated products. It is known that the best conditions to effect this are found in working at a low temperature, and by employing concentrated acid and dry oleic acid.

I describe my *modus operandi* briefly:—Oleic acid was cooled to  $0^\circ C.$  by ice; the congealing of the acid does not interfere with the subsequent operation, as the temperature rises soon. Sulphuric acid, also cooled down, was then allowed to fall drop by drop into the oleic acid, whilst the mass was agitated vigorously. The temperature was not allowed to rise beyond  $5^\circ C.$ , although no detrimental effect was observed when the temperature rose to  $25^\circ C.$  towards the end of the operation, as was the case in experiments on the large scale. No evolution of sulphurous acid was noticeable, and the material was not blackened. This is in contradistinction to the action of vitriol at higher temperatures which was carried out for the sake of comparison (see below). The product became, on standing, a buttery mass. It was boiled with water repeatedly until the wash-waters were free from acid.

The decomposition with water just described seemed in some experiments to yield a better material when the mixture of oleic acid and sulphuric acid was allowed to stand 24

hours; other experiments, however, did not bear this out, and seemed to prove that time was not an important factor. This is a point to be ascertained yet on the large scale.

In the following table (Table No. 1) a number of experiments is given, the quantities of sulphuric acid, calculated to one molecule of oleic acid, being varied. The amount of unsaturated substances was measured by the iodine number of the product. The original oleic acid was prepared from good tallow; it absorbed 80 per cent. of iodine.

TABLE NO. 1.

Action of Sulphuric Acid of Varying Strength on Oleic Acid.

1	95	3	6.74
1	95	3	8.46
1	103	3	16.04
	(fuming acid.)		

This table is full of suggestions for a number of experiments that are being carried out on the large scale. Contrary to expectation, the greatest amount of saturated products is not obtained when acid was used of 100 and more per cent. of  $SO_3H_2$ . There appeared this further drawback in the employment of acids of such high strength, that the product was liquid at the ordinary temperature, and gave emulsions with water, so that the sulphuric acid had to be washed out by means of a solution of Glauber salts, whereas in all other cases washing with water gave two well-defined layers. The same drawback was experienced in the case of treating oleic acid with vitriol at  $132^\circ C.$  Also the quantity of water mixed with the crude product has apparently some influence on the chemical changes.

It should be noted here that practically no evolution of sulphurous acid was observed, whilst working at low temperatures; therefore no loss of substance occurs, and the yield of the raw product must be more than 100 per cent. of the oleic acid worked upon. If we assume for a moment that addition of sulphuric acid to oleic acid takes place exclusively, according to the equation—

Hydroxystearo-sulphuric acid.

and that on boiling with water the decomposition takes place, according to the following equation:—

141 grms. of oleic acid should yield 150 grms. In an actual experiment 145 grms. of the crude product were obtained, but, of course, this is not meant as a confirmation of the assumption made. For not only are anhydride (stearolactone) and other products formed, but the action of sulphuric acid on oleic acid reaches, from a practical point

of view, a limit, as a glance at Table No. 1 will show (see above).

The crude products obtained by the experiments described in Table No. 1 were examined as set out in Table

No. 2. Hitherto, it has only been possible to carry out, on a semi-large scale, using over 1 ton of material, the interaction of 1 mol. of oleic acid with 1 mol. of sulphuric acid of about 95 per cent. of sulphuric acid.

The fact that  $\beta$ -hydroxystearic acid on being distilled undergoes considerable deterioration from a candlemaker's point of view—for hydroxystearic acid has a melting-point of  $82^\circ\text{C}$ . in its pure state—suggests the idea of removing it from the crude product, before subjecting it to distillation. The use of solvents is, of course, out of question, and the only practically feasible process is hydraulic expression. This is being tried on the large scale, and it is hoped that, by suitable processes, the necessity of distilling may be obviated.

In the experiments described below, with the exception of that given in Table No. 6, the hydroxystearic acid was not eliminated before distilling.

The crude products characterised in Table No. 2 were subjected to distillation, which, in the case of the laboratory experiments, was carried out in a flat bottomed cylindrical

copper still (a by no means suitable apparatus), and in the case of the works experiments an ordinary still was used. Superheated steam was employed, and the distillation was effected, for reasons of convenience, under atmospheric pressure instead of *in vacuo*. It will, of course, be understood that these experiments are comparable in a limited sense only; the distillates were broken up into fractions when they appeared to change in consistency, and the residues varied considerably in colour, thus proving that distillation might have been carried further in some cases. In no case, however, was distillation continued until pitch only remained in the still.

The results thus obtained are given in the following Table, No. 3, the numbers 1—3 given in the first column correspond to those in Table No. 2.

TABLE No. 3.

It should be borne in mind, that the iodine numbers do not correspond to the equivalent amounts of oleic acid, the solid iso-oleic acid absorbing the same amount of iodine as the ordinary oleic acid. A glance at the melting points shows that iso-oleic acid has been formed in considerable quantities, whereas stearolactone can be present but in small quantities judging from the small differences between saponification and acid values. This is remarkable as stearolactone is supposed to distil without decomposition.

For the sake of comparison I add the results obtained on treating oleic acid with 1 mol. of concentrated  $\text{SO}_4\text{H}_2$  at  $132^\circ\text{C}$ . See Table No. 5.

TABLE No. 5A (LABORATORY EXPERIMENT).

Product obtained by the Interaction of Sulphuric Acid and Oleic Acid at  $132^\circ\text{C}$ . and then distilled.

	Yield.	Acid Value.	Saponification Value.	Melting Point.
	Per Cent.			° C.
First Fraction ..	10.8	181.16	201.3	Liquid
Second Fraction ..	39.0	167.38	193.9	25.5—30
Third Fraction ..	16.6	152.68	184.9	25.5—32
Residue.....	29.4	..	..	..
Loss .....	4.2	..	..	..
	(corrected, 26.8			

The residue is very high indeed. In mitigation of this high number it must be stated that it contained 9 per cent. of ash (Glauber salts from the washing, see above), but this still leaves for the corrected number  $29.4 - 2.6 = 26.8$  per cent. The proportion of stearolactone is, however, higher than in the case of crude products No. 1—3, Table No. 4.

The same experiment was carried out on the large scale. The results thus obtained are given in Table 5b.

TABLE No. 5B (WORKS EXPERIMENT).

Product obtained by the Interaction of Sulphuric Acid and Oleic Acid at  $132^\circ\text{C}$ . and then distilled.

	Iodine Number.	Acid Value.	Saponification Value.	Melting Point.
				° C.
Crude product .....	53.90	169.8	..	..
Bulk distillate from crude product.	71.60	186.2	202.0	26.70

" oil .....	69.45	184.8	202.2	Liquid
Hot-pressed cake ..	72.10	202.8	206.7	43.05

(titer test)

It is evident that acidification at the high temperature can never be a paying process, on account of the great loss, and it can only be a question of examining more closely acidification at a low temperature.

From the practical point of view, the most important factor, next to the yield, of the pressed cake is its melting point, as some minor technical difficulties will, no doubt, be overcome. A report on the experiments on the large scale must be deferred to a future occasion.

In conclusion, I submit the results of an experimental distillation of a crude product obtained by the interaction of 1 mol. of oleic acid and sulphuric acid of 95 per cent.  $\text{SO}_4\text{H}_2$ , freed from hydroxystearic acid.

TABLE No. 6.

Distillation of Crude Product freed from Hydroxystearic Acid.

Yield.		Melting Points.	
I.	II.	I.	II.
First fraction ...	Per Cent. 24.0	Per Cent. 23.4	Liquid
Second " ....	24.0	20.2	24—29
Third " .....	(32.9)	(13.9)	24.4—29.4
Fourth " .....	( 7.8)	(22.9)	20.0—25.5
Residue.....	5.1	5.7	28.6—30.5
Loss .....	6.2	4.9	..

The considerable amount of liquid products obtained must not be looked upon as consisting entirely of unchanged oleic acid. These liquid substances consist to some extent of anhydrides, and further experiments must decide whether they contain ordinary oleic anhydride—which I prepared some years ago by heating oleic acid with acetic anhydride (this Journal, 1890, 666)—or products of polymerisation.

#### DISCUSSION.

Dr. RIDEAL, while admitting the great scientific value of the paper thought that it would have been appropriate if it had been read before the Chemical Society, as at present the results of the author's experiments did not seem to warrant any commercial application on a large scale.

Mr. W. MANSBRIDGE considered the statement put forward by the author to be extremely interesting from the theoretical point of view, but that, from the standpoint of the candle-maker, they offered very little encouragement. Even the best fractions of the material treated had very low melting points, and further distillation appeared to be necessary, the result of which would be partially to return them to a liquid condition, unfitting them entirely for the manufacture of candles. They had already many cheap sources of stearic acid of low quality, what was wanted was something of a high quality. Some years ago he had met with a sample of stearic acid made by Radison's process, which gave very fair candles, but its use was abandoned because the process of re-distillation was found to be too expensive. It appeared to him that in the present case they would be met with a similar difficulty. The margin between the ordinary brown oleic acid and the hard stearine of cotton oils was less than 3/4, and the cost of re-distillation would soon do away with that margin. He therefore did not see much prospect of oleic acid coming into use as a source of candle-making material.

Dr. J. LEWKOWITZ, in reply, while admitting the general correctness of Mr. Mansbridge's views, explained that in the hurry of summarising his paper he had omitted a point which would seem to promise better results. The crude product referred to undoubtedly gave candle-making material, but it required pressing, and the question resolved itself purely into one of yield. The raw product contained the two substances, stearolactone and hydroxystearic acid, and it was now for them to endeavour so to treat it as to avoid the production of the liquid acid. From the candle-maker's point of view distillation was undoubtedly a drawback. That point was fully dealt with in the paper, and his view was that they should try to arrive at some means short of distillation which would yield a white material suitable

for the purpose. Some of the experiments were made at a very low temperature—near freezing point—and some at a high temperature, 130—and the latter yielded a considerable loss. He did not attach any importance to the apparently considerable loss in the works experiment because those experiments were made very roughly in unsatisfactory apparatus, and the results were only given as an auxiliary to the laboratory experiments.

The Chairman regretted that from want of time the discussion had been so restricted. He did not agree with Dr. Rideal's view, for unless chemists saw the theoretical side of the problems they had to deal with, such problems would have a poor chance of solution.

#### NOTE ON OZONE GENERATORS.

BY EDWARD BEANES.

HAVING read, with a considerable degree of interest, the paper of Mr. E. Andreoli on "Ozone: Its Commercial Production," &c. (this Journal, 1897, 89—93), and having also noted the number of patents recently taken out on this subject, I thought that probably a brief recital of a few points of hard-earned experience from an old worker in this difficult field would be acceptable.

For the commercial application of ozone, the generator with glass plates, which was introduced years ago by me, would appear to be the only way, so far as can be at present seen, to obtain a large area. Point-bearing electrodes have been advocated, I know, but experience has shown me that points should be avoided. For the successful production of ozone, the electrodes should be as highly charged with electricity as possible, but such charging cannot be adopted with point-bearing electrodes because sparks would be produced, and ozone, already formed, would be destroyed. With very highly charged electrodes (most conducive to ozone formation) even specks of dust or dirt might give rise to sparks through the formation of points. The only way to avoid sparks with point-bearing electrodes is to avoid charging these electrodes so highly as to reach the sparking point, but this would be at the sacrifice of capacity for the production of ozone; yield would be greatly diminished.

The air to be ozonised should be dried, and filtered through cotton-wool; otherwise small solid particles may become deposited on the electrodes, and sparking may ensue, as already explained.

There is no doubt that nitrous vapours would be formed as the result of sparking, and with these a peculiar odour, but ozone would be destroyed. Looking at the character of a large number of so-called "chemical patents" annually issued, it is not impossible that the conditions laid down in sundry of those patents, ostensibly for the production of ozone, will rather favour the formation of oxides of nitrogen—in other words, of nitrous fumes.

I may, in conclusion, perhaps, just call attention to a slip in a statement in Mr. Andreoli's paper, *loc. cit.*, page 89, col. 2, and 30 lines from the bottom, where it is stated that "Ladd constructed an ozone generator, which consisted of parallel sheets of glass." &c. It is true that Ladd constructed such a generator, but he did so as ordered and employed by me; it was my generator, and the first in which sheets of glass were used.

The following have been elected to fill the vacancies, and will take office in July next:—Committee: A. Smetham and Frank Tate.

SESSION 1896-97.

Meeting held on Wednesday, April 7th, 1897.

DR. C. A. KOHN IN THE CHAIR.

#### AN IMPROVED FORM OF BUNSEN BURNER.

BY HUGH MARSHALL, D.Sc., F.R.S.E.

A GREAT drawback with the ordinary form of Bunsen burner is the liability of the central jet to become choked up by anything falling down the tube. A single drop of water is often sufficient to extinguish the flame, and a fused borax bead is still more objectionable, owing to the difficulty of properly clearing the jet. This is troublesome enough in ordinary laboratory work, but is much worse with a large practical class. Various methods of getting over the difficulty have been tried more or less successfully. I think, however, I have now succeeded in evolving a form of burner which is a considerable improvement on preceding ones.

The improvement consists in replacing the central jet by a suitably inclined lateral opening in the wall of the burner itself. The burner is left open right through, and the side air holes are done away with. An air regulator can be

fitted on the base in the form of a pivoted diaphragm. A simple form of the burner is illustrated in the diagram. This represents a section through the gas-supply tube and inlet (to the right of drawing) and one limb of the tripod base (to the left). The upper tube screws into the lower portion. This consists of a very shallow tripod with circular opening for the tube. At one side of the opening is a block into which the gas-supply tube is fixed and through which the gas inlet is drilled. The inclination of the inlet and its diameter depend somewhat on the richness of the gas used.

The advantages of the burner are, that the gas inlet does not become choked; anything dropping down the tube passes right through to the beech. Further, if the gas inlet is properly arranged, the flame can be turned down very low without it striking back or the air supply requiring regulation. Again, the air regulator fitted on the bottom cannot jam in the way the usual circular regulator does; in fact, it can be completely removed by the aid of a screw-driver in a few seconds: it is unnecessary except when a luminous flame is desired.

The burner is now in use in Edinburgh and Aberdeen Universities, and works well. It is manufactured only by Messrs. Baird and Tatlock, being provisionally patented.

## THE MANUFACTURE AND INDUSTRIAL USES OF PERSULPHATES.

BY HUGH MARSHALL, D.S.C., F.R.S.E.

WHEN requested by the Chairman of the Section to give a paper on "The Manufacture and Industrial Uses of Persulphates," I explained to him that whilst I had prepared considerable quantities for my own use and studied many of their reactions, I had no practical experience of these salts from a manufacturer's point of view. It followed, therefore, that any paper would consist largely in a compilation of material already published, though not in a connected form readily accessible to members of the Society. Your Chairman thought, however, that such a paper, giving an account of my own work, and a *résumé* of the most important work done by others, might still be of use, if only to draw attention to the possibilities of these new oxidising agents. On the Continent the persulphates have received, and are receiving, a considerable amount of attention, but in this country they seem to have been totally neglected, so far as I am aware.

The anhydride of persulphuric acid was first prepared by Berthelot in 1878. He obtained it by submitting a mixture of dry oxygen and sulphurous anhydride to the silent electric discharge in an ozonising tube. It is an oily liquid, freezing to white crystalline solid at lower temperatures. It can be sublimed at a moderate temperature. It decomposes spontaneously in the course of a few days, forming sulphuric anhydride and oxygen. It dissolves in water, giving an acid solution, which soon decomposes, forming sulphuric acid and oxygen; it dissolves in sulphuric acid, and this solution is more stable. The composition of the anhydride is represented by the formula  $S_2O_8$ .

Berthelot also showed that the oxidising liquid formed round the anode during the electrolysis of fairly concentrated sulphuric acid contains a substance other than hydrogen peroxide, which had up till then been supposed to be the sole cause of the oxidising action. The properties of the electrolysed sulphuric acid were exactly similar to those of a solution of persulphuric anhydride in sulphuric acid, and Berthelot assumed that during the electrolysis of the acid a hydrate of persulphuric anhydride—persulphuric acid—had been formed.

Berthelot studied the conditions affecting the formation of persulphuric acid by electrolysis, more especially as regards the concentration of the sulphuric acid. He did not prepare the salts; in fact, it was for some time supposed that these could not exist, persulphuric acid being classed along with hydrogen peroxide as an "indifferent" substance. This view had immediately been put forward by Mendeleef, whose ideas of the "periodic law" did not admit of a salt-forming oxide of sulphur higher than  $SO_3$ . Subsequently, however, Berthelot showed that persulphates certainly could exist in solution.

In 1891, while engaged in an investigation on the electrolytic oxidation of cobalt salts, I incidentally obtained a small quantity of a potassium salt, which analysis proved to have the composition represented by the empirical formula  $K_2SO_8$ , and which therefore was a salt of Berthelot's persulphuric acid. The general properties of the salt also agreed with those of persulphuric acid. Only a small quantity of the substance was obtained, and attempts were made to prepare further quantities by simply electrolysing potassium hydrogen sulphate solution in the apparatus employed for the cobalt electrolyses (Chem. Soc. J. 1891, 771). This consisted of a platinum basin of 200 c.c. capacity, cooled externally by a stream of water. In the centre of this was placed a porous jar containing dilute sulphuric acid, into which dipped a thick coil of platinum wire to act as cathode. The basin contained a saturated solution of potassium sulphate in dilute sulphuric acid, and itself constituted the anode. The current was supplied by a secondary battery, and averaged in the experiments about 3 amperes. Solid persulphate began to separate after a day or two, and thereafter deposited fairly rapidly. When a considerable amount had collected, it was drained off and dried on porous plate. The mother-liquor was diluted somewhat and resaturated with potassium sulphate, after

which the electrolysis was continued. It was found that the crude persulphate thus obtained could be purified by dissolving it in boiling water, filtering quickly, and cooling the liquid. The loss was small, although slight decomposition did take place.

Similarly, it was found that the corresponding ammonium salt could easily be prepared by employing ammonium sulphate in place of potassium sulphate. It separated solid in the anode cell in the same way, and was similarly treated. The loss on purification in this case was much greater owing to the ammonium salt being much more soluble in water. (Ice-cold water dissolves only 1.8 per cent. of the potassium salt, but 58 per cent. of the ammonium salt; so that a strong solution of ammonium persulphate produces an abundant precipitate of potassium persulphate when added to a strong solution of, say, potassium acetate.)

Other sulphate solutions gave no deposit of persulphate on electrolysis, the normal or acid salts being apparently less soluble in the mother-liquor, and separating out first. Certain other persulphates were, however, prepared indirectly; the ammonium salt formed the starting point, so it was prepared in much greater quantity than the potassium salt.

In order to prepare ammonium persulphate in quantity more conveniently than was possible in the small apparatus first employed, a new apparatus with much larger basin was tried. Berthelot in his early papers had stated that he preferred to use a small anode (of platinum wire), to prevent as much as possible decomposition of persulphuric acid in contact with platinum. As, however, I had not observed in my former experiments any special tendency to such decomposition, although the surface of platinum was large, and as the apparatus had given good results in preparing large quantities of cobaltic solutions, I expected to get equally good results with it in the present case. In this I was disappointed, no persulphate separating even after some days with a current rising to 5 amperes. The apparatus was therefore completely changed so as to use a smaller anode, still in a large vessel. The latter consisted of a beaker standing in an outer vessel containing cooling water. In the beaker, to one side, was suspended a porous jar containing dilute sulphuric acid in which dipped the cathode, formed of a sheet of thin platinum foil. The anode was composed of a long, thin platinum tube in which cold water could be circulated. The beaker was filled with a saturated solution of ammonium sulphate in dilute sulphuric acid. With this apparatus, using a current of 3–5 amperes, good yields were obtained, especially when a very small anode, got by dipping the tube only a short distance into the liquid, was employed. It was found advisable to keep two solutions going, one being saturated with ammonium salt whilst the other was being electrolysed. If the solutions were not changed frequently, ammonium persulphate crystallised out when the sulphate was added, showing that there was deficiency of ammonium salt in the liquid. Sometimes a perforated vessel containing crystals of ammonium sulphate was suspended in the upper layer of solution during the electrolysis. When solid persulphate had collected in the beaker to a considerable depth, the mother-liquor was transferred to a similar beaker, in which the operation was continued. The proper draining of the persulphate mud was at first somewhat difficult. The plan which succeeded best was to sink in it a porous jar closed with an india-rubber stopper, from which a glass tube led to a large bottle, from which the air was pumped. The liquid was gradually sucked out, and a dry, hard mass of crude ammonium persulphate resulted. If so desired, this could then be further purified by recrystallisation from water.

Several kilos. of ammonium persulphate were prepared in this way without difficulty.

The impossibility of preparing persulphates when a very large anode was employed, led me to change my views as to the way in which they were formed. The formula which had at first been adopted for the persulphates was  $M_2SO_8$ . This was based on a determination of the electrical conductivities of solutions of the potassium salt, the values found agreeing with those given by Ostwald for potassium perchlorate. If that formula were correct, we might assume that persulphuric acid was formed simply by the

discharge of the  $\text{HSO}_4$  ions conveying the current, these, and not  $\text{SO}_4$ , forming the majority of the anions in solutions of sulphuric acid or acid sulphate of the strength employed. In that case it was difficult to see why the amount formed should be so diminished by increasing the anode surface. If, however, the true molecular formula for persulphate should be  $\text{M}_2\text{S}_2\text{O}_8$ , then the case is entirely different. Persulphuric acid would then be formed by two discharged  $\text{HSO}_4$  ions uniting together, and there would be greater opportunity for such union the closer the ions were packed together at the moment of their discharge, that is to say, the higher the current density. To obtain a high current density with a large anode means a very strong current; but with moderate current the same effect is procured by correspondingly diminishing the anode area. To decide the matter definitely, estimations of the molecular weights of the various persulphates were made by freezing-point determination. These all pointed to the doubled formula. Similar results were obtained by other observers. An experiment of a different kind was also tried. A solution of barium persulphate was electrolysed in a U-tube, with platinum electrodes. Barium sulphate rapidly formed round the cathode, but not at all round the anode. If the persulphate ion were  $\text{SO}_4$  we should expect it when discharged to give at least some sulphuric acid by acting upon the water. Instead of that, however, we get only persulphuric acid and oxygen; so that this experiment also, if anything, favoured the double formula. All doubt was finally removed by a redetermination of Ostwald's conductivity values for potassium perchlorate, which were shown to have been formerly inaccurate.

We may therefore consider the formation of persulphate from sulphate by electrolysis as very similar to that of tetrathionate from thiosulphate by the action of iodine. Persulphate is in fact analogous to tetrathionate, as exhibited by the corresponding formulae  $(\text{MSO}_3)_2\text{O}_2$  and  $(\text{MSO}_3)_2\text{S}_2$ ; just as anhydrosulphate,  $(\text{MSO}_3)_2\text{O}$ , corresponds to trithionate,  $(\text{MSO}_3)_3\text{S}$ . The names persulphuric acid and persulphate are therefore now somewhat unfortunate, as the persulphates have no close relation to the perchlorates and permanganates.

To get good yields of persulphate it is evident, then, that we should have: first, an anode solution containing the largest possible proportion of  $\text{MSO}_4$  (practically  $\text{HSO}_4$ ) ions; second, high current density; third, low temperature. The first ensures that the largest possible portion of the current goes to provide the  $\text{HSO}_4$  groups required for the formation of persulphate; it implies the removal of already formed persulphate as rapidly as possible from the anode. The second secures that a large proportion of the discharged  $\text{HSO}_4$  groups unite together to form persulphate, and do not cause other, unproductive, reactions. The third is necessary because the acid liquid containing persulphate easily decomposes when warmed; possibly also there would be less persulphate actually formed, the other reactions predominating as the temperature rose. It is probable that persulphuric acid is the substance formed in the electrolysis of the various salts, the potassium or ammonium persulphate resulting by double decomposition with the potassium or ammonium sulphate present.

As a matter of fact, these conditions, so far as they relate simply to the electrolysis of sulphuric acid, had been carefully studied by Richarz as early as 1885, but I was unacquainted with his original paper (Ann. d. Phys. u. Chem. xxiv, 1885) at the time of my work. He gives the results of whole series of experiments on the effects produced by varying the above conditions. Another point discovered by Richarz is that, after an anode has been in use for a short period, the yield of persulphuric acid unexpectedly falls, but that the yield resumes its former amount if the anode is withdrawn and made red hot. Apparently the surface of the anode is acted upon in some way, a slight roughening being produced.

More recently the conditions affecting the formation of persulphuric acid have been very fully studied by Elbs and Schönherr (Zeitschrift für Electrochemie, 1895—1896), who were at first also unaware of the full extent of Richarz's work. Their results bear out those of the latter, and as they cover more ground, I shall refer to them later.

I need only say a few words about the other persulphates which I prepared. None could be obtained by direct electrolysis of the sulphates in dilute sulphuric acid. Those tried in this way were sodium, lithium, magnesium, zinc. Attempts to get pure crystallised specimens of them by various double decompositions—for example, through the barium salt—were also unsuccessful; they are apparently very soluble in water. Small quantities of approximately pure sodium salt were prepared by the action of pure sodium hydroxide on strong solutions of the purified ammonium salt, and evaporation *in vacuo*. They could not be got to crystallise, however, and gave only crystalline crusts contaminated with sulphate. The barium, strontium, and calcium salts are easily obtained pure by the action of the corresponding hydroxides on a strong solution of ammonium persulphate, and evaporating the filtered solutions *in vacuo*. They all crystallise with 4 mols. of water, and are very soluble, especially the calcium salt. They dissolve in absolute alcohol, the solution in the case of the barium and strontium salts soon depositing a monohydrated salt, practically insoluble in the liquid. The calcium solution does not do so, and the addition of ether to it throws down the tetrahydrated salt unchanged. A small quantity of lead salt was prepared by treating the barium salt with dilute sulphuric acid in slight excess and dissolving lead carbonate in the persulphuric acid solution thus obtained. It is very soluble and difficult to crystallise. It contains 2 or 3 mols. of water of crystallisation. Lead persulphate was of a certain interest, as it had been suggested that its behaviour might throw light on the chemistry of secondary batteries. It decomposed very quickly, forming lead sulphate and free acid, but no peroxide, so that it is very unlikely that it plays any part in the charging of a secondary cell. The contrary view is nevertheless held by some chemists, though it is strongly combated by Elbs.

I shall now give a few of the principal results obtained by Elbs and Schönherr in their investigation already mentioned. Their experiments are of importance, supplying data for obtaining the best yields by electrolysis; but it is to be remembered that the yields stated refer to the amount formed in solution, and not to the quantity of solid persulphate obtainable.

The apparatus employed consisted of a divided cell formed by a porous jar of 100 c.c. capacity, standing in a beaker. A cylinder of lead or platinum of 150 sq. cm. surface, surrounding the jar, formed the cathode. The anode was a platinum wire or foil dipping into the jar. The cell was surrounded with ice. Sometimes the arrangement was reversed, a ring of platinum wire in the outer cell forming the anode, and a coil of lead pipe in the jar acting both as cathode and as a cooling worm. The liquids to be investigated were of course placed in the anode division, sulphuric acid always in the cathode division.

#### *Influence of Acid Concentration.*

Current density = 100 amp. per sq. decim. Temp. 5°–6°.

The maximum effect was obtained with acid of 1.45 sp. gr.

Yield for 1st hour, 69.5 per cent. of possible.

" 2nd " 49.5 " "

The fall during the second hour is probably largely due to the accumulated persulphuric acid itself undergoing electrolysis.

#### *Influence of Current Density at Anode.*

Acid of 1.38 sp. gr. Duration of exp. = 50 min.

Current density = 4 amp. per sq. decim.

Yield = 0.7 per cent. of possible.

Current density = 28 amp. per sq. decim.

Yield = 53.3 per cent. of possible.

Current density = 500 amp. per sq. decim.

Yield = 67.5 per cent. of possible.

#### *Influence of Temperature.*

Acid of 1.38 sp. gr. Duration of exp. = 60 min.

Temperature = 2° C. Yield 64 per cent. of possible.

" 27° C. " 33 " "

" 60° C. " 0.9 " "

*Influence of other Substances dissolved.*

A great many experiments were carried out in which other sulphates besides sulphuric acid were present. In many cases, as, for example, with zinc and magnesium, these had no noteworthy effect. In others there was a large increase in the persulphate yield. The sulphates which produced the best results were those of nickel, potassium, ammonium, and aluminium, the increase being most marked in the latter case: sodium sulphate, strange to say, had practically no action.

It was further found that a very small quantity of hydrochloric acid added to the sulphuric acid (0.03 gram. in 50 c.c.) caused a most remarkable increase in the yield; for example, in one case the yield rose from 43.9 per cent. to 69 per cent., and in another, from 10 per cent. to 57.3 per cent. Possibly the high result in the case of aluminium sulphate was partly due to the fact that the sample used contained a trace of chloride.

Generally speaking, the results obtained in the experiments under this head are quite inexplicable.

*Influence of the Condition of the Anode Surface.*

An ordinary platinum anode must be frequently removed and ignited, the surface being kept as bright as possible. A platinised electrode gives very poor results, but also becomes efficient when made red hot, the surface then assuming a metallic lustre. An anode placed horizontally is better than a vertical one, as in the former case the convection currents caused by escaping gas remove the newly-formed persulphuric acid more quickly from the neighbourhood of the anode, which is of importance.

Finally, the authors conclude from their various results that ammonium persulphate is the cheapest and most convenient to prepare, using a moderately high current density, a strong solution of the sulphate, with or without sulphuric acid, and adding ammonium carbonate from time to time to keep up the supply of ammonium salt. If potassium persulphate is wanted, it is better to prepare it from the ammonium compound by double decomposition.

In such experiments the percentage yield can be got by determining the oxidising power of a known fraction of the solution and comparing it with the theoretically possible for the current during the time of the experiment (1 ampère-hour could produce, at most, 3.63 grms. persulphuric acid); or by comparing the quantity of oxygen evolved with that evolved in a voltameter placed in the circuit, the yield of persulphuric acid being proportional to the difference between them relatively to that evolved in the voltameter. Instead of the volume of oxygen given by the voltameter, half the volume of the hydrogen obtained at the cathode in the apparatus itself might be taken for an approximate result.

A fresh development in connection with the preparation of persulphates has taken place comparatively recently, and may be of considerable importance. Some time ago, Löwenherz applied for, and was granted, a German patent for the preparation of sodium persulphate by the action of caustic soda on the ammonium salt. Later, he took out a new patent for the preparation of it directly in the electrolytic cell. This he effects by thorough cooling of the liquid, high current density, and the occasional addition of soda to the solution. The apparatus is the usual divided cell, a porous jar standing in a vessel of similar height and of about three times the capacity. The vessel is of metal (presumably lead), contains sulphuric acid and water mixed in about equal volumes, and itself constitutes the cathode. The inner cell contains a saturated solution of sodium hydrogen sulphate, and the anode is a piece of platinum wire or foil. The liquid is cooled by cold water, circulating in a coil in the inner cell, and surrounding the outer vessel. The current employed is about 3 amperes per sq. cm. of anode, at 15 volts, but may rise considerably above that. From time to time during the process, sodium carbonate, either in solution or fused in its water of crystallisation, is added to the inner cell. In course of time solid sodium persulphate separates at the bottom of the porous jar. When sufficient has collected the jar is removed, and the solution poured off into another jar, in which the process is

continued. The process is continuous but for this changing of the cells, necessary once in about 12 hours.

If this process is economical as regards current, the preparation of sodium persulphate should rank before that of the ammonium salt, as the original material is cheaper. In use, the sodium salt would also be much preferable to the potassium or ammonium salts. It is far more soluble than the former, and more generally applicable than the latter—if alkaline solution was desirable, for example.

It seems to be somewhat generally supposed that the persulphates are very unstable salts, and cannot be kept for long. This is certainly true of solutions, and of those salts which have water of crystallisation, but does not apply to those salts which can be got pure and dry. Potassium salt is the best example of such, its sparing solubility rendering it capable of easy purification. It undergoes practically no change at the ordinary temperature. Samples of it prepared five or six years ago, recrystallised and carefully dried, still have bright shining crystal faces and are almost quite free from sulphate. The ammonium salt cannot be easily prepared so pure as the potassium salt to start with, and does not keep quite so well. Still, a sample prepared five and a half years ago, which had been once recrystallised from water, powdered, treated with ammonia gas, and dried, still contains 97 per cent. of persulphate. Other samples not so carefully treated, now contain much more sulphate than the above. In presence of water the decomposition of persulphates is much more rapid.

The most striking chemical properties of the persulphates is their powerful oxidising action, whether used in neutral, acid, or alkaline solution. In many cases, however, the action is probably not a direct oxidation, a molecule of persulphate ( $\text{M}_2\text{O}_8$ ) taking up two atoms of a second metal to form 2 mols. of sulphate. Such action would correspond more to the direct action of bromine or iodine. Many reactions of the persulphates are most simply explained in this way. Among these are the following:—

Action on chlorides, bromides, iodides; sulphate and free halogen are produced (most of these persulphate reactions proceed slowly at ordinary temperatures, more rapidly on warming):  $\text{K}_2\text{S}_2\text{O}_8 + 2\text{KI} = 2\text{K}_2\text{SO}_4 + \text{I}_2$ .

The conversion of ferrocyanide into ferricyanide is similar:  $\text{K}_2\text{S}_2\text{O}_8 + 2\text{K}_3\text{FeCy}_6 = 2\text{K}_2\text{SO}_4 + 2\text{K}_3\text{FeCy}_6$ .

Also that of manganate (in alkaline solution) into permanganate:  $\text{K}_2\text{S}_2\text{O}_8 + 2\text{KMnO}_4 = 2\text{K}_2\text{SO}_4 + 2\text{KMnO}_4$ .

An interesting example is the action on solution of thiosulphate, resembling that of iodine, tetrathionate and sulphate being produced—

This affords an easy method of preparing tetrathionates from the corresponding persulphate and barium thiosulphate. In this case insoluble barium sulphate and soluble tetrathionate are directly produced—

There is a considerable evolution of heat in this reaction, as may be observed by mixing concentrated solutions of sodium thiosulphate and ammonium persulphate. A gradual but very marked rise of temperature takes place.

Somewhat similar to these actions is that on ferrous salts, converting them into ferric. Thus ferrous sulphate with ammonium persulphate and water gives a brown solution from which iron ammonium alum crystallises out—

This reaction is employed for the quantitative determination of persulphate, with the aid of a standard solution of permanganate.

The action of persulphate solutions on the metals themselves is also interesting, many of the latter dissolving more or less rapidly; so that we have here a case of a metal dissolving in a solution of a normal salt and producing a solution containing normal salts only.

Zinc, aluminium, cadmium, and magnesium simply dissolve up without any specially noticeable phenomenon—

Cobalt also dissolves, giving a pink solution, and forming a slight dark deposit. Nickel sheet or wire is hardly attacked at all, but an electrolytic deposit of the metal dissolves more rapidly.

Mercury is rapidly attacked. If pure solution of potassium persulphate is poured on metallic mercury, a slight black deposit quickly forms, but soon gives place to a considerable yellowish-white precipitate. In presence of free sulphuric acid, a white precipitate only is produced. This is also the case with ordinary solutions of ammonium persulphate.

Copper is dissolved, giving a solution of cupric sulphate, while a slight reddish deposit is also noticeable on the metal.

Lead is attacked only superficially, the bright surface tarnishing from the formation of a thin film of sulphate, which apparently prevents further action.

Silver is dissolved by persulphate solution. If a piece of wire or foil is suspended in the solution it becomes gradually corroded, while a black deposit forms on the metal and at the bottom of the vessel. This afterwards dissolves with evolution of gas. Probably silver sulphate first forms:  $K_2S_2O_8 + 2Ag = K_2SO_4 + Ag_2SO_4$ . From this silver peroxide is formed by a second reaction—

Metallie iron dissolves very easily in solution of persulphate; with concentrated and slightly acid solution of ammonium persulphate the action is violent. If ordinary iron is used, a deposit of carbon remains. Iron is quickly attacked by the solution, even if it contains free ammonia, ferric hydroxide being formed; and, as it is probable that no carbon compound is produced under such circumstances, this might form a convenient method of obtaining the total carbon in iron analysis. The reaction is being investigated for this purpose.

Gold and platinum are not attacked by persulphate solutions.

Persulphates cause more or less complete precipitation of peroxides when added to solutions of certain metallic salts; for example, those of manganese, silver, and cobalt. In other cases, as those of lead and nickel, precipitates of peroxides are obtained only after the addition of alkali. In the case of manganese the oxidation can be carried still further by digesting the mixture on the water-bath for some time, when a pink solution of permanganic acid or of alkaline permanganate is slowly formed. Similarly, in presence of alkali, chromic salt can be converted into chromate by means of potassium persulphate.

Many organic substances are oxidised by acid or alkaline persulphate solution. Thus, many colouring matters are easily bleached by it; for example, indigo, litmus, turmeric.

The above are some of the most interesting reactions of persulphates which I have investigated. Recently I have been studying some of them, along with others, somewhat more fully, and hope to be able to make a communication on the subject later.

As regards the technical uses of persulphates, I can give little information of a definite character. Numerous suggestions for their employment have been made, but whether or not these have really found practical application it is difficult to discover. Thus, they have been proposed as bleaching agents, and for use in medicine as disinfectants. For several years potassium and ammonium persulphates have been manufactured in quantity by Dr. A. Curchod, Nyon, Switzerland, and he has supplied them to dealers and various manufacturers. In many cases they were wanted for experimental investigations in dyeing, bleaching, the manufacture of dyestuffs, &c., and apparently have found a certain applicability in some of these departments.

Some time ago potassium persulphate was put upon the market, under the name of "anthion," as a hypo-eliminators for use in photography. The special advantages claimed for it were that it completely destroyed the thiosulphate without attacking the image. It undoubtedly destroys the thiosulphate, but the resulting tetrathionate is probably as difficult to remove by washing, and, if allowed to remain at all in the negative or print, would probably be quite as objectionable as thiosulphate; further, as persulphate solution does attack metallic silver, there is almost certain to be some effect on the image.

Although I have been so unsuccessful in obtaining definite particulars of the industrial employment of persulphates, perhaps some members of the Section who employ oxidising agents on the large scale may obtain hints as to possible uses of them from the diverse reactions which have been already noted. Of course, a good deal depends upon the price at which persulphates can be produced on a manufacturing scale. On this point I have no data. The present retail price in small quantity is about 3s. to 4s. per lb. A year or two ago it was double that. The commercial potassium salt contains as much as 90 or more per cent. of persulphate; the ammonium salt very much less.

Even though persulphates should not become of much use on a large scale, they are convenient substances to have in a laboratory. In many cases they can be used in place of hydrogen peroxide, bromine, iodine, &c.; and, as we have seen, can be preserved for a long time without decomposition.

*Meeting held on Wednesday, May 5th, 1897.*

DR. C. V. KOHN IN THE CHAIR.

## THE VOLUMETRIC ESTIMATION OF ZINC.

BY EDWARD GEO. BALLARD, A.R.S.M., F.I.C.

IN the volumetric determination of zinc by a standard solution of sodium sulphide, more or less difficulty is often experienced in ascertaining the exact point at which all the zinc is precipitated and the sodium sulphide becomes present in excess. This is usually accomplished by adding to the ammoniacal solution of zinc under examination some flocculent ferric hydrate, and watching for the moment that the darkening of the flakes takes place, which happens as soon as an excess of sulphide has been added. This needs much care and practice in order to obtain uniform results, owing to the fact that unless the solution of zinc be kept in constant agitation the iron is very liable to blacken before all the zinc is precipitated. This, of course, may be overcome by filtering off small portions of the solution from the suspended zinc sulphide and testing a drop of the filtrate with ferric hydrate on a slab, or by using a solution of lead in the same way, or by employing lead paper. I have found the following method very delicate and rapid in determining the end of the titration, and it is based upon the fact that the suspended sulphide of zinc has no action on metallic silver, whereas the smallest excess of sulphide of sodium in the solution will produce a stain upon a bright silver surface. A small bright plate of silver is procured, and at intervals during the titration a drop of the zinc solution containing suspended ZnS is taken out on a glass rod and placed upon the silver plate, and allowed to remain there for 10 to 20 seconds. No blackening of the silver surface occurs until there is an excess of sodium sulphide present, when the stain upon the silver plate is evident at once, and the titration may be considered finished.

The number of drops of the standard solution of sodium sulphide required to produce the stain in the time mentioned, may be ascertained in a quantity of water equal in bulk to that of the zinc solution operated upon, and afterwards deducted from the total used in calculating the result. One part of Na<sub>2</sub>S in 20,000 of water will produce a stain.

Another way to use the silver-plate indicator is to run in the sulphide to small excess, and then titrate back with a solution of zinc of known strength, watching the disappearance of the stain on the silver plate in this instance. Time is thus gained when testing a substance containing an unknown quantity of zinc for the first time, but in cases where the amount is approximately known, the former method suffices, the greater part of the sulphide being run in at once, and the silver-plate indicator applied during the addition of the last portions only.

*Precaution.*—Although it has been stated that the precipitated sulphide of zinc has no action upon the silver plate, yet in the presence of a large excess of ammonia in the cold there is a slight action; therefore it is desirable to

observe the precaution to avoid, as far as possible, adding more ammonia than is required to redissolve the precipitate first formed in rendering the solution of zinc under examination alkaline. However, if the temperature of the solution of zinc be raised to about 180° F., a much larger excess of ammonia may be added without interfering with the accuracy of the test or the final estimation of the zinc. Under any circumstances I prefer titrating the solution of zinc hot.

The first appearance of the stain on the silver plate can be more easily distinguished in a diffused light, such as that reflected from a sheet of white paper, or a white card, and more especially if the drop be removed at the end of 10 or 20 seconds by means of a small blotting pad or piece of folded filter paper.

A porcelain dish is the most convenient vessel in which to perform the titration. Another point to ensure accuracy is to be careful that the silver plate is clean and free from grease. A little chalk and ammonia is useful for this purpose.

### APPARATUS FOR GAS ANALYSIS.

BY J. KENT SMITH AND J. W. TOWERS.

READ BY J. KENT SMITH.

SOME two years ago one of us had occasion to perform a large number of gas analyses in connection with the changes taking place in producer-gases of different compositions after passing through the regenerators of a Siemens steel furnace, and a short time previous to this a large number of analyses of coal-gas obtained in the Smet-Solvay process of coking. The necessities of these cases, together with some experimental work entailed, were the origin of the present apparatus. The results obtained, and the very favourable comments of several chemists who have seen the apparatus working, prompted us to put it before you this evening.

We first submit to you a modified gas sampler, more especially adapted for taking continuous or average samples of gas, and working with mercury. That mercury is the only liquid which may be employed for accurate work is, we think, universally established. Many operators recommend the use of water, previously saturated with the gas to be examined. This I, personally, have found unsatisfactory, especially in regard to the analyses of illuminating coal-gas. Some time ago I had occasion to draw some average samples of coal-gas, representing a 24 hours' make, both raw and purified gas being sampled. The collecting bottles were filled with water taken direct from the large station meter in which the raw gas was measured. Samples were also collected "dry" at short intervals over the 24 hours and analysed for  $H_2S$  and  $CO_2$ . While in the dry samples the percentages of  $CO_2$  and  $H_2S$  gave as an average 2.6 per cent. in the crude gas and 0.7 per cent. in the purified gas, in the samples collected over gas-water the results were respectively 2.0 per cent. and 1.3 per cent., thus showing that  $CO_2$  had actually been dissolved in the one case and taken up from the water in the other.

This is certainly an extreme case. The sampling bottles were subjected to a considerable range of temperature, but this is a point very generally to be encountered when drawing average samples. Again, the saturated water was saturated in both cases with "raw" gas. In spite of this, we are of the opinion that the above figures are a strong proof that "saturated water" is anything but an advisable containing fluid for an average gas sampler.

Our sampler (Fig. 1) consists of a hollow sphere of stout glass mounted on a solid stand, having a capillary blown on to the upper extremity carrying a three-way glass tap of 1 mm. bore. At its lower extremity on the one side is a tubulure of 2 mm. bore, and on the other side a capillary carrying a single-way glass tap of 1 mm. bore, the exit tube of which is bent to a seal, thus preventing over-running and consequent loss of sample. The upper tap has a ridge blown on it just beyond the glass ending, and a strong rubber band fit into the groove, forming a washer, which prevents the tap from springing out of place. The tubulure is attached by thick rubber pressure tubing to an ordinary Orsat bottle, which acts as a mercury reservoir. About midway up the rubber tubing a screw clip is placed.

The sampler is filled completely with mercury by raising the Orsat bottle, opening the sealed tap till the mercury flows out, closing it, and keeping the mercury rising until

Fig. 1.

GAS SAMPLER.

the capillary at the top is filled. The clip being shut, the bottle is then placed underneath the seal and the collecting pipe pumped or blown through by means of the three-way tap, and by adjusting the lower tap a constant sample is accumulated.

In taking a sample of gas with a mercury sampler over a lengthened period, difficulty is always experienced from the liability of the mercury to stop running. This is caused by particles of dirt collecting at the inlet and outlet of the bore of the tap, and in addition to this the repulsion between mercury and glass has a tendency to stop the flow. When the mercury is set to drop at the rate of 60 to 80 drops per minute, the flow will usually stop when the head of mercury above the tap is reduced to about 3 in. with perfectly clean mercury; dirt will, of course, stop it at any time.

We have found that the insertion of a fine jet in the bore of the tap, with the point placed so as to meet the stream of mercury, to a great extent overcomes both difficulties (Fig. 2). Small particles of dirt will either pass

Fig. 2.

through the jet or fall on one side and collect in the space round the jet, and the mercury will continue to run until the head is reduced to about 1 in.

There is this objection to the use of the jet: the tap can be used at one speed only, because the jet must always be at full bore. It is very easy, however, to make the jets; a minute or two suffices to make one, if the one in use is not of right size. They are made by pushing a tapering capillary tube through the plug of the tap until the point is reached at which it fills the bore; this point is marked, the tube withdrawn and heated for a second in a small flame at about an eighth of an inch from the mark, then drawn out quickly to the size required, and the tapering piece, about a quarter of an inch long, altogether cut off.

In order to make the speed of aspiration more uniform, a tube of 1 to 2 ft. may be attached, if desired, to the sampler, to give a greater fall; this must, of course, be bent at the lower end to form a seal.

For drawing an average sample of gas at different periods of the day the apparatus may be connected up for the first sample, and an aliquot amount of gas drawn. It may then be left *in statu quo*, and previous to drawing the next portion of the sample the pipe is cleaned of "stale gas" by blowing or pumping through the three-way tap according as the gas to be examined is under pressure or suction.

The sampler is particularly adapted to drawing samples for the purposes of checking the work of boiler firemen.

It is advisable in all cases that the apparatus should be as near the gas flue as possible. The collecting pipe should be as short as possible and of a narrow bore. It may conveniently be widened at the intake end, and any dust arrested by means of a plug of loosely packed asbestos. A piece of stout walled, narrow bore glass tube may be used, enclosed in an outer iron tube, the intervening space being packed with asbestos. The whole sampling apparatus may be carried in a small separate case if desired.

#### *The Gas Analysis Apparatus.*

This apparatus presents many features common to a great many of the forms of apparatus in the market. From the results of two years work done in it we feel we are justified in saying that we have produced an apparatus which is—

- (1.) Accurate.
- (2.) Rapid.
- (3.) Portable.
- (4.) Simple, and last but not least,
- (5.) Easily cleaned.

- (1.) Accurate, in that—  
We work over mercury.

Fig. 3.

We use a large sample (*i.e.*, up to 100 c.c.) of gas. We have no capillary tubes which are not under actual measurement.

Our risk of leakage is reduced to a minimum, and

We have a special adjustment for accurate reading without the aid of a cathetometer.

- (2.) Rapid, in that the adjustment of the absorption bulbs is very quickly performed, and the pipettes themselves offer special advantages for rapid absorption.
- (3.) Portable, in that the whole apparatus, together with—  
Four sets of absorption bulbs,  
Battery and coil for explosion, and  
The sampler already described, is carried in the case before you.
- (4.) Simple, in that the whole apparatus carries only two taps, one of these being used for regulating.
- (5.) Easily cleaned, the endiometer being removable by simply disconnecting one rubber joint and drawing out the fore part of the split shelf.

This last point will, we think, recommend itself strongly to chemists who are required to make a considerable number of gas analyses.

The apparatus consists of—

A endiometer tube fitted with platinum electrodes drawn to a capillary at its upper end, this capillary being bent twice at right angles and fitted with a three-way tap (*sketch*). The lower end of the endiometer is drawn out to a tube having a bore of 2 mm., and is connected to the first upright of a horizontal **F** piece. The second upright of the **F** piece is connected to a balance or pressure tube of 8 mm. bore, contracted near the top to a fine calibre, and opening out again for a length of 10 cm.

This contraction prevents projection of the mercury from the pressure tube should the levelling bottle be brought up quickly. The pressure tube is of sufficiently wide bore to overcome any error in levelling due to capillary attraction, and enables the apparatus to be worked with very much less mercury than would be necessary if the endiometer and pressure tube were of the same diameter. The horizontal arm of the **F** piece is connected to an ordinary Orsat bottle, a large single-way tap of 2 mm. bore set in the base of the apparatus, being interposed. By means of this tap levelling is much simplified. To prevent the tap springing under the high mercury pressure put upon it a mahogany slot-fastened casing is superimposed. Both endiometer and pressure tube are contained in glass jackets closed at both extremities, and having milk-glass backs. The upper cork of the endiometer jacket is split, and platinum wires connected to the electrodes are led through it. Arrangements for a constant water flow may be adapted.

The endiometer is graduated to 100 c.c. in one-fifths, the zero point being at the outer extremity of the bore of the three-way tap. It is supported by a split shelf, through which the lower end of the tube runs, while the rectangular bend at the top is supported by a baize-lined groove in the wooden casing of the stand. The exit capillary tube on the three-way tap has 2 bulbs blown upon it. A sliding, removable spirit level is carried by a pair of uprights in front of the endiometer and balance tubes, and is fitted with a hair-line, for the purpose of securing an exact reading. With this 0.05 c.c. may be easily read.

The absorption vessels (Fig. 4) are of a special form, consisting of a vertical series of bulbs, mushroom-shaped,

Fig. 4.

ABSORPTION BULBS.

to prevent any gas bubbles being intercepted at their upper end, and flattened at the bottom. The connecting-tube of each bulb in the set rises slightly above the bottom of the bulb immediately above, so that in each bulb a layer of the absorbent liquid is retained. The gas is thus exposed to the action of several successive layers of the absorbent, giving the bulb a greatly increased absorbing capacity, with a minimum of bulk. In addition, the fact that the gas entering at the top is first spread out, and meets with the freshly-wetted sides of the bulb, and then has to pass through a narrow space, where it has practically to bubble through a very thin layer of liquid, greatly promotes absorption, while the absorptive surface of liquid is nearly six times the area of the bulb section at its widest part.

The containing jar is contracted at the top, and fused on to the stem of the bulbs. It contains a tubular opening, through which it can be filled by means of a small funnel with a bent stem. A rubber hand-ball is attached to the tubulure, which serves as a pressure-vessel for forcing the reagent up the bulbs after adjusting them, and protects the reagent from oxidation. A small rubber cap closes the mouth of the bulbs when not in use. They can be emptied by simply removing the rubber ball, inverting the bulbs, and shaking gently. The bulb for copper chloride solution is not fused to the containing jar, but suspended by means of a rubber stopper. This enables a piece of copper gauze to be placed in the containing jar, outside the bulbs.

A comparative trial of the bulbs was made with a sample of producer-gas, selecting CO as the most "obstinate" constituent. A large sample was taken and entirely freed from  $\text{O}_2$  and oxygen. The percentage of CO contained in the CO-freed gas was 25.0 per cent. Acid copper chloride solution was used which had been previously used several times. Each trial absorption vessel was filled at the same time with the same solution, and an equal quantity of gas was drawn into the endiometer for each experiment.

1.) In a plain glass bell-tube of the usual type, 270 mm. x 25 mm., packed with glass tubes, 18 per cent. of the total amount of CO present was absorbed at the first pass (about 30 seconds duration).

2.) Using the same sized glass bell-tube, but substituting copper gauze for the packing tubes, as is the practice of many chemists, 28 per cent. of the total amount of CO was absorbed in the first pass of the same duration. Copper gauze is objectionable for accurate work, owing to its strong tendency to retain gas bubbles.

3.) With our own form of bulbs, using the same amount of gas and the same copper solution, 65 per cent. of the total amount of CO present was absorbed in the first pass, whilst practically the whole of the CO present was absorbed in five passes.

Other trials of our bulbs have, when producer-gas of a somewhat similar composition is worked with, given average results of well over 60 per cent., the best figure

reaching to nearly 70 per cent., and the worst being no lower than 55 per cent.

The stand is of mahogany, and has a cupboard which may be rack-fitted for packing six absorption pipettes. It is fitted with shelves holding a dry cell, and a  $\frac{1}{2}$ -in. spark induction coil. It also contains a drawer for holding the endiometer tap, a shelf for holding the sampler and a bracket (with packing block) for holding the absorption bulbs in place. It has sliding doors completely enclosing it back and front, and small auxiliary slot-fastened covers are fitted to protect the only two slightly projecting glass parts. A handle for carrying the case is attached.

The apparatus is worked as follows:—100 c.c. of gas is drawn in through the three-way cock, the excess gas over 100 c.c. being expelled in the usual way. The levelling must be very carefully done, as it must be remembered that a difference of 1 mm. mercury is equal to over 13 mm. of water.

The three-way cock is then turned so as to give a through passage from the inlet to the outlet. The first absorption bulb is slipped on, with a well-fitting connecting piece, of medium thick rubber. By pressure on the hand-ball the reagent is made to rise through the bore of the three-way tap until it stands in the upright portion of the outlet tube. By turning the three-way tap quarter round, communication is made between the endiometer and the absorption pipette, and the reagent falls a little, pulling with it a small quantity of gas from the endiometer. Pressure is then put on by means of the mercury bottle, and the whole of the gas driven into the pipette. The mercury bottle is then lowered, the speed of the gas travelling back checked by means of the lower tap as the absorbent rises in the pipette, and the three-way tap shut off the moment the absorbent comes up to the tap. After the constituent to be estimated is completely absorbed, the three-way tap is turned half round, and the pipette quickly disconnected and capped. The capillary may be cleansed by drawing in and expelling a little water by suction at a short piece of rubber kept fixed on the outlet of the three-way. Any number of successive absorptions may be made by a moderately skilled manipulator without a bubble of air or a drop of absorbent reagent being drawn into the endiometer.

#### Reagents.

(1.) *Ethyl Alcohol* (1 c.c. on mercury followed by 1 c.c. of water on mercury) removes "hydrocarbons." This may be conveniently done by utilising the sampler as the absorption pipette. Butterfield says these hydrocarbons are benzene and its homologues and are identical with the condensation products on cooling to  $22^\circ \text{C}$ . (Dewille). Sutton says they consist of hydrocarbons of the series  $\text{C}_n\text{H}_{2n+1}$  and  $\text{C}_n\text{H}_{2n+2}$ .

(2.) *Cadmium Chloride* in strong solution, slightly acidified, may be used for the  $\text{H}_2\text{S}$  estimation, but this is preferably estimated in a separate portion of gas with standard iodine.

(3.) *KHO*.—Good caustic potash not purified by alcohol should be used. A solution of  $40^\circ \text{Tw.}$  to  $50^\circ \text{Tw.}$  is a strength sufficient for all general work.

(4.) *Alkaline Pyrogallol Solution* is undoubtedly the best reagent to use for the determination of oxygen. Clowes has pointed out that when the proportion of oxygen present in the gas is large, carbon monoxide is frequently evolved, the amount generally being greater the higher the ratio of pyrogallol acid to potash in the absorbing solution. Even practically pure oxygen may be wholly absorbed by using a solution of 160 grms. of potash with 10 grms. of pyrogallol in 200 c.c. of solution without evolution of CO. For ordinary work a solution rather weaker in alkali and with a greater proportion of pyrogallol may safely be used.

(5.) *Fuming Sulphuric Acid* of the greatest obtainable strength is used for heavy hydrocarbons =  $\text{C}_2\text{H}_6$ , &c. Before use it is diluted with about 10 per cent. of its volume of ordinary 1.84  $\text{H}_2\text{SO}_4$ . This reagent gives a higher absorption than bromine water. The latter reagent is, moreover, very troublesome when working over mercury, as it corrodes the mercury surface and makes reading difficult, and frequent cleaning necessary.

It has been shown by many chemists that fuming sulphuric acid removes a small amount of oxygen from the gas. With this statement our experience coincides.

The "reduction products" and  $\text{SO}_2$  vapour must be removed by  $\text{KHO}$  before reading.

(6.) *Cuprous Chloride* may be used in either a hydrochloric acid or an ammoniacal solution. The latter is perhaps slightly the quicker absorbent, but is much more troublesome to prepare.

The  $\text{HCl}$  solution may be made by boiling 70 grms. of fine copper oxide with 1,000 c.c. of hydrochloric acid for half an hour, adding gradually during the first 10 minutes 56 grms. of copper powder, or fine filings. The solution is made up to its original volume with gradually added water and decanted into a tightly stoppered flask containing rolls of copper gauze. The solution should be colourless after standing a little. It turns brown when in contact with oxygen.

Acetylene and ethylene are both absorbed by ammoniacal cuprous chloride.

The  $\text{HCl}$  vapour has a very low tension, but in accurate work it may be removed by  $\text{KHO}$  before reading.

*Order of Estimation* should be: "Hydrocarbons,"  $\text{CO}_2$ ,  $\text{H}_2\text{S}$ ,  $\text{O}$ ,  $\text{C}_2\text{H}_2$ , &c.,  $\text{CO}$ .

The  $\text{H}$  and  $\text{CH}_4$  may then be estimated by explosion with oxygen.

$\text{CO}$  may also be estimated together with  $\text{CH}_4$  and  $\text{H}$  by explosion, but this we do not recommend. The somewhat tedious  $\text{CO}$  absorption is certainly done away with, but an additional oxygen absorption must be made. In addition nitrogen free oxygen gas must be used, or else air (in which the per cent.  $\text{N}$  is known). In the latter case the explosion must be performed on a smaller quantity of gas, not much exceeding 10 c.c.

After the discussion the working of the apparatus was demonstrated.

Meeting held on Friday, May 7th, 1897.

THE PRESIDENT IN THE CHAIR.

## A METHOD OF SEPARATING TIN, ARSENIC, AND ANTIMONY.

BY WILLIAM DANCER, B.Sc.

JUDGING from the number of papers which have been read before various Sections of the Society of Chemical Industry during the past 12 months, it is very evident that serious efforts are being made at the present time to solve the problem which has long been a source of trouble to analysts, the old methods of separating these metals being not only tedious, but also yielding results which troubled the peace of mind of the analyst considerably as to their accuracy.

I have now the pleasure of bringing before the notice of the Society another attempt to arrive at a solution of the problem by a method upon which I have been working for some few months as opportunity has allowed. At first I intended to claim it as simply a qualitative separation of the three metals, but having obtained some fairly good quantitative results, especially as regards the separation of tin from antimony, I venture to submit the process to the consideration of my brother analysts, premising that I have not fully investigated all the reactions which take place in the course of the analysis, merely giving details of the process and a few of the results obtained, hoping that someone having more time at his disposal and better qualifications than myself may take the question up and work it out thoroughly.

The method depends mainly upon the reactions which take place when the sulphides of the metals are treated with a solution of calcium hydrate.

Antimony sulphide dissolves rapidly and completely as a colourless sulphantimoniate or antimonite of calcium.

Arsenic sulphide is also quickly dissolved and decolorised, but after a short time partially precipitates as arseniate or arsenite of calcium.

Tin sulphides on treatment with a sufficient quantity of lime water are speedily decolorised, and at the same time converted into an insoluble crystalline compound, the exact composition of which I have not determined. Microscopical examination shows three distinct forms of crystals, needle-resembling calcium sulphate forming the largest portion of the precipitate, small grains of calcic carbonate, and a third form of crystal which varies according to the conditions under which the reaction has taken place; in the cold, these crystals appear as six-rayed stars. If, however, the temperature has been raised to near the boiling point, cubical crystals are formed.

I think these crystals are stannic or metastannic oxide. According to all the literature I have been able to find on the subject, the precipitate is a sulphostannate or stannite of calcium, but the following reactions I think prove this to be incorrect: it is soluble in cold dilute hydrochloric acid, the solution having a faint opalescence; it is also soluble in dilute nitric and sulphuric acids, hydrated stannic oxide being precipitated on boiling the solutions of the two last-named acids.

Caustic and carbonated alkalis only partially dissolve the precipitated tin, but the whole of it may be dissolved in sulphide of ammonium.

The main fact, however, with which we have to deal is that the tin is entirely precipitated from the solution of sulphide and hydrate of calcium; it settles rapidly and filters easily, and can be washed with boiling water. It will be evident from the above that the qualitative separation of tin from antimony becomes a very simple operation, the mixed sulphides washed free from acid requiring only to be diffused in a sufficient quantity of fresh, clear lime water to entirely decolorise them; this may be done at the ordinary temperature, but heating to about  $80^\circ\text{C}$ . accelerates the reaction and renders the tin precipitate denser; the filtrate from this will contain all the antimony, which may be recovered as sulphide by adding an excess of acid. I may here remark that it is immaterial whether the tin is in a stannous or stannic condition, but it is not advisable to have an excess of sulphur present, as sulphide of tin is slightly soluble in polysulphide of calcium; there must be an excess of hydrate of calcium to effect the total precipitation of the tin.

If arsenic be present together with the tin and antimony in quantity not exceeding 5 or 6 per cent. of the tin, the whole of it will be found in solution with the antimony, from which it may be separated in the following manner:—Strong ammonia is added—about 5 c.c. to each 100 c.c. of the solution, which is then heated in a covered beaker to near boiling; glacial acetic acid is added drop by drop until a slight permanent precipitate is formed; it is then boiled until the precipitated sulphide of antimony becomes dense and settles quickly, leaving the liquid clear and slightly acid to litmus paper, though still having a rather strong smell of ammonia. After settling, the solution may be filtered whilst still hot, and the sulphide of arsenic be thrown out by adding an excess of hydrochloric acid.

When a considerable quantity of arsenic is present a portion of it will be precipitated with the tin, and a separation may be effected by treating the precipitate with abundant yellow sulphide of ammonium to dissolve all, except the calcic carbonate, which is always present when the analysis has been made in an open vessel. The solution is diluted considerably and boiled, caustic lime made by heating pure calcic carbonate is added gradually, and the boiling continued until the ammonia is nearly all expelled; it is then allowed to cool, and filtered. The sulphide of arsenic may be precipitated from the filtrate by hydrochloric acid.

The quantitative separation of the three metals is conducted on the same lines as above described, with, of course, the necessary precautions of well washing the precipitates, &c.

Perhaps the simplest way of explaining the process will be to describe an analysis of the three metals taken in nearly equal quantities; and I may here remark that, owing to the slight solubility of both hydrate and sulphide of calcium in water, only small quantities of tin can be taken for analysis; otherwise large volumes of liquid would require to be filtered and dealt with, 0.1 gram of tin as sulphide taking nearly 30 c.c. of lime water to convert it entirely into the insoluble condition.

Taken—

	Gram.
Pure tin.....	0.1
Antimony as tartar emetic.....	0.1
Arsenicous anhydride.....	0.1

Fused in small porcelain crucible with 1 gram. dehydrated potassium carbonate and 1 gram. sulphur. After burning off as much of the last-named substance as possible, and cooling, the melt was dissolved in a small quantity of hot water and filtered from a trace of sulphide of iron into a beaker capable of holding 600 c.c., the filtrate—which, together with the wash water, should not be more than 50 to 60 c.c.—carefully treated with hydrochloric acid in slight excess, sufficient only to ensure that all the potash is converted into chloride; pure calcic carbonate is added in sufficient quantity to make it neutral, and 300 c.c. fresh, clear lime water poured in, the beaker placed on gauze over a lamp and heated to about 80° C. for four or five minutes. A bulky nearly white precipitate is formed, and the liquid becomes pale yellow in colour; after cooling and settling, 50 c.c. of the solution are passed through a filter, using preferably one of the hardened filters; an equal volume of clear lime water is added. If no further precipitation takes place, the whole of the solution is decanted through the filter; the precipitate is washed twice by decantation with lime water and then with hot water, leaving as much as possible of the precipitate in the beaker. The filtrate is now placed over a lamp to boil down, whilst the precipitate is dealt with in the following manner:—The portion on the filter is washed off with hot water into the beaker containing the rest by means of the wash bottle. The filter is subsequently moistened with yellow sulphide of ammonium and thoroughly washed with hot water into the beaker, 2 or 3 c.c. more sulphide of ammonium are added, the whole made up to about 400 c.c. and heated to boiling; pure caustic lime is now gradually added, about 1 gram. in all, and the boiling continued until the tin falls out of solution; this will occur when the ammonia is all driven off. The solution is pale yellow in colour, and when cold should give no further precipitate on addition of lime water.

After filtering, the precipitate is dried and ignited, and separated from the calcium by boiling in dilute nitric acid, again filtered, well washed, and weighed as stannic oxide.

When treated in this manner, the precipitated tin retains its crystalline condition, and filters and washes easily. The separation of arsenic from tin by this method is not complete if, in the alloy or compound taken for analysis, the arsenic is in excess of the tin; in such a case the above process would require to be repeated.

The filtrate from the tin containing the antimony and arsenic are added together and boiled down to about 400 c.c., 30 c.c. of ammonia (sp. gr. 0.880) run in, and glacial acetic acid added drop by drop until a slight permanent red precipitate is formed; the boiling is continued until the sulphide of antimony becomes dense and settles quickly,

leaving the solution clear and slightly acid to litmus paper. The boiling must not be too long continued, or the sulphide of antimony may become so finely divided as to pass through the filter paper. After settling, the sulphide of antimony is filtered off, and as it still contains a small quantity of arsenic, it is dissolved in ammonia and lime water, a few drops of sulphide of ammonia being added, if necessary, and the solution again precipitated, boiling with acetic acid. The antimony is determined by titration with iodine in alkaline tartrate solution, dissolving the sulphide in strong hydrochloric acid in presence of a little iodine—a process devised by Dr. J. Clark (this Journal, 1896, 255).

The arsenic is precipitated from the filtrates from the antimony by addition of rather a large quantity of strong hydrochloric acid as sulphide, and only completely after long standing. After filtering and washing, the sulphide of arsenic is dissolved off the filter into a large flask with strong ammonia, diluted considerably with water, and boiled until free from sulphuretted hydrogen, a few drops of dilute sulphuric acid added, and again boiled until clear and free from precipitated sulphur; it is then cooled, made alkaline with carbonate of soda, starch solution added, and titrated with iodine.\*

† The arsenic determined as magnesia salt.

‡ Arsenic determined by boiling solution of sulphide in ammonia with large quantity of water and titrating with iodine in alkaline solution.

I may here note that arsenic may be separated from antimony by evaporating the calcium solution of the sulphides to complete dryness: the sulphide of arsenic is decomposed; the sulphide of antimony remaining unchanged may be dissolved out of the residue by repeated washings with lime water, filtering off, and reprecipitating as sulphide by adding hydrochloric acid. The residue, containing arsenite of calcium and carbonate, is cautiously treated with dilute sulphuric acid, filtered off from excess of sulphate of lime, and a little free sulphur boiled to expel sulphurous acid, made alkaline with carbonate of soda, cooled, and titrated with iodine.

I have made a few experiments with hydrate of barium on the sulphides of the three metals, but, so far, they have not proved very satisfactory.

In conclusion, my thanks are due to Messrs. Roberts, Dale, and Co., of this city, for permission to publish these results, which have been obtained in their laboratory.

#### NOTE ON THE ADULTERATION OF SILKS.

BY M. L. LANGDON, F.R.S.

AFTER a highly interesting historical sketch of the silk industry, and a slight *résumé* of the processes in vogue for the weighting of silk, Sir Thomas Wardle, at the last meeting of the Section, attributed the decay of the English silk industry to this weighting or, as termed in the lecture, adulteration of silk. I must take strong exception to this ascribed cause of decay, which, however, certainly did commence about the same time as the Swiss and French dyers started the chemical weighting of silk. This weighted silk was used for the manufacture of low-priced fabrics, and a great demand for these arose, and was not catered for to any degree by the English silk manufacturers, either through want of energy on their part, or else inability to have their yarns weighted to the desired point by the English silk dyers. If the former, then the cause of the decay is self-evident; if the latter, were any steps taken to meet the demand?

After the reading of the paper, I put the following question to Sir Thomas Wardle:—Can the English silk dyer weight black warps up to 26–28 oz., and black souple up to 40–42 oz.; and, if not, has any attempt been made, as in the U.S.A., by means of imported talent, to arrive at this result? The reply was, that yarns could be weighted up to 24–26 oz. in this country; consequently I must assume that the English silk dyer cannot supply the required demand for the heavier weighted silk yarns, and I therefore should like to draw the attention of the English silk dyer to two possible ways of meeting this demand and the foreign competition: firstly, by following the example of the leading calico printers of this country, and engaging highly trained chemists to work out the different processes for them (I believe English calico printing has benefited largely by this step, and other industries might well follow suit, especially as there is now a fair supply of highly trained English chemists), or else by importing Swiss or French foremen silk dyers, to teach the most modern continental methods of silk dyeing. This latter was the means adopted in the U.S.A. Since the importation of one dyer about 25 years ago, an industry has been built up by periodic importations which now employs some two or three thousand men under the necessary scientific direction, both chemical and mechanical, in works fitted up with the most modern machinery. Now, to meet this demand for highly weighted silk yarns, and to turn the same out in quantity, if the English silk dyers cannot or will not do it (although I feel sure there are several English silk dyers who, if only properly supported, would come to the front), why do not the

manufacturers combine and start a co-operative dyehouse provided with modern machinery and under scientific direction to dye the yarns in quantity. By this I do not mean dyehouses to dye about 50 lb. of yarn at a time, but dyehouses capable, for colours or black warps, of holding at least 100 lb., and for black souples 250 lb. (I may say from practical experience that dyehouses of this size are in use; and I feel convinced that if this is done, and the manufacturers cater for the taste of the public, and not try to force on them what they do not require, the English silk industry would soon occupy its old predominant position.)

There is a silk association in this country which certainly has succeeded in obtaining some little employment for the Spitalfields weavers, but has evidently missed the true question, *viz.*, of meeting the demand of the public in this and other countries for a low-priced article, and also the advisability of calling in chemical assistance—not of chemists who have learnt a little qualitative and quantitative analysis during the course of a year or two at college—but of men trained in research work. I believe practical and well-trained chemists are conspicuous by their absence in the Lock and Macclesfield districts, although I am told one or two of the dyers do sometimes seek outside assistance in this line.

Much as it would be pleasing to see Sir Thomas Wardle's idea of the practical abolition of silk weighting carried out, such a scheme in my opinion would not be feasible, and might even be considered visionary. Some little good might be done if the dyers of other countries would support the Swiss dyers in their endeavours, as mentioned by Sir Thomas Wardle, to limit the weighting. This they would doubtless have to do in self-protection, owing to the dangers of excessive over-weighting; and in furtherance of this view would suggest the following limits:—

	Oz.
White and coloured warps .....	16–18
„ „ „ souples .....	18–20
Black warps .....	22–24
„ souples .....	22–24
„ cordons .....	20–22

There is another view of the question, *viz.*, Can the silk manufacturer make use of the weighted yarn when he receives them, and does he know what weighted yarn is required for any fabric he may be required to make? This I do not think, however, comes within the province of this Society.

I trust that these few remarks may cause a discussion on this interesting subject, which should not be lightly passed over by this Society.

#### DISCUSSION.

Mr. HARRY GRIMSHAW thought it most important to ascertain the cause of decline in the silk industry of Great Britain. Sir Thomas Wardle had suggested that it was due to adulteration, while Mr. Langdon attributed it mainly to the lack of competition between English dyers and those abroad in the production of a cheap silk. He was inclined to think that the distribution of wealth would have a tendency to produce a great change in the demand for cheaper silks; but then there was the question of cheap labour abroad, which would have to be taken into account before we could compete successfully with the foreigner.

Dr. BOWMAN remarked that it was difficult for the British silk trade to compete with that of other countries, inasmuch as the foreigner had not the same desire to comply with the Adulteration Acts as was the case in England.

Dr. BAILEY thought the question of adulteration in the silk trade was a very wide one, and the constant change of fashion was in a great measure responsible for the demand for a cheap article. It was a question which could not be considered from a chemical point of view.

#### A NOTE ON THE THEORY OF DYEING.

BY ERNEST RENTZ, F.C.S., AND FRANK J. FARRELL, B.Sc.

To explain according to the chemical theory the nature of the phenomena of dyeing in the case of wool and silk, it has been assumed that the fibres in question are amido-

carboxylic acids, the constitutions of which may be provisionally represented by the formula—

in which X is an unknown radical or radicals.

According to this view the acidic colouring matters (sulphonic acid derivatives of azo dyestuffs, nitro-phenolic compounds, eosins, &c.), in dyeing, saturate the amido groups, while the dyeing with basic colouring matters is a result of the attraction exerted upon the easily dissociated colour bases by the carboxyl groups. Without entering into any discussion of the nature of the process of dyeing wool and silk, it is sufficient to point out that the conclusion regarding the chemical natures of wool and silk (about which exceedingly little is known) has been largely deduced from a consideration of the dyeing properties of the fibres. The evidence apart from this is meagre, and, as far as the presence of carboxyl groups in silk is concerned, is principally the fact that carboxy compounds are formed when that fibre is decomposed by barium hydrate (Schützenberger and Bourgeois), dilute sulphuric acid (Cramer, Waltenberger, and Stadeler, and Weyl), or alcoholic potash (Richardson). The compounds produced when wool is similarly decomposed have not been so closely studied. With regard to the amido groups, P. Richard (Bull. Soc. Ind. Mulhouse, 1888; this Journal, 1888, 841) has shown that wool and silk, when they are treated with nitrous acid, become diazotised and give coloured compounds on bringing them into alkaline solutions of phenols (see also Richardson, this Journal, 1893, 426; Dreaper, *ibid.* 1894, 95; Watson Smith, *ibid.* 1896, 245). Doubt has been expressed concerning the interpretation of this reaction. We have, therefore, repeated Richard's work. We find the products of the action of nitrous acid on wool and silk behave in all respects as diazo compounds, combining with phenols and amido bases, undergoing the general reactions for this class of substances observed by Griess and Sandmeyer, &c.; and, further, that the wool and silk azo compounds are decomposed when heated with an acidified solution of stannous chloride, the regenerated wool and silk being capable of being again diazotised and combined with phenols and amido compounds.

The quantity of diazotisable nitrogen present in wool is only 1.0–1.2 per cent., that is,  $\frac{1}{15}$ — $\frac{1}{12}$  of the total nitrogen present. Notwithstanding this, it might be supposed that the dyeing with acidic colouring matters took place through the medium of the diazotisable nitrogen (presumably the free amido group), the rest of the nitrogen being unaffected by the processes adopted for the removal of the diazotisable amido group, since there is sufficient of the latter to account for the absorption of the amounts of colouring matters usually applied. We find, however, that the wool which has been deprived of its diazotisable amide nitrogen, dyes with acidic colouring matters apparently as well as does wool in its ordinary state. The dye-baths are exhausted in both cases to the same extent, and the colours, so far as our experiments range, are as fast to soaping and to light. As might be expected, the basic colouring matters dye the “de-amidated” wool equally as powerfully as they dye ordinary wool.

The method of “de-amidating” wool referred to consists in treating it with nitrous and hydrochloric acids at the ordinary temperature for 10–12 hours, washing, and boiling with (1) alcohol, or (2) cuprous chloride and hydrochloric acid, or (3) water. The colours of the wool thus treated are respectively (1) brown, (2) very pale buff, and (3) brown. The modified wool, after treatment again with nitrous acid, does not in any of the three cases yield colours when acted upon by alkaline phenol solutions. It contains, as mentioned above, 1.0–1.2 per cent. less of nitrogen than the original wool.

Silk may be similarly “de-amidated,” and the product behaves towards colouring matters like ordinary silk.

It would appear, therefore, that in the dyeing of wool and silk with acidic colouring matters the amido groups present in the fibre-substances play either no part at all or at most an unimportant one.

## POTASSIUM PERCARBONATE, AND THE OXIDATION OF THE LEUCO BASE TO ACRIDINE YELLOW.

BY ARTHUR H. LYMN.

Potassium percarbonate is obtained by electrolysing a saturated solution of potassium carbonate at low temperatures, about  $-10^\circ$ . The salt is deposited in the anode space, and is filtered and dried rapidly to prevent decomposition. It is at first bluish, and on drying becomes white.

When heated above  $100^\circ$  it is decomposed as follows:—

In ice-cold water it dissolves without being decomposed. The decomposition is quicker and more complete according as the temperature is raised, and takes place in accordance with the following equation:—

When brought into contact with alkalis and gently heated a current of pure oxygen is evolved:—

With acids, carbon dioxide is evolved and hydrogen peroxide is formed quantitatively—

From the above it appears that the salt oxidises in acid, neutral, and alkaline solutions.

Drs. Constant and von Hansen have tried its bleaching powers on cotton, wool, jute, silk, hair, &c., with more or less success, the experiments having been only conducted on a small and incomplete scale.

An abstract on the salt will have been seen in the Journal of this Society, 1896, 815, and further details will be found in the Journal of the Society of Dyers and Colourists, Vol. XII., No. 12; also in the “Zeitschrift für Electrochemie,” Vol. III., p. 445, a new article has just come out under the title “Ueber die Darstellung und Eigenschaften des Kaliumpercarbonats,” by A. von Hansen.

*Oxidation of the Leuco Base to Acridine Yellow.*—Ger. Pat. 52,324 (Leonhardt and Co., in Mülheim). As is well known, the leuco base is prepared by the condensation of metatolylenediamine,  $\text{C}_6\text{H}_3(\text{CH}_3)(\text{NH}_2)_2$ , with formaldehyde in presence of sulphuric acid to tetraamidodimethylmethane, from which the leuco base is formed, through elimination of one molecule of ammonia, by heating with dilute hydrochloric acid under pressure.

The condensation can take place either in methyl alcoholic or aqueous solution, preferably in the latter.

According to the patent, the final oxidation is carried out by means of ferric chloride, air being also technically used; bichromate, nitrous acid, &c., can also take their place as oxidisers. The dyestuff itself in dilute solution gives a characteristic yellow and green fluorescence. This hydroacridine takes up oxygen easily, the dye being somewhat precipitated on exposure to air, and entirely by boiling the solution for some time or passing air through in the heat. The dry leuco base is fairly stable, and is readily soluble in water and dilute acids.

The product obtained by heating 7 grms. of the tetraamidodimethylmethane with 18 grms. hydrochloric acid (concentrated), and 50–55 c.c. water in a sealed tube at 150° C. for six hours, was diluted with water, and to this was added potassium percarbonate and acid. On addition of acid the liquid frothed considerably, which froth disappears slowly. The percarbonate was added until no further precipitate was formed. The filtrate gave no precipitate with ferric chloride, or in passing air through in the heat, from which one may assume that the oxidation was complete. The reddish-brown precipitate was filtered, washed, and dried in a vacuum desiccator, and weighed 3.5 grms. The substance so obtained was redder and had a purer appearance than the commercial product. It was soluble in water, the dilute aqueous solution showing the characteristic yellow and green fluorescence of acridine yellow. It dyed silk with the same strength as the product made by the author by oxidation with ferric chloride, but, if anything, somewhat purer in appearance, and had a very much greater colouring power than the commercial product, a  $\frac{1}{2}$  per cent. skein dyed with this substance being more strongly dyed than a 2 per cent. skein with the commercial product. The percarbonate would therefore seem to be a very suitable oxidising agent in this case. It possesses the great advantage that the bicarbonate which is formed on oxidation in neutral solution, as also the chloride or other salt formed in acid solution, are easily washed out of the product with water, and it is thus unnecessary to wash with hydrochloric acid, as is the case after oxidation with ferric chloride.

*Experiments on a larger scale.*—125 grms. of the condensation product obtained from 203 grms. of metatolylenediamine with formaldehyde and sulphuric acid were heated for about eight hours under 8–10 atmospheres pressure in an autoclave with 324 grms. concentrated hydrochloric acid and 1 litre of water. The product so obtained consisted of a dark red liquid, a sediment of hydroacridine crystals, and a difficultly soluble sediment. The whole was diluted, stirred up, and divided as equally as possible into four parts, two of which were oxidised with ferric chloride, one with air, and one with potassium percarbonate. Practically speaking, the yields were equal, 26 grms. being obtained by ferric chloride (with double quantities), 13 grms. with air, and 12 grms. with percarbonate—in each case about 23 per cent. of the theoretical quantity from the metatolylenediamine employed. The oxidation with the percarbonate was executed under precisely the same conditions as in the previous experiment. These products were not quite as soluble in water as the products made on a small scale, and leave considerable ash on burning. The commercial product shows in these respects very similar properties.

In order to ascertain whether the oxidising action of the percarbonate in acid solution is due to the intermediate formation of hydrogen peroxide according to the equation—

the following experiments were undertaken.

Four sealed tubes, each containing—

	Grms.
Condensation product.....	31
Concentrated HCl.....	9
Water.....	27

were heated in the same furnace for six hours at 150° C. In each case the contents were previously made as homogeneous as possible. The contents of—

No. 1 were treated with hydrogen peroxide alone, whereby practically no precipitate was formed; but on addition of more acid the substance came down freely.

No. 2 were treated with hydrogen peroxide and acid.

No. 3 were treated with potassium percarbonate without additional acid.

No. 4 were treated with potassium percarbonate and acid, as in previous cases.

In each case the oxidising agent was added until no further precipitate was formed; moreover, ferric chloride produced no more precipitate in each portion. The differences in the yields are probably due to the fact that it is impossible to subject the tubes to exactly the same temperature in the furnace.

*Results.*—No. 1 gave 1.2 grms. chocolate-brown product.  
No. 2 gave 1.8 grms. light-brown product.  
No. 3 gave 1.3 grms. brown product.  
No. 4 gave 1.0 gm. chocolate-brown product.

All four products are soluble in water, possess the characteristic fluorescence, and give the same effect on silk. These substances have a different appearance one against another, and their densities also seem to vary, inasmuch as the one collects at the top and the other at the bottom of the liquid.

*Experiments with Isolated Hydroacridine in a Carbonic Acid Gas Atmosphere.*—The hydroacridine is partly oxidised by air at the ordinary temperatures when in a wet state, but can be isolated in a fairly pure state by filtering the contents of a sealed tube in an atmosphere of carbon dioxide under suction and quickly transferring to a vacuum desiccator. This product melts above 300 under decomposition. Four small portions were dissolved in water.

To No. I. hydrogen peroxide was added without acid, and very little precipitate was formed.

To No. II. hydrogen peroxide and acid in excess were added. In this case a copious precipitate was formed as above.

To No. III. potassium percarbonate was added without additional acid and the precipitate was formed.

To No. IV. potassium percarbonate and acid were added. The precipitate came down freely, as in the last two cases.

On repeating the experiments with isolated hydroacridine in the air with an hydrogen peroxide purchased in England, the author found that the precipitate was copiously formed without additional acid as in the other cases. This may perhaps be accounted for by a difference in the amount of available oxygen in the two hydrogen peroxides, or a difference in the quantity of acid in solution.

It is more economical to work with the percarbonate with excess of acid than otherwise, since in the latter case much of the oxygen formed escapes. The experiments seem to confirm the assumption that the action of potassium percarbonate in acid is due to the intermediate formation of hydrogen peroxide.

All the products had a much higher dyeing power than the commercial product, both on silk and on cotton mordanted with tannin. On cotton the colours are of a greenish-yellow, but the percarbonate product shows a much purer yellow than the others. On silk the difference is not so noticeable.

The action of ammonium persulphate was also tried under the same conditions as the percarbonate, but gave a very dark grey substance which neither produced in water solution the characteristic fluorescence, nor was it completely soluble. It dyed silk brown, at the same time partly taking away the gloss.

*Summary.*—In the oxidation of diamidodimethylhydroacridine to acridine yellow—

Potassium percarbonate with additional acid gives very good results.

Potassium percarbonate without additional acid gives also good results, though in this case the action is slower and not so economical.

Hydrogen peroxide with additional acid acts similarly to the percarbonate under these conditions.

Hydrogen peroxide without additional acid also gives the precipitate.

Ammonium persulphate gives an entirely different product, which was not further investigated.

Attempts to oxidise the leuco base to crystal violet with potassium percarbonate also made in the Polytechnikum laboratories did not prove successful.

The above investigation formed part of that made for obtaining the diploma in the technical chemical course of the Federal Polytechnic School in Zürich, and the author wishes here to express his most sincere thanks to Prof. Gnehm for his kind help and suggestions in it, and to Dr. Constam for furnishing some notes on the salt as well as a sample of the same.

Dr. GROSSMANN exhibited an apparatus for testing indigo and other colouring matters, a full description of which had been read by him the previous evening at the Bradford Section of the Society of Dyers and Colourists.

## THE SAMPLING AND ANALYSIS OF COKE, AND VALUATION OF COAL FOR COKING PURPOSES.

BY W. F. KEATING STOCK, F.I.C.

ERRATUM IN DISCUSSION.

(*This Journal*, 1897, 398.)

IN Mr. Stock's reply, read from line 6 as follows:—With regard to Mr. Proctor's question, he (Mr. Stock) thought that the writer in the *Comptes Rendus* was at fault in that he attempted to extract his phosphorus with *aqua regia*; for it was well known that if much peroxide of iron was present the acid mixture had little effect upon it until the nitric acid was largely broken up.

And from line 13 read:—He had not noticed the occurrence of titanio acid in coal ash, although local fire-clays, associated with coal seams, sometimes contained as much as 3 per cent. In presence of titanio acid it would be difficult to extract the phosphorus, &c.

SESSION 1896-97.

Meeting held at Wyvern Hotel, Leicester, on Wednesday,  
April 28th, 1897.

MR. F. J. R. CARULLA IN THE CHAIR.

## AN ATTEMPT TO PREPARE METHYLENE.

BY J. J. SUDBOROUGH.

AFTER drawing attention to the great interest—from a theoretical point of view—attaching to the preparation of compounds of the type of carbon monoxide, a compound which stands in quite an isolated position as regards the numerous other carbon compounds, the author pointed out the various attempts which had been made to prepare the hydrocarbon methylene  $\text{CH}_2$ , drawing special attention to those of Butlerow.

The communication concluded with an account of some experiments which the author himself had undertaken some three years ago at the suggestion of Prof. Victor Meyer. The substance made use of in each case was methylene iodide,  $\text{CH}_2\text{I}_2$ . When heated to its boiling point for some time, a considerable amount of iodine separated out, but little or no gas appeared to be evolved. When the iodide was dropped on to sand contained in a flask and heated to about 500°, it was completely decomposed; much carbon was deposited, and hydrogen iodide, together with other gaseous products, were also formed, but no trace of ethylene—a compound which is generally formed on the decomposition of methylene iodide—could be found. Methylene iodide reacted vigorously when warmed with an excess of fine silver powder; a certain amount of carbon was deposited and a considerable quantity of gas evolved. The greater part of this latter consisted of ethylene,  $\text{C}_2\text{H}_4$ , since it readily combined with bromine, yielding ethylene dibromide (b. pt. 130°C.). A certain amount of a hydrocarbon which was not absorbed by bromine, but no hydrogen could be found in the residue. The hydrocarbon on analysis proved to be methane,  $\text{CH}_4$ , no doubt formed by the decomposition of methylene into methane and carbon.

## DISCUSSION.

Prof. F. CLOWES said that personally he was gratified to hear the record of Dr. Sudborough's experiments. A record of failures was by no means without instruction. While listening to the paper, it had struck him that acetylene,  $\text{C}_2\text{H}_2$ , might be persuaded to part with half its carbon, and thus act as a starting point. There would, of course, be difficulties in the way, as the author had mentioned, but there seemed to be no reason why  $\text{C}_2\text{H}_2$  should not part with some of its carbon.

The CHAIRMAN suggested that some substance might be found that would hold methylene in solution much in the way that ammonium was retained by mercury in the well-known ammonium amalgam.

Dr. J. J. SCHNEIDER, in reply, said that Prof. Clowes seemed to think that he (the author) had succeeded in decomposing methylene into carbon and methane,  $\text{CH}_4$ . But, judging from the experiments, he thought that there was no chance whatever of achieving such a result. Although ethylene could be decomposed into carbon and methane, it was doubtful if the temperature at which the reaction occurred was high enough to bring about such a decomposition. It was more probable that the methane was obtained by the decomposition of the methylene first formed.

## THE REMOVAL OF MINERAL OIL STAINS FROM COTTON FABRICS.

BY S. J. PENTECOST, F.R.S.

AMONG the many difficulties which beset the path of the bleacher and dyer of cotton fabrics, perhaps none are more serious than those arising from the presence in the finished goods of mineral oil stains. The lace bleacher finds it extremely difficult to get rid of the blacklead that is used to lubricate the lace machine, and which occasionally finds its way on to the fabric. But in this case he can see clearly when the black stain has been removed; while in the case of a mineral oil stain, he knows that though it has apparently been completely removed, it is liable to reappear, after goods have been stocked a few weeks, in the form of a light yellow stain.

The presence of these unsaponifiable oils on the fabric, arises generally from one or both of two causes:—

1. It often happens that drops of oil from the machinery or shafting above the fabric, fall upon it and thus cause a stain; while possibly a bearing which has been allowed to get hot and to "squak," has a superabundance of oil applied to it, with the result that the heated oil is thrown on to the piece, thus causing a large number of small stains. These spots of oil often contain iron or brass dust carried from the bearing.

2. Some manufacturers of lace and hosiery goods find it necessary to lubricate their yarns before putting into the machine, and for this purpose a good saponifiable fat or oil is generally used, which of course helps, rather than hinders, the cleansing of the goods in the bleaching process. But the temptation offered by cheap oil leads some to use so-called stainless oils, which are mixtures of mineral and vegetable oils, the former in some cases largely preponderating. So long as a good emulsion is produced by mixing it with a little dilute alkali or with soap, the presence of the mineral oil is not noticed by the maker of the fabric, and the latter is thus rendered liable to be faulty when finished.

It is much to be deplored that mineral oils should be used for this purpose, but if the question of cost makes it imperative or desirable, the proportion of hydrocarbon oil mixed with the saponifiable oil should never exceed 50 per cent.

Of the stains from these two causes, the most persistent are those produced by the heated bearing or shafting, and if the goods containing them have lain in stock for some time—say three months or more—the difficulty of removing them is much increased. Indeed, it is often found, when the goods have been bleached, that the fibre has become disintegrated, and a small hole in the fabric is the result where the stain had previously appeared.

In the case of fabrics which require "gassing," such as some lace fabrics, muslins, cambries, &c., no doubt the heat causes the mineral oil to penetrate more deeply into the fibres, and thus renders the stains more difficult of removal.

Various methods have been proposed for the elimination of these oil stains besides those used by many bleachers who keep their processes secret. The value of many of these latter may well be doubted, especially if that mentioned by a bleacher who gave evidence in a recent law case may be taken as a type. Speaking of the

possibility of removing mineral oil stains from cotton fabrics, he said that this could be done by a process of his own, which he could not divulge, but that even this process tendered the fabric. No wonder the judge remarked that in that case it was quite as well to keep the process a secret.

Perhaps one of the most usual methods of dealing with these stains in detail, as well as one of the most effective, is to impregnate them with olive oil or olein, allow it half an hour to thoroughly permeate the stained part, then boil the goods in a caustic soda lye for six or eight hours.

It should be remarked here that if the mineral oil used is mixed with an equal proportion of a vegetable oil, it is much more easily removed, and the ordinary process of bleaching is generally sufficient, if the stains are fresh. In a paper published in the *Bull. de la Soc. d'Industrie de Mulhouse* in 1889, E. Scheurer shows that a mixture of 5 parts of Scotch petroleum with 5 parts of cotton, rape, or olive oil is removed by one lime boil of six hours, followed by a sour, and ley boil of soda ash and resin for 10 hours, while a mixture of 6 parts of Scotch petroleum with 4 parts of vegetable oil was not removed by that treatment, and involved danger of the after-development of the stains on the finished fabric. He also found by experiment that a vegetable oil mixed with the mineral oil was more easily removable than a mixture of fatty acid (*viz.*, olein) and unsaponifiable oil, when boiling with soda ash and resin. Further, a mixed oil containing 6 parts of Scotch petroleum and 4 parts of vegetable oil was more readily removed when the soda ash and resin boil was preceded by a lime boil and sour. He suggested that this was probably owing to the lime soap formed with the cotton fats, absorbing the mineral oil from the interior of the fibre, in the same way that pipeclay and plaster act when applied to remove grease stains from finished fabrics. In boiling with caustic soda he found the addition of a small quantity of resin to the boil (about 1 oz. to 2 galls. ley) was an advantage in removing the oil; it formed a sufficient quantity of soap to emulsify the natural fats of the cotton.

Another method which has been successfully used for the removal of these stains is to steep them all night in a bath containing—

Soap .....	1 lb.	} 4 galls.
Ammonia, 0.880 sp. gr. ....	1 oz.	
Turpentine .....	2 oz.	

afterwards boiling and bleaching in the usual way.

Quite recently E. Schweitzer has proposed the use of aniline oil or phenol in soap solution for removing mineral oil stains. In an article in the *Bulletin de la Société d'Industrie de Mulhouse*, he says: Since aniline possesses the property of dissolving many bodies which are insoluble in ordinary solvents, he conceived the idea of trying its effect for the removal of stains (*e.g.*, mineral oil stains). As a result of his experiments he patented a process in which the stained goods are steeped in a bath of 5 quarts aniline oil, 9 lb. soap in 20 gallons of water for half to five hours, and then boiled and bleached in the usual way: an alternative method is to add the aniline oil or phenol to the lye in the kier just before boiling, and to proceed as usual. When phenol is used half the quantity suffices. A patent for a similar process was applied for about the same time by Messrs. Ferguson and McMeekin, of Belfast, who immerse the fabric in a liquid said to be capable of dissolving the mineral oil. The composition of the said liquid is:—

H <sub>2</sub> O .....	10 to 15 galls.
Soap .....	5 lb.
Soda ash .....	4 ..
Ammonia extract of soap .....	2 ..
Oil .....	1 pint.

The oil may be shale oil, paraffin oil, resin oil, aniline, or phenol.

The fabric is immersed for 5 to 12 hours, and it is claimed the treatment removes the oil stains and improves the finish of goods. The first of these two methods was reported to be satisfactory by M. Jacquet after a trial in which 2,000 pieces of cotton cloth were bleached; but he

admitted that a number of the stains still remained after the treatment.

Pressure of business has prevented me making the series of bleaching trials which this treatment appears to me to demand; but a short trial was made on some well-twisted cotton fabric which had been previously bleached.

The fabric was impregnated with ordinary American mineral oil over one half its surface; then divided into four equal parts (each having half stained). They were then left in a stove at 110° F. for two hours, and treated as follows:—

No. 1, boiled 1 hour with 1 oz. of soap,  $\frac{1}{4}$  oz. of phenol in 1 pint of water.

No. 2, boiled 1 hour with 1 oz. of soap, 1 oz. of aniline oil in 1 pint of water.

No. 3, boiled 1 hour with 1 oz. of soap in 1 pint of water.

No. 4, steeped in  $\frac{1}{4}$  oz. of turpentine,  $\frac{1}{2}$  oz. of ammonia, and 1 oz. of soap in 1 pint of water, and then boiled for five minutes.

After rinsing and drying, the stain appeared to be removed in every case; but on re-examining them two days after, Nos. 1 and 2 showed the stain distinctly, while Nos. 3 and 4 had a very faint appearance of stain.

The idea implied in M. Schweitzer's article, that the aniline or phenol acts as a solvent for the mineral oil, is, I believe, a mistaken one. Probably their penetrating power may enable them to permeate the cotton wax and substance of the fibre, and to bring through the cell walls the mineral oil which has found its way to the centre of the fibre, which the alkalis alone cannot touch. In other words, they may assist the emulsive action of the soap and alkali.

It is found in practice that if, before boiling, the fabric is well scoured in a dolly or in washing stocks with a soap solution and the addition of a little carbonated alkali, the mineral oil stains are more thoroughly and easily removed, than when boiled in the kier at once. By this procedure also, any iron or brass dust off bearings or shafting is removed before being fixed by the acid, &c. used in bleaching.

Much of the unsatisfactory work arising from these stains might doubtless be avoided if in the bleaching process sufficient time were given in the first boil for the natural oil and cotton wax of the fibre to be completely saponified and removed. Scheurer has shown that with the best materials for the ley boil, goods must be boiled for six hours before the cotton oil can be saponified and the way cleared for the emulsion of any remaining waxy and unsaponifiable matter; but in the lace trade, at least, customers often insist upon the bleacher returning goods in that time (viz., six hours), bleached and dried. The short boiling thus enforced only removes the oil on the surface, and the major part of the mineral oil is imprisoned by the cotton wax, &c. remaining, and forms an objectionable stain on the finished fabric; or, if at first apparently cleared, it subsequently oozes to the surface of the fibre and develops into a pale yellow stain.

The ley boil should be done under pressure with caustic soda, a little resin, and a small quantity of a good tallow soap. The speed at which the liquor circulates in the kier influences the emulsive power of the detergent liquor, a quick circulation being advantageous. A good tallow soap (being cheaper than olive-oil soap) should be used in preference to the mottled soaps made from bone grease, &c., which latter are so largely used by bleachers in consequence of their low price. It will be found that a sound tallow soap is much more effective where obstinate stains have to be dealt with.

The dolly, a machine used by lace and hosiery bleachers, is almost a necessity for removing the worst of these stains. Its action is to beat the goods while immersed in the detergent liquor. Those stains which survive this treatment can be taken singly and hammered on a bench with a small wooden mallet, dipping them occasionally into a strong soap solution.

In the case of removing stains from dyed and finished fabrics, which cannot be wet out again without spoiling, benzene, which acts as a solvent for mineral oils, can be used. The stain is impregnated with the solvent and then

pressed between blotting paper or other absorbent material, thus removing the benzene with the oil in solution.

This solvent is not used on the large scale by the bleacher, as, apart from other objections to its general use, the expense is prohibitive.

#### DISCUSSION.

Mr. H. FORTH admired the author's pluck in tackling this subject. Talking of mineral oil stains on fabrics always frightened bleachers and dyers. Notwithstanding most careful treatment, these stains appeared months after the goods had gone away. Many attempts had been made to remove these stains, but usually without success. He agreed with the author that it was oil from the bearings or other parts of the machinery which caused the mischief. Fine white cashmere shirts with silk in them often showed stains after a very long time. Oil stains also appeared on the papers in which the goods were wrapped. The paper absorbed the oil, and the customer of course condemned the articles.

Mr. S. F. BURROGH had recently had some difficulty with regard to slight stains, which he attributed to mineral oil. He would be glad to hear of a test to ascertain whether they were mineral oil stains or not.

Mr. J. T. WOOD asked whether benzoline could not be used. It was used now on a very large scale for extracting grease from leather. A machine which recovered the benzoline would involve little or no expense except for plant.

Dr. SUPPACOTT thought that by no single process could these stains be removed. They were due to various substances. Mineral oils could probably be removed by extraction by benzine or benzoline. Those mineral oils which were used for lubricating were allied to benzoline. The stains due to small particles of brass or iron from the bearings could not of course be removed in the same way as mineral oils. Possibly they might be removed by some of the methods mentioned. At any rate, the stains due to metals ought to be removed before the fabric was bleached, as otherwise the material would be liable to rot in the process of bleaching. The stains due to mineral oils could be removed before or after—it was immaterial. From a common-sense point of view was not prevention better than cure? Were there no means at hand by which they could prevent the staining of the fabric? Could they not design a guard to screen some of the bearings from the fabric?

Dr. CLOWES said that in the course of a long experience at the University College at Nottingham, the question of these stains had arisen on more than one occasion, and both the causes referred to by the author were present in the fabrics which were submitted to himself. There were brown stains in the finished fabric due to iron and due to mineral oil. In one instance they proved that the stain was due to iron by burning the raw fabric and estimating the quantity of iron in the ash, and then treating the finished fabric in the same way. The ash of the finished fabric contained a large quantity of iron, obviously picked up in the course of making and finishing. There was no process in the finishing which would remove the iron. The bleaching would tend to fix the iron rather than to remove it, and unless the iron were removed specially as suggested there seemed no chance of getting rid of it. In one case the source of certain stains alleged to be caused by mineral oil was ascertained, not by examining the stains themselves, but by examining the oil which had been used for preparing the yarn. Yarn was commonly greased with lard before it was passed through the rollers, which had iron surfaces. In the case of iron stains, the oil which had been used for preparing the yarn was found to be acid, and the iron was introduced by the action of the acid on the iron surface of these rollers. In another case mineral oil was undoubtedly present in the oil used for this purpose. He supposed that that was an acknowledged operation. It was known to be mixed with vegetable oils. They proved this by simple experiment. The fact of the presence of mineral oils explained why there was such difficulty in removing the stains. They would expect to remove them by washing with soap, but this was found to be impossible after the goods had been kept. They could remove the appearance

of the stains, but the goods were ultimately sent back again, the stains having reappeared. Mineral oil stains of some standing could not be removed by simple mechanical treatment, or short treatment with solvents. No doubt it was possible to get a thin film of the oil off, but not the bulk of the oil which had penetrated into the fabric. The goods stood by, and the oil from beneath gradually worked its way to the surface again. Probably the fabric would require very prolonged treatment to get rid of all the oil.

The CHAIRMAN agreed with Dr. Sudborough, that "prevention was better than cure"; but in order to say whether prevention was possible, one should know the character of the machinery. Perhaps Mr. Paton, as an engineer, would enlighten them.

Mr. PATON said hot bearings ought not to exist. There was always a reason for bearings getting hot, and it was preventable. While he had no special knowledge of these machines, yet on general principles he might say that the flying of oil could be prevented. Bearings were now made which required oil once in six months, and during the whole of that time there was not the slightest appearance of oil. The more troublesome of the two classes of stains appear to be from the bearings, and these were usually preventable. Now the subject has been brought forward, some engineering members of the Society might be called in to confer with the chemists in order that the difficulty might be remedied.

Mr. R. M. CAVEN said if, as seemed to be the case, the use of mineral oil almost necessarily involved stains, was it not counting failure to put mineral oil in that used for dressing fabrics? Should not vegetable oil be used, entirely to the exclusion of mineral oil?

Mr. PENTECOST, in reply to Mr. Forth, said that he had merely dealt with the difficulty as regarded cotton fabrics; and the treatment recommended for cotton would, of course, be too severe for silk and wool. With regard to Mr. Wood's remark as to whether benzoline could not be used on a large scale where the benzoline was recovered, there seemed to be no likelihood of bleachers complicating their plant any further. It would be too expensive, taking into account the price paid for bleaching. There was also the danger of fire, but this could be overcome. It would also be necessary to store the goods before treating them, if the process was to be effective. He questioned whether many of these mineral oil stains could be completely removed by an ordinary treatment with benzine without the preliminary removal of moisture. He confessed he could not satisfactorily explain why old oil stains were found to be tender. He had found some that were somewhat tender before the goods passed through the bleaching process. The metal dust mixed with oil from bearings might account for it. Dr. Sudborough asked whether these stains could not be prevented. They could, and easily. The best method of prevention was simply to use oils which were saponifiable. This could be done at an infinitesimally small extra cost; but the desire to get a cheap oil led people to adulterate with mineral oil, and the buyer did not know that the oils so adulterated caused such mischief. The bleacher did not generally find much difficulty in distinguishing between an iron stain and a mineral oil stain. The former was removed by treatment with strong HCl, and subsequent thorough rinsing in water and weak alkali to remove all trace of acid. The iron stain never reappeared after this treatment. Dr. Clowes had alluded to the oil which he examined. He probably referred to the same oil which was sent to him (the author) on a piece of lace two or three weeks afterwards. The piece, with one end stained in the oil, after passing through the usual bleaching process, showed a large yellowish stain distinctly visible. He at once set it down to mineral oil, and returned the piece to the dollies, and gave it a 10 hours' boil. The stain was completely removed. On making enquiry 9 or 10 months after this he found that there had been no reappearance of the mineral oil stain.

Dr. CLOWES explained that the goods to which he had referred might have stood with the oil in contact, so that the oil would be much more likely to penetrate. Possibly in the case mentioned by Mr. Pentecost the penetration was not allowed.

## THE OLEOREFRACTOMETER.

BY S. P. BURFORD.

Mr. BURFORD described the oleorefractometer of Messrs. Amagat and Jean, which he had found especially valuable in analysing a large batch of samples of butters, for example—and by its means he was able to select those "deserving of special attention." He would not condemn a sample on the strength of these indications, but as a means of sorting the good from the bad he considered the instrument invaluable. The instrument was described in an article by Dr. Muter in the *Analyst*, May 1890, pp. 87—89. M. Jean had discovered a typical oil that gave no refraction, and with which the outer receptacle was always filled. Mr. Burford had found that lard oil answered the same purpose.

## ERRATUM.

This Journal, 1897, 310, col. 1. The sketch which should represent a suspended "vacuum-jacketed tube" has been accidentally placed in a wrong position. It should have been turned 90° to the right, so as to bring the twisted wire by which the tube is suspended into a vertical position.

Meeting held on Monday, March 29th, 1897.

MR. T. FAIRLEY IN THE CHAIR.

## A METHOD OF ESTIMATING THE WEIGHT OF SOLID MATTER IN THE AIR.

BY J. B. COHEN, PH.D.

IN connection with a series of experiments, which were undertaken with the view to estimating the impurities in the atmosphere of Leeds, I attempted to determine the weight of suspended matter in the air. I roughly appraised the quantity at not much above 1 mgrm. in 100 cb. ft., which would necessitate therefore a large volume of air and extreme accuracy in weighing. The first method, subsequently relinquished, consisted in aspirating the air by means of a small electric Blackman fan and intercepting the dust by a glass plate smeared with glycerin, which was then washed, the washings filtered and the solid matter weighed. The volume of air aspirated was measured by an anemometer. I mention the method in case anyone may feel disposed to improve upon it, but under the conditions I employed I found it unsatisfactory. The second plan was to filter a smaller and more carefully measured volume of air and to weigh the solid matter as before. I had the use of a very delicate balance for the purpose.

I employed, to begin with, an open zig-zag tube coated inside with a thin layer of vaseline, which permitted a rapid flow of air. In order to determine if vaseline lost weight in the course of aspirating large volumes of air over its surface or gained by absorption of moisture, the tube was heated to  $100^{\circ}$ , and air, filtered through cotton wool, aspirated rapidly by means of a vacuum pump for four hours. In another experiment the same process was conducted for five hours at the ordinary temperature and in a third experiment at a slower rate (24 cb. ft.) for six hours. The loss in the first case was 1 mgrm. and in the last two, 0.2 mgrm. There was therefore a slight loss at the ordinary temperature.

Four experiments were then made on unfiltered air with the following result:—

Number of Experiment.	Time.	Number of Cubic Feet Aspirated.	Gain in Weight.
	Hours.		Mgrms.
1	6	27	0
2	6	27	0.3
3	6	26	0.3
4	6	35	0.3

Adding on the 0.2 mgrm., which the vaseline loses in the same time, the average gain in weight would correspond to 1.36 mgrm. in 100 cb. ft. of air.

On examining the zig-zag tube with a lens, the quantity of dust in the bends gradually decreased, until the last bends appeared entirely free from specks, from which it might be concluded that the dust was completely removed in its passage through the tube. The method finally adopted as giving the most accurate results was the following:—

A cotton-wool plug was used as the filtering medium. In order to ascertain if the size of the plug to be employed was effective as a filter, it was fixed into a wide opening of a similar zig-zag vaseline tube to that previously used, and air aspirated through it for several hours. No specks appeared on the vaseline in any part of the tube. This plug was fixed into an open wide glass tube with a constricted tail piece for filtering, and transferred to a stoppered bottle for weighing. Some difficulty was experienced at first in obtaining the plugs of a constant weight. Cotton-wool is exceedingly hygroscopic, and after being dried at  $100^{\circ}$  will rapidly absorb moisture from the air as the temperature drops. I found on one or two occasions when the plugs were accidentally left in the steam oven a short time after steam was turned off; the temperature having dropped a few degrees, that they invariably weighed more, even though left in a desiccator over sulphuric acid during the night.

When the plugs were heated in the steam oven for the same number of hours, placed straightway in the desiccator over sulphuric acid, and weighed against a similar plug, heated and dried under precisely similar conditions, the plugs attained a constant weight. 17 weighings of the check bottle with its plug were made between March 8 and June 4, 1894, and the maximum variation was 0.4 mgrm., the variation from the mean being 0.2 mgrm. The difference between the check and experimental plug, which was adjusted by a few small weights, is obviously less. As a matter of experience whenever tested, the weights were practically identical. The form of apparatus is shown in the diagram.

A is a leaden tube fixed through the window. Through a cork diaphragm within this is fixed an open glass tube B. The wide portion contains the weighed cotton-wool plug. The glass tube B is connected with an empty bottle C, and a Desaga water-jet aspirator, which is fixed into a large wash-tower E, so that air can be aspirated through B and C, and delivered to the experimental gas meter F for measurement.

The experiments were carried on in the Philosophical Hall, near the centre of the town, and air was aspirated through an aperture in a window, about 15 ft. above the ground.

The air was aspirated for about six hours daily. During May and June at the rate of 25–35 cb. ft. a day. Sometimes the plug was weighed after one day, sometimes the experiment was continued two, three, or four days. Two sets of experiments were conducted alternately, giving the following results:—

Number of Experiment.	Cubic Feet Aspirated.	Gain in Weight.	Weight per 100 Cubic Feet.
		Mgrms.	
1	436.94	5.2	1.19
2	681.75	8.1	1.2

from which we may conclude that the weight of solid matter in Leeds air is nearly 1.2 mgrms. per 100 cb. ft. As this solid matter is perfectly black, we may assume that it consists for the most part of soot. Though so small in weight it represents for the whole bulk of Leeds air a quantity approaching 8 cwt. of solid suspended impurities in the atmosphere at every moment of the day.

#### DISCUSSION.

The CHAIRMAN drew attention to the necessity for standardising anemometers, and especially in allowing for the nature of the opening, as similar experiments made with differently shaped apertures gave different results.

Mr. F. H. RICHARDSON enquired whether any experiments had been made with pyroxylin as the absorbent for the dust, as he had used it for the estimation of micro-organisms with much success. He was of opinion that Dr. Carnelly's flasks might be used for these determinations, water or glycerine being employed as the absorbent media. This would be very useful in microscopic work at any rate.

Mr. H. D. MACKER understood that Dr. Cohen's determinations only referred to the *dry* dust in the atmosphere. He would like to know whether the moisture had been estimated also, since micro-organisms and other organic constituents all contain more or less water.

Dr. COHEN, in reply to Mr. Richardson, remarked that he had not been attempting the estimation of micro-organisms in these experiments—hence the small quantity of air that he had aspirated. As regards the weight of micro-organic impurities he considered it almost negligible, for considering the number of these particles in the air it was extraordinary how little increase of weight there was.

#### SOME METHODS OF ANALYSIS OF CHROME SALTS.

BY PROF. H. R. PROCTER, F.I.C.

THE methods which I am about to describe lay no claim to originality in principle, but are simply the result of a search for convenient means of determining the principal constituents of the various chrome liquors now largely used in leather manufacture, and were originally intended for publication in a little book which I have in the press on the methods of analysis in use in the leather industries. Some of my friends, however, expressed the opinion that the information may also be useful to chemists engaged in dyeing and other kindred manufactures, who are not likely to see the book to which I have referred, and I have therefore ventured to bring it before the Society.

The determinations generally required for these purposes consist in that of chromic acid in its free state and in acid and normal salts, of the normal and basic salts of chromium

combined with other acids, and of chromic oxide as obtained in the ash of fabrics and leather after ignition, by which it is rendered extremely insoluble. In this last case the most practicable way of getting the chromium into solution is to convert it into chromic acid by fusion with a mixture of 3 or 4 parts of sodium carbonate and 1 part of sodium peroxide, for 10 or 15 minutes. If the ash is finely pulverised before fusion, this should be sufficient, but if any green residue is left on solution in water, the operation must be repeated. A nickel crucible may be used, but for occasional work the damage to a platinum crucible is not very serious. The alkaline melt must be boiled with water for at least half an hour before acidification to destroy excess of peroxide, as hydrogen peroxide reduces chromic acid, while oxidising it in part to perchromic acid. (*Cf.* this Journal, 1895, 1917; 1896, 155.) The chromic acid may then be estimated in the solution by titration with iodine and potassium iodide and thiosulphate as about to be described. For mere detection of chromium in an ash, fusion in a borax bead is a delicate test, a very intense green colour being produced even in the oxidising flame, while the green produced by ferrous iron is pale, and passes into a yellow-brown in the oxidising flame, becoming much paler as it cools.

The atomic weight of chromium is given by Ostwald at 52.15, oxygen being reckoned as 16, and it is therefore more accurate to take the round number 52 than the frequently adopted 52.5, and certainly sufficiently so for technical purposes; while it has the convenience that  $\text{CrO}_3$  is then exactly 100, which considerably facilitates calculation. On this reckoning the molecular weight of potassium bichromate is 294. It must be remembered that chromic acid may be looked at from the double point of view of a dibasic acid, of which  $\frac{1}{2}$  gram-molecule will be required for 1 litre of normal solution; and of an oxidising agent, of which  $1\frac{1}{2}$  atoms of oxygen are active, and which will therefore liberate 3 atoms of iodine, &c., and of which  $\frac{1}{2}$  gram-molecule only is required for a normal solution. Similarly, considering bichromate, we see that the molecule contains two chromic acid groups both "half bound," and therefore only saturates as much alkali as the one molecule of free chromic acid, while as an oxidising agent it contains 3 atoms of loosely combined oxygen, and liberates 6 atoms of iodine, and that therefore only  $\frac{1}{2}$  gram-molecule or 49 gram. is required for a normal solution. I must apologise for mentioning such elementary facts, but shall have to make use of them later, and have found that the two different normal strengths are sometimes confusing at first sight. Both acidimetric and oxidising methods may be used advantageously for analytical purposes.

Chromic acid may be estimated gravimetrically by precipitation as lead or barium chromate, but still more easily and satisfactorily by reduction (by alcohol or sulphurous acid) to chromic oxide ( $\text{Cr}_2\text{O}_3$ ) and subsequent precipitation by ammonia.

Of the volumetric methods, the one generally recommended depends on the oxidation of a ferrous salt by the chromic acid, as in Penny's method of estimating iron. A convenient method, where only occasional determinations are required, is to weigh about 1 gram. of pure ammonio-ferrous sulphate from a weighing bottle into a flask or beaker, adding a little water, and, say, 10 c.c. of dilute sulphuric acid, and titrate it with the chromic solution of which the strength is to be determined until a drop withdrawn by a glass rod gives no greenish tinge with a freshly prepared solution of potassium ferrieyanide on a white plate. Three molecules or 1,176 of the ferrous salt correspond to 1 molecule or 100 of  $\text{CrO}_3$ , from which the strength of the solution is easily calculated. The principal objection to this method is the character of the end-reaction, which is always more troublesome than one dependent on a change of colour in the body of the solution, and the necessity of weighing out the ferrous salt every time on account of the liability of ferrous solutions to oxidation by the air.

Where many analyses have to be made, I have found the iodometric method of Zulkowsky much more convenient and very accurate and rapid; and especially so with very dilute solutions such as are used in tanning and dyeing. Some of the text-books talk about distillation of the liberated

iodine, and others convey the impression that digestion under pressure in a closed flask is necessary for the complete liberation of iodine from potassium iodide by chromic acid, but in my experience the reaction is almost instantaneous at ordinary temperatures, and at least is quite complete in the cold in a few minutes in a stoppered bottle.

The method is conveniently carried out as follows:—A measured quantity of the chromate or chromic acid solution, which should not contain more than about 0.01 gram. of potassium bichromate or its equivalent, is placed in a stoppered bottle of 200 or 300 c.c. capacity, and 10 c.c. of a 10 per cent. solution of potassium iodide and 5 c.c. of concentrated (or a corresponding quantity of dilute) hydrochloric acid is added. The bottle is closed and well shaken, and allowed to stand at least a few minutes, when it is titrated with a N 10 solution of pure sodium thiosulphate (24.8 grms. per litre) until the brown coloration of the liberated iodine has nearly disappeared, when about 1 c.c. of  $\frac{1}{2}$  per cent. starch solution is added and the addition of the thiosulphate continued till the violet of the starch iodide has given place to the pale greenish-blue of the chromic chloride. With very slight practice this point is perfectly easy to hit. As the violet tinge sometimes reappears by some secondary oxidation, its first disappearance should be noted as the end-point. As has already been stated, each molecule of chromic acid liberates three of iodine, and consequently each c.c. of N 10 thiosulphate is equivalent to 0.0049 gram. of bichromate, or 0.0033 of chromic anhydride. If pure thiosulphate solution is not at hand, an approximately normal solution is made by dissolving 25 grms. of ordinary "hyposulphite of soda" in a litre of water, and titrating 20 c.c. of N 10 bichromate solution, as above described with iodide of potassium. If the same quantity of the two chrome solutions be used, their strengths will be directly proportionate to the thiosulphate used in each case. A similar method may be used to estimate the thiosulphate in "hypo liquors" by adding the liquor to be tested from the burette to the iodine solution obtained by treating 10 c.c. of 10 per cent. potassium iodide solution, acidified with hydrochloric acid, with 20 c.c. of N 10 bichromate, which will correspond to 0.496 gram. of pure thiosulphate. No accurate results can be obtained by titrating thiosulphate direct with bichromate, as the oxidation is complex, and proceeds further than that with iodine. The iodide used must be free from iodate, and the hydrochloric acid free from chlorine, both of which may be tested by a blank experiment, when, if either are present, iodine will be liberated, colouring the solution brown, and giving the usual reaction with starch. If pure chemicals cannot be obtained, the amount of iodine so liberated must be determined and allowed for.

It is frequently desirable not only to determine the total quantity of chromic acid present, but the relative amounts as free acid and bichromate, or as bichromate and neutral chromate. It is obvious that all three of these cannot exist in the same solution, but it must not be forgotten that free chromic acid may co-exist with other free acids, and that by any alkalimetric process they will be estimated together. Neutral chromate reacts neutral with phenolphthalein, while bichromate and free chromic acid are acid to it. If, therefore, bichromate and neutral chromate are present, the former can be estimated by adding standard sodium or potassium hydrate solution in presence of phenolphthalein till the latter is reddened. Every c.c. of N 10 alkali will in this case correspond to 0.0147 gram. of potassium bichromate, 0.01 of half-bound chromic acid (present as bichromate), or 0.005 gram. of free chromic anhydride, the question being one of acidity simply, and not of oxidising power; and hence free chromic acid will consume double as much soda as when "half-bound," in bichromate.

If a solution contains 0.1 gram. of  $\text{CrO}_3$  in whatever form, it will require 30 c.c. of N 10 thiosulphate to reduce the iodine it evolves from potassium iodide. If the chromic acid is free, it will also require 20 c.c. of N 10 sodic hydrate to make it neutral to phenolphthalein; while if it is present as bichromate, only 10 c.c. will be required, and in the case of neutral chromate none at all. We may therefore deduce the following rule:—

If the N 10 soda required to neutralise the chromic acid is less than one-third the N 10 thiosulphate, each c.c. of soda corresponds to 0.01 of  $\text{CrO}_3$  as bichromate or to 0.0147 of potassium bichromate, and the remainder of the chromic acid indicated by the thiosulphate will be present as neutral chromate. If the soda required is more than one-third the thiosulphate, each c.c. in excess of one-third corresponds to 0.01 of free  $\text{CrO}_3$ , and the remainder indicated by the thiosulphate is bichromate. If the soda exceeds two-thirds of the thiosulphate the whole of the chromic acid is free, and the excess of soda over two-thirds corresponds to some other acid. The pale yellow colour of the neutral chromate scarcely lessens the distinctness of the end reaction with phenolphthalein.

It is also possible to estimate the free chromic acid directly by the method described by Mr. Carlton Heal and the author in a paper on the "Analysis of Used Chrome Liquors," which was published in this Journal, 1895, 248; and probably for very exact work this would be preferable to the indirect method just described.

The determination of chromium in solutions of chrome salts is, of course, readily performed gravimetrically by precipitation with ammonia, but its rapid volumetric estimation is much less easy. Naturally if it can be converted into chromic acid, its estimation by the methods already given will present no further difficulty. The problem is to find an oxidising agent which is powerful enough to convert the whole of the chromium into chromic acid, but which can itself be completely removed from the solution before titrating, without at the same time reducing any of the chromic acid formed, or which is incapable of liberating iodine or oxidising thiosulphate. Hydrogen peroxide naturally suggests itself, but though it is capable of oxidising chromic to perchromic acid, it also acts on it as a reducing agent with evolution of oxygen. Sodium peroxide in alkaline solution oxidises chrome salts rapidly to chromic acid, but must be completely destroyed by boiling before acidification, which demands half an hour, and with all possible care the results seem apt to be lower than the truth. Nitric and chloric acids are unsuitable from the difficulty of getting rid of them and their products after the oxidation is finished. On the whole potassium permanganate seems to be the most suitable oxidising agent. Crookes, in his "Select Methods," quotes a process suggested by W. J. Sell for the analysis of chrome steel and similar compounds, in which he oxidises with permanganate in a solution rendered acid with sulphuric acid, and after neutralising and filtering off the manganic oxide, estimates the chromic acid iodometrically. However well this may answer the purpose for which it was originally intended, it is rendered inapplicable in the present case by the fact that in tanning, and I suppose in dyeing solutions, chlorides are frequently present, and in acid solution in contact with manganic oxide, chlorine is evolved, which it is almost impossible to get rid of, and which, on the one hand, is apt to make the results too high by liberating iodine, while on the other, free hydrochloric acid in presence of chromic acid leads to loss by partial reduction of the chromic acid, and by volatilisation as chlorochromic acid. Crookes describes another method in which the salts of chromium are oxidised by standard permanganate in alkaline solution, and their amount estimated by the volume consumed, a point being taken as the end reaction when the supernatant liquid was pure yellow, free from any trace of green or pink. I have not found this nearly sufficiently delicate, at least with the dilute solutions with which I have had to deal, but the following modification has been found to give satisfactory results, and to be very easy to work. A measured quantity of the chrome solution, which should not contain more than about 0.05 grm. of  $\text{Cr}_2\text{O}_3$ , is rendered decidedly alkaline with sodium hydrate, raised to a boil, and potassium permanganate added till the supernatant liquor remains pink after boiling for two or three minutes. Alcohol is then added drop by drop to the boiling liquid till the pink disappears, and the solution, after cooling, is made up to a known volume, say, 250 c.c., and filtered. The chromic acid is then determined with potassium iodide and thiosulphate in, say, 50 c.c., as has been already described. The alcohol does not reduce the alkaline chromate solution, at least under the conditions described.

Beside the estimation of chromium it is often desirable to determine the basicity or otherwise of the liquors. I cannot suggest any direct means of doing this, but in absence of ammonia, and of bases precipitated by sodium carbonate, the total acidity in combination with chrome is easily found by a modification of Hehner's method of determining the permanent hardness of waters. A known excess of sodium carbonate is added and the solution boiled for a short time, made up to 100 c.c., filtered, and the sodium carbonate titrated back in an aliquot part. I have not found any necessity for evaporation to dryness. The same method may be applied under the same conditions to alumina salts, and in the writer's hands has given much more satisfactory results than Bayer's method of direct titration in presence of methyl orange, or its modifications. In the case of sulphate of alumina 5 grm. of the sample is dissolved in about 40 c.c. of water, 50 c.c. of N 1 sodium carbonate is added and the mixture is boiled for a short time, made up to 100 c.c., filtered, and 20 c.c. representing 1 grm. of the sample is titrated with N 1 acid and methyl orange.

#### DISCUSSION.

The CHAIRMAN reviewing the methods suggested by Prof. Procter for the estimation of chromium considered that any iodometric method was likely to be superior to those in which ferrous sulphate in any form was used. He thought that after fusing a chromium compound with sodium peroxide, the excess of the latter might be more quickly removed by boiling after addition of sodium bicarbonate since the peroxide is unstable in presence of carbon dioxide. He drew attention to the fact that in reducing a chromate to chromic oxide by means of alcohol, especially if the alcohol is now quite pure, too much of the latter must not be used as some non-volatile organic compound seems to be formed which is capable of preventing the complete precipitation of the chromium. The ammonia should be added only in slight excess.

Mr. C. RAWSON said he had used caustic soda with phenolphthalein for the estimation of bichromate but he found that better results are obtained by adding the alkali in excess and then titrating back again, than by direct titration. He had also used lacmoid paper to titrate chromate (alkaline to lacmoid) in presence of bichromate (neutral to lacmoid), acid being run into the solution until a drop of the latter placed on a piece of lacmoid paper causes no change of colour.

Prof. PROCTER, in reply to Mr. Ward, said that sodium peroxide does not seem to be prepared perfectly pure but generally contains some iron which, however, does not interfere in any way with the estimation of chromium.

Mr. FAIRLEY incidentally mentioned a mode of indicating standard solutions free from doubt or ambiguity. The quantity of substance taken is made the numerator of a fraction, and the volume in which it is finally dissolved the denominator. Thus sulphuric acid solutions may be written:—

Normal sulphuric acid, or  $\frac{N}{1} \text{H}_2\text{SO}_4$ , or  $\frac{49 \text{ grm.}}{1,000 \text{ c.c.}} \text{H}_2\text{SO}_4$ ;  
Decinormal sulphuric acid, or  $\frac{N}{10} \text{H}_2\text{SO}_4$ , or  $\frac{4.9 \text{ grm.}}{1,000 \text{ c.c.}} \text{H}_2\text{SO}_4$ ;  
Centinormal sulphuric acid, or  $\frac{N}{100} \text{H}_2\text{SO}_4$ , or  $\frac{0.49 \text{ grm.}}{1,000 \text{ c.c.}} \text{H}_2\text{SO}_4$ ;  
&c. &c. &c.

A discussion followed on this proposal.

Hon. Local Secretary:

Dr. H. Schweitzer, 77, William Street, New York, U.S.A.

The names in italics are those of Members of Committee who retire at the end of the current session.

The following have been elected to fill the vacancies, and will take office in July next:—*Vice-Chairman*: T. J. Parker, *Committee*: H. Clementson, W. D. Horne, G. A. Prochazka, Clifford Richardson, and G. W. Thompson.

*Meeting held on Friday, April 23rd, 1897.*

PROF. CHAS. F. CHANDLER IN THE CHAIR.

Before the business of the evening commenced, Mr. R. T. Antony exhibited Chassigne's New Colour Photographs, and Mr. C. K. Munns exhibited a new Petroleum Welsbach Lamp.

### THE DETERMINATION OF THE SPECIFIC GRAVITY OF MOLASSES.

BY J. C. HOOT.

Molasses containing about 40 or 50 per cent. sugar, which is the residue of the sugar works and refineries, has a specific gravity of about 1.400. The determination of the specific gravity of this molasses is very frequently necessary in the sugar laboratories, whilst the viscosity of, and the amount of air contained in, the molasses, makes it impossible to take the correct specific gravity with an hydrometer.

Sidersky (*Zeitschrift für Rübenzucker Industrie*, 1881, page 192) mentions a method which gives good results. According to this method, the molasses is heated in a funnel about 5 ins. diameter, placed in a hot-water funnel. The tube of the funnel is closed by a glass rod covered with a piece of rubber tubing. The molasses gets thin by the heating, and the air bubbles rises to the surface, forming a scum preserving the molasses from evaporation. When all the air bubbles have reached the surface, the funnel is placed on a support, the glass rod is lifted out of the funnel tube and, after allowing the first part of the molasses to run off, it is caught in a 50 c.c. flask, which has been previously dried and weighed. When the molasses has nearly reached the mark on the flask, the glass rod is lowered into the funnel tube, thus stopping the flow of the molasses. The flask and contents are now cooled to 15° C. and weighed; water at 15° C. is then added to the mark, and the weight is again taken. The water does not mix with the molasses, and it is therefore an easy matter to add water to the mark very accurately.

The specific gravity is then calculated as follows:—

Flask, with molasses .....	Grms.
Flask, empty .....	85.346
Molasses .....	69.512

After adding the distilled water at 15° C:—

Flask, with molasses and water .....	Grms.
Flask, with molasses .....	86.280
Water added .....	0.934

The 50 c.c. flask contained, therefore, 50 c.c. — 0.934 c.c. = 49.066 c.c. molasses.

The molasses weighed 69.512 grms., and the specific gravity, consequently, is  $\frac{69.512}{49.066} = 1.416$ .

I have devised a modification of this method which does away with one weighing and makes the calculation very easy. The molasses is heated in the hot-water funnel just as in the method of Sidersky. The molasses is run into the 50 c.c. flask up to about 1 c.c. from the mark. After cooling down to 15° C., a potassium carbonate solution of 1.400 sp. gr. (38.45 per cent.  $K_2CO_3$ ) is added to the mark. The flask with the molasses and the carbonate solution is now weighed and the specific gravity calculated as follows:—

Flask, with molasses and potassium carbonate ..	Grms.
Flask, empty .....	86.618
Molasses and potassium carbonate ..	70.784

Specific gravity =  $\frac{70.784}{50} = 1.4157$ .

In this example we took a molasses of 1.416 sp. gr. and filled the flask up to 1 c.c. from the mark; we have therefore—

$$49 \times 1.416 + 1.400 = 70.784.$$

The difference is then only 0.0003. When the molasses has a specific gravity of 1.350 or 1.450, the flask being filled up to 1 c.c. from the mark, and potassium carbonate solution of 1.400 sp. gr. is used, the difference is 0.001, which can be considered of no importance.

The potassium carbonate solution should always be made of about the same specific gravity as that of the molasses to be tested. The following table gives the percentage of potassium carbonate present in solutions of different specific gravities at 15° C.

	Specific Gravity.
34.20 per cent. potassium carbonate .....	1.350
35.05 " " " .....	1.350
35.90 " " " .....	1.370
36.75 " " " .....	1.380
37.60 " " " .....	1.390
38.45 " " " .....	1.400
39.30 " " " .....	1.410
40.15 " " " .....	1.420
41.00 " " " .....	1.430
41.85 " " " .....	1.440
42.70 " " " .....	1.450

### THE DEFINITION OF A LAKE.

BY MAXIMILIAN TOCH.

A composite definition, culled from the older and newer chemical and literary authorities, tends to indicate that a lake pigment is an organic dye precipitated on an inorganic base. The word lake implies a colour used for glazing purposes and, formerly, lakes were used to that end almost entirely. Time and fashion have little regard for custom, and what was considered a lake pigment 25 years ago is, in many instances, not manufactured at all to-day.

The United States Customs Tariff of 1894 says that lakes should be dutiable at 25 per cent., and a vermilion containing lead should be dutiable at 6 cents per lb. It further says, that all blues containing ferrocyanide of iron shall be dutiable at 6 cents per lb., and all chromium colours and all blues containing ultramarine at 3 cents per lb. The fact that a lake is not definitely described in the tariff may lead to some confusion, but it can easily be demonstrated that there are a variety of pigments which are of such composition that they may either be lakes, or paints, or both. If the tariff be strictly interpreted, all the eosine colours of the scarlet order would be vermilions containing lead, because they are invariably eosines precipitated by nitrate or acetate of lead on a base of lead oxide, clay, alumina, barium sulphate, starch, or any suitable medium. If a solution of eosine be taken and precipitated by nitrate or acetate of lead a colour is obtained, which is an article of commerce sold under various names and may be regarded as a true lake. It has excellent covering property, is fairly permanent, and can be made in any shade from a pale vermilion to a deep ruby, according to the methods of manipulation and the grade of eosine used. Calculating the amount of lead contained in a sample of this kind, the percentage would be 42 per cent. oxide of lead and 58 per cent. bromofluoresceic acid, the change occurring because lead replaces the sodium originally contained in the yellowish shade of eosine. This is unquestionably the highest type of lake that can be made, and in going down the scale, if the same ingredients be used and reduced with 10 per cent. of alumina and 25 per cent. of lead oxide (orange mineral), a colour is obtained, which in one branch of the trade sells as scarlet lake, and in another branch of the trade is used and sold under the name of coach grinders' vermilion. That this is a lake there is no doubt, and that it is a vermilion there is no doubt either. The question naturally arises over an article of this kind, is it dutiable at 25 per cent. as a lake, or is it dutiable at 6 cents per lb. as a vermilion containing lead? There are hundreds of red lakes which look like vermilion, and in some industries are used as vermilions, and in other industries used as lakes, and nearly all of them contain lead as a part of the base. If they contain originally eosine, they contain subsequently lead, because lead is used as the precipitant.

A blue made by precipitating potassium or sodium, ferrocyanide with a ferric salt is known in commerce as Prussian blue, and if part of this blue be precipitated in conjunction with alumina hydrate, a colour is obtained which in some industries sells under the name of blue lake, and in other industries sells under the name of Antwerp blue. As Antwerp blue, this colour is datable at 6 cents per lb. because it contains ferrocyanide of iron: as blue lake, this colour is datable at 25 per cent. In a like manner are chrome greens precipitated with alumina hydrate for producing certain lithographic ink colours and known commercially as permanent green lake, or such other names as the makers fancy or the consumers whom would dictate.

From the examples quoted and the inferences made, I contend that it is not within the province of the general chemist to decide whether a pigment under examination be a lake or not. Time was when the analytical chemist's opinion was taken conclusively as to the potability of a given water. Matters have changed and now it is the chemist who has the knowledge of bacteriology who decides as to the noxious or innocuous quality of the water. All the published definitions of a lake are so vague and general that they admit of too many exceptions and include a vast number of colours which should be taken or classed separately.

#### DISCUSSION.

Mr. ANSBACHER considered a lake to be a pigment consisting of an organic colouring matter or dye chemically combined with some material, usually aluminium or some derivative combination, which may be either pure or else containing a certain quantity of white pigment, which is added either to dilute the intensity of colour of the organic compound or else to give it the proper working quality.

Many manufacturers called the products that they sent out lakes when they were not really lakes at all; and a colour containing orange mineral could not justly be classified as a lake, because a lake was assumed to be a colour containing but little body with some transparency, which in the case of orange mineral was added only to give it body. A lake was a pigment which was not supposed to have much body, and which was used in connection with other pigments which possessed body to give it intensity of colour.

Mr. J. A. ULLMANN took exception to the definition just given because of what was known in commerce, and sometimes called "white lake," *viz.*, hydrate of alumina, which was purely inorganic in character; but it was called white lake because it had the qualities of transparency, which are generally desirable in lakes. The name of lake should be given to every pigment which had some degree of transparency, or else should be confined entirely to the old lakes as they were formerly made.

Mr. ANSBACHER had never heard the term "white lake" used, and he had been in the trade for five years.

Dr. ALSBERG entirely disagreed with Mr. Ullmann. In the first place, a lake was certainly nothing but a colouring matter, chiefly organic, precipitated by some means on a transparent or semi-transparent substratum, as ordinary aluminium hydrate, to which may have been added starch, simply as an adulterant. He had never heard of a lake such as Mr. Toch specified, which he took to be a slip of the tongue, containing lead oxide. He presumed that he meant sesqui-oxide, red lead, or, as it was known commercially, "orange mineral."

The author referred to the 1894 tariff. That tariff contained two paragraphs, one of which referred to vermilion red containing quicksilver, which was datable at 20 per cent. *ad valorem*, and another paragraph referring to vermilion reds not containing quicksilver, but containing or made with lead, which paragraph was probably introduced into that tariff simply for the reason that some time previous to its passage some so-called imitations of vermilion had been made. These imitations were always precipitated on the sesqui-oxide of lead with red lead and the orange mineral of commerce, although some might contain white lead, oxide of zinc, and so on, partly as adulterants and partly as a means of altering the shade. If they contained whites, the resulting colour was not

quite so yellowish. It was more of a bluish tone, and the reason they were separated from the vermilion proper was that there was no means of determining their value. For instance, orange mineral, which at that time paid a duty equivalent to about 60 per cent. *ad valorem*, was coloured with a mere trace of eosine so as to avoid paying the duty, which was 3½ cents per lb. People in Europe simply took 100 lb. of orange mineral or red lead, and added a few ozs. of eosine in solution, which they sent to the United States market, and which paid 25 per cent. *ad valorem* instead of 60 per cent. He also dissented from the author's statement about ferrocyanides being lakes. The author stated that a well-known firm, Messrs. Windsor, Newton, and Co., of London, described "Antwerp blue" as a lake. He (Dr. Alsberg) had known the article a good many years and had manufactured many thousand pounds of it. It was nothing but a mixture of ferrocyanide of iron with some aluminium hydrate for certain purposes; but nobody ever thought of classifying that colour as a lake. Nor had he ever heard that certain chromium colours which Mr. Toch did not specify, and which could be only either the oxide or the sesqui-oxide, the article known in commerce as the so-called hydrate. Sesqui-oxide, manufactured according to Binlay's process by the fusion of potassium bichromate with picric acid, and subsequent washing, was the pure sesqui-oxide, sometimes toned up either with a trace of ultramarine blue or ferrocyanide of iron, so as to give it a little more bluish tone instead of the yellowish tint which it had originally. The other chromium colour must be a mixture of lead chromate and ferrocyanide of iron only. Those certainly were not lakes. They lacked every property of a lake. A lake had never been known to mean anything but a colour precipitated on a transparent or translucent substratum.

Mr. TOCH, in reply, said that if he mentioned the orange mineral as a lead oxide, he did it on the authority of a very learned man, who said orange mineral has not yet been classified as a complete compound, and should not be anything else, because of various uncertain conditions. He denied that a lake must be precipitated on a substratum more or less translucent, since pure eosine precipitated by nitrate of lead was undoubtedly a lake, and yet it was not precipitated on anything. It was simply a precipitate, and was a compound which was absolutely new. Dr. John W. Draper, in a book which he published in 1842, defined a lake as alumina which carried down a colouring matter similar to that of cochineal or the extract of some of the West Indian woods or some of the Oriental woods. That was so until the newer changes came up. A lake was entirely different at the present day to what it was 25 or 30 years ago. The tariff of 1894 said vermilion red containing lead should pay a duty of 6 cents a lb. Vermilion red containing lead might also be a lake, because if an absolutely true lake might contain 42 per cent. of lead, calculated as oxide, why could not a colour be a lake which only contained 10 per cent. of orange mineral, another form of lead oxide? He brought the matter up to show the absurdity of that very paragraph of the tariff of 1894. He had asked the Board of Appraisers whether they would determine what a lake was. They said they would prefer to leave that for other people. They would simply say whether a certain colour was a lake or not; but a colour might be imported from Germany, for instance, which was worth about 8 marks a lb. To the uninitiated eye it looked exactly like vermilion, but to the Board of Appraisers and their chemists that colour might pass as vermilion red containing lead, at 6 cents per lb. Those things had happened, and it was just because the Government made incorrect discriminations that paragraphs like the above should be excluded. Messrs. Windsor, Newton, and Co. did not claim their Antwerp blue to be a lake. They claimed it to be a ferrocyanide of iron precipitated on alumina, and he merely mentioned it because, according to the old definition, this was a lake because it was precipitated on an inorganic base.

Mr. ANSBACHER said that one could not add orange mineral, which was an oxide of lead, to a lake without affecting the colour to such an extent that anyone who

had experience could at once determine that that was a vermilion. Whenever that lake contained orange mineral it no longer was a lake, and should be classified accordingly.

Mr. ULLMAN said that in former times certain pigments were known as lakes, and their distinctive character was their transparency; and, therefore, when eosine and similar so-called lakes were introduced, it was on account of their similarity to the lakes that they were brought into commerce under that name. It therefore seemed to him that the name "lake" could justly be given to such colours only that resembled the old lakes, and, as Mr. Ausbacher said, this particular quality was greatly diminished so soon as any such pigment as orange mineral was added. The name "lake" should be given exclusively either to those old-time lakes as they were formerly prepared, or, if it were to be extended, to all colours that possessed these properties. Accordingly it would also apply to those translucent substances that were sometimes known as white lakes, which had no colour at all. If they had to choose between confining the name "lake" to its original use or else extending it considerably beyond, he agreed with Mr. Ausbacher that if anything were added to a lake which modified its distinct qualities it then ceased to be a lake in the proper sense.

### SOLUBILITY OF LIME IN PRESENCE OF SODIUM AND POTASSIUM CHLORIDES AT VARIOUS TEMPERATURES.

BY GODFREY L. CABOT.

The following research, which I carried out as a student in Zurich 13 years ago, and which has never been published, was undertaken to ascertain the effect of temperature and of sodium and potassium chlorides in solution upon the solubility of lime.

It will be perceived that the solubility of lime in saline solutions diminishes with the increase of temperature; secondly, that the addition of chloride of potassium or sodium increases the solubility of lime till over 6 per cent. of the chloride is in solution, at which point the maximum solubility is passed, and the solubility diminishes to a minimum where the aqueous solution is saturated.

At the boiling point (99° centigrade at Zurich) the saline NaCl solutions containing between 60 and 120 grms. of common salt per litre dissolved a little over  $\frac{1}{10}$  of 1 per cent. of lime. The relative increase of solubility with increase of salt seems a little larger at the boiling point than at the zero point. At ordinary temperatures the solubility is less than at zero point and much more than at the boiling point. It further appears that after 60 grms. of salt per litre is

exceeded, the solubility of lime in water diminishes, but not so rapidly in proportion to the change of the salinity as it previously increased. In a saturated aqueous solution of salt the solubility of lime is about 25 per cent. less than in pure water at ordinary temperatures. At 99° centigrade it is about 8 or 9 per cent. less than in pure water. In pure water the solubility of lime diminishes with rising temperature less rapidly between 0° and 15° than between 15° and 99°.

In saturated solutions of either KCl or NaCl it diminishes with rising temperature more rapidly between 0° and 15°, and less rapidly between 15° and 99°. The solubility of NaCl increases so little with an increase of temperature as not to materially affect the result of the experiments in NaCl solutions saturated at different temperatures. I have even seen it stated that it was not at all more soluble at the boiling point than at zero point. I beg, however, to corroborate the opinion of the majority, backed by quantitative experiments, that it does increase in solubility with the increase in temperature. If a saturated solution of common salt at 100° be cooled, out of contact with the air, it will deposit salt. In the case of chloride of potassium the solubility of the lime is uniformly less than in corresponding solutions of common salt. The maximum solubility for zero and ordinary temperatures seems to occur in a little stronger solution than was the case with common salt; just how much I did not ascertain, but the maximum will not considerably exceed the solubility attained with a solution containing 60 parts of KCl per litre. For saturated solutions the problem is made harder by the increased solubility of chloride of potassium as the temperature increases, and we find that the curve of solubility continues out in a straight line downward as far as the increasing solubility of KCl takes it.

The general relations mentioned in connection with solubilities in salt solutions obtain also in the KCl solution, but there is a peculiarity which I did not mention in connection with the salt solution because it is quite obscure, but which becomes very obvious and apparent in the case of chloride of potassium, namely, that at the boiling point the solubility of lime in either salt or chloride of potassium solutions increases to a much stronger solution of the salt than at ordinary temperatures or the freezing point.

Apparently the maximum solubility of the lime at the boiling point is in both cases where the amount of the chloride in solution is about 120 grms.; but the curve of solubility is so flat on top that this maximum cannot be located very accurately. It is apparently later in the case of chloride of potassium than in the case of chloride of

sodium. It takes a larger proportion of chloride of potassium to dissolve the maximum possible amount of lime than it does of chloride of sodium.

Whether these proportions coincide with the relative molecular weights of chloride of sodium would be difficult to determine, owing to the experimental error in dealing with such minute deviations. On the same co-ordinate paper I have prepared a series of curves to show the effect of temperature on the solubility of lime in different solutions of the chloride. In other words, the temperature varies with the abscissa, and the strength of the solution with the ordinate. This brings out a noticeable fact: that the solution of common salt having 240 grms. per litre dissolves at the zero point a trifle more lime than pure water, and at the boiling point over 20 per cent. more, and the curves of solubility representing 60 grms. and 30 grms. lie pretty close together throughout their length. In the case of chloride of potassium these three lines start, to be sure, at about the same points—in other words, at zero temperature.

The solubility of the lime varies little between 30 grms. of chloride of potassium and 120 grms. of chloride of potassium in aqueous solution; but at the boiling point there is a difference of some 12 per cent. or more. The solubility in solutions of chloride of potassium of zero grms. and 240 grms., and saturated at zero centigrade, lie close together, and converge as they approach the boiling point.

To sum up briefly the results of the investigation, we see that the solubility of lime in solutions of either chloride of potassium or of sodium increases to a maximum at about one-fifth of saturation, and then diminishes to a minimum at the saturation point, where it is lower than in pure water. The chloride of sodium solutions dissolve more lime at all temperatures and degrees of concentration than equal solutions of chloride of potassium. That in each case the maximum solubility of lime in the chloride solution is at the lowest temperature, and at about 60 to 120 grms. of the chloride per litre, and that the minimum solubility occurs at the saturation point and at the highest tempera-

ture. That an increase of temperature at all times and in any of these solutions diminishes the solubility of the lime, and at any given temperature the minimum solubility is found in the saturated solution.

I had no very definite practical object in my experiments; they were simply purely scientific research, intended to throw light on the general relations of substances in solution.

I attribute the additional solubility of lime in saline solution to a partial reaction, whereby chloride of calcium and hydrate of sodium are formed in juxtaposition. Such reactions I consider of great importance to the theory of chemistry, and I hope they will be more thoroughly studied in the future. They are not dwelt upon in books, but every practical or theoretical chemist realises their great importance and significance; and a more exact record of these partial reactions would be of great assistance in technology, and save many useless attempts to accomplish the impossible.

Suppose that my research had shown, in place of this wave-like curve, a hyperbola with its cusp at the left; in other words, supposing that the solubility of lime in salt had increased in an increasing ratio with the strength of the saline solution? This might have led us to infer that with chloride of potassium, under pressure, it might have been even possible to avail ourselves of the reaction, and manufacture hydrate of potassium on a commercial scale. The actual results have absolutely closed this particular door, and by so much limited the field for future technical investigators.

#### THE DETERMINATION OF TANNIN BY MEANS OF HIDE POWDER.

BY JOHN H. YOCUM.

THERE are two general methods in use for making tannin determinations—the hide powder and the Lowenthal.

The latter method is oxidation in acid solution of all the organic material obtained in an extraction of raw tanning material by means of permanganate of potash, then removing the tannins by means of a gelatine solution and oxidising the remaining organic matter under the same conditions.

In the hide powder method the solids in a tannin solution are determined by evaporating to dryness and weighing, the tannins are removed from a separate portion of the solution by means of hide, and the remaining non-tanning substances determined by evaporation and weighing, the difference being the material removed by hide or tannin.

In the technical examination of tanning material, the method that gives results that are approximately true measures of the tanning value must be accepted, *i.e.*, determines those organic bodies that go with the hide to make leather irrespective of their chemical composition. During the operation of making leather there is opportunity for both chemical and physical reactions. There occurs a chemical reaction between the hide and the tannin, and a physical reaction of the nature of a dyeing operation.

A true chemical union probably occurs between the hide fibre or the inter-cellular gelatine of the hide and the tannins, but this is only a part of the tanning operation, as tannins, colouring matter, &c., dye the fibre, and are held in solid solution, hence a purely chemical method will not determine those organic bodies that go with the hide to make leather, and an empirical method becomes a necessity.

Part of every soluble compound in a tanning solution is taken up by the hide, but it is only those that have the special property of "tanning" that are completely removed when the hide is in excess, the amount of non-tanning materials that are taken up depending upon the condition of the hide, concentration of solution, &c., and is relatively small in any case.

The Lowenthal method does not regard these conditions, but determines the amount of material that will precipitate gelatine, and, aside from the difficulties of operation, particularly the duplication of conditions of oxidation each time, we do not know the amount of oxygen necessary in any individual case for the oxidation of the particular tannin we are working with, and consequently are not able

to calculate directly the amount of material removed by the gelatine. For these reasons the Lowenthal method has been superseded by the hide powder method very largely.

The hide powder method has several modifications, probably the best being that adopted by the Association of Official Agricultural Chemists at its recent meeting in Washington. By strict attention to the details, concordant results can be obtained, as the following results show. These results were obtained by three chemists working with this method and using the same hide powder.

#### SUMMARY OF EXTRACT ANALYSES.

##### Total Solids.

Analyst.	Sample I.	Sample II.	Sample III.	Sample IV.	Sample V.
A.	42.40	41.07	42.19	42.66	41.93
B.	41.20	39.73	40.78	41.20	40.73
C.	41.31	40.32	40.89	41.32	40.82

##### Soluble Solids.

A.	41.20	39.68	41.47	41.88	41.53
B.	40.90	39.17	40.23	40.50	40.39
C.	40.41	39.43	40.24	40.58	39.95

##### Non-Tannins.

A.	16.58	17.04	16.57	18.20	16.94
B.	15.18	15.70	14.98	16.73	15.45
C.	15.89	16.47	15.49	16.58	16.86

##### Tannins.

A.	24.62	22.64	25.20	23.68	24.59
B.	25.72	23.47	25.25	23.75	24.85
C.	24.52	22.96	24.75	24.00	23.09

This method obviates many of the objections to previous schemes proposed for the use of hide powder as a measure of the tannin in raw materials, but still has the variations due to differences in the hide powder itself.

Washing the hide immediately before adding it to the tannin solution, and making a correction for dilution due to the moisture in the wet hide, removes the soluble hide error.

The use of mechanical means of shaking makes the method a rapid one, and completes the tanning operation before there is time for the production of more soluble hide. The empirical method of filtration gives comparable results on the soluble solids, and the suggestion that 20° C. be the temperature of the filtration removes a source of error, as the reids go into solution quite rapidly as the temperature rises, and *vice versa*. Testing the non-tannin filtrate for soluble hide and for tannin are essentials of the method.

The test for soluble hide is precipitation by means of an excess of tannin solution; it is quite delicate, as the tannate of gelatin is insoluble in an excess of tannin. The reverse test—that for tannin by means of an excess of gelatin—is not sufficiently delicate, as the tannate of gelatin is soluble in excess of the gelatin solution. I have been using for this test a solution of gelatin in dilute alcohol—a saturated solution that does not gelatinise. This is made by adding 5 grms. of gelatin to 100 c.c. of water, warming, and, when dissolved, adding 40 c.c. of 90 per cent. alcohol, and filtering off the precipitate at a temperature a few degrees below that of the laboratory. In making this test a turbidity is to be expected in dilute solutions rather than a precipitate, which is best viewed in a Nessler tube.

The use of a uniform amount of hide in solutions of uniform density is a matter of such importance that I present the following data regarding it. Using a solution of a commercial tanning extract, 10 and 20 grms. to the

litre, and following the method otherwise for non-tannins, 1 obtained—

10 Grms.	20 Grms.
Grm. 0.1778 0.1790 0.1796 0.1775	Grm. 0.3680 0.3690 0.3685 0.3677
Average 0.1785	Average 0.3683

40 grms. of pressed washed hide, equivalent to 10.60 grms. dry hide, were used to 200 c.c. of the tannin solution, and in all cases the non-tannin filtrate was free from soluble hide and from tannin.

Using 200 c.c. of a solution of 20 grms. commercial extract to the litre, and varying the hide, 40 grms. of wet-pressed hide, equal to 10.60 grms. dry hide, gave 0.3683 gm. non-tannins from 100 c.c. of the non-tannin filtrate that was evaporated, while 50 grms. wet-pressed hide, equal to 13.25 grms. dry hide, gave 0.3493 gm. under like conditions. These are averages of four determinations, and in all cases the non-tannin filtrate was free from soluble hide and tannin. These figures show that the additional 2.65 grms. of dry hide took as a dye 0.0380 gm. of non-tannins, equal to 0.0142 gm. per gm. of dry hide, while 10.60 grms. of dry hide removed 1.2858 grms. from the extract solution, equal to 0.1212 gm. per gm. of dry hide. In connection with this, a solution of commercial glucose was made containing 8.3840 grms. dry material to the litre; a non-tannin determination was made following the method. The residue on the non-tannin weight from 100 c.c. was 0.7548 gm.

40 grms. of wet-pressed hide were used, equal to 10 grms. dry hide. 10 grms. of dry hide had taken 0.1672 gm. of glucose as a dye or 0.0167 gm. to a gm. of dry hide. Corrections for the dilution caused by the wet hide were made in each instance. These results show that variations in concentration of solution and amount of hide used are factors that must be regarded.

Variations in the amount of non-tannin material due to differing kinds of hide powder cannot be so easily regulated, and is the source of more discord in result than any other point in the method.

I tested seven different lots of hide powder by shaking 5 grms. of the air-dry hide with 200 c.c. of water containing 6 grms. of gallo-tannin, with the following result:—

1 removed 0.4094 gm. of gallo-tannin per gm. of hide.	
2 .. 0.8552 ..	"
3 .. 0.1884 ..	"
4 .. 0.1037 ..	"
5 .. 0.2331 ..	"
6 .. 0.1867 ..	"
7 .. 0.4519 ..	"

Samples 3, 4, 5 and 6 did not meet the requirements of this method for hide powders, while 1, 2, and 7 did. Three chemists working with these hide powders got the following results on the same extract:—

	Per Cent.
A. Hide powder 1 gave non-tannins.....	17.97
B. " 2 " " .....	15.37
C. " 7 " " .....	17.85

While C obtained on same extract—

	Per Cent.
With hide 1 non-tannins .....	17.50
" 2 " .....	16.55

It is therefore essential that, where tanning materials are being bought upon analysis, that the chemists be supplied with the same hide powder and observe the same method in its use.

The variations in hide powder are not due so much to the use of different kinds of hides as a source of supply, but to the means employed in preparing it.

## A COMPARISON OF FUEL GAS PROCESSES.

BY F. L. SLOCUM.

THE practical supplying of fuel gas to the public in sufficient quantities and of satisfactory quality has now been an established industry for little over a decade. Like many other industries, the beginning was made with supplies from nature, and are still largely obtained from this source. The successful prosecution of fuel gas supply in the last ten years has fully and accurately demonstrated the advantages derived in using gaseous fuel in every branch of industry and domestic economy, as well as developing very completely the most economical appliances for handling and burning the same; in other words, the business of distributing, supplying, selling, and burning fuel gas is well-developed and the public thoroughly educated to its use. This applies, of course, in its fullest sense to the natural gas belt, but is by no means confined to it, as the annual statements of nearly all gas companies throughout Europe and America show an annually increasing percentage of consumption of their total output for fuel and power purposes, and this at a price which is far above a comparative price with solid fuel in almost every instance.

As gas undertakings are divided into two parts—the manufacturing and distributing departments—and as the supply of natural gas is failing, we are confronted, in the natural gas region, with the serious necessity of developing the manufacturing processes so that they will be adaptable to the supplying of artificial fuel gas under all conditions. The last few years have seen processes and methods come and go almost out of number, yet through the numerous negative results as well as real advances there has been withal some permanent gain. The probable lines on which fuel gas will be produced have been clearly established, and a marked beginning made in each field. This is indeed something, for the field is a large one.

The methods of producing fuel gas can be divided into three classes—

First: *Coal gas* by distillation, including by-product ovens.

Second: *Bituminous coal water-gas producers*, or intermittent machines using bituminous coal, blasting or heating with air, and then decomposing steam.

Third: *Producers*, or continuous machines, of Mond and Siemens' type.

The above divisions are classified according to the heating value of a cubic foot of the gas which they respectively produce, and will be taken up in the same order.

Perhaps the greatest detriment to the more rapid development of successful fuel gas processes has been the so far unattainable ideal in heating value per unit of the natural product, i.e., 980 B.T.U. per cubic foot. Numerous heat unit analyses of natural gas at Pittsburg made with the Junker's calorimeter show the average to be 978 to 980 B.T.U., the gas often analysing nearly pure  $\text{CH}_4$ . I therefore use for all calculations with Pennsylvania natural gas 980 B.T.U. as the proper average. This, however, does not hold true with other fields; for example, a recent examination of the natural gas supplied at Louisville, Ky., gave—

	Per Cent.
$\text{CH}_4$ .....	87.75
$\text{H}_2$ .....	1.31
Total combustibles .....	89.06
$\text{CO}_2$ .....	6.60
$\text{N}_2$ .....	4.34
Total non-combustibles.....	10.94
Grand total .....	100.00
The calculated British thermal units	
per cu. ft. ....	= 936.8
Junker's calorimeter gave .....	939.0

Error very likely caused by hydrocarbon vapours, as Junker's calorimeter is an excellent check on analyses.

The highest attainable heating value in manufactured gas is from coal gas; this gives 600 to 625 B.T.U., which is approximately two-thirds the indicated efficiency of the

natural. This makes natural gas the ideal, and has led, of course, to unnumbered fruitless attempts to duplicate it. The only possible way has been by means of petroleum, and petroleum will not be considered here in any form, as its value in the liquid or natural form per million heat units is sufficient to debar further manipulation with the object of producing fuel gas to compete with coal. The fuel gas of the future will almost unquestionably be a very much lower gas in heating value per cb. ft. than is now generally sought. It is not going to be so much the question of the heating efficiency of a cubic foot of gas with the consumer as the cost of his gas per available million heat units. The question of delivery, therefore quantity, does not interest him.

**First: Coal Gas Process.**—There is little unsaid on this question. The present methods of manufacture are fully abreast of the times in the quality and quantity of gas obtained from a given coal. The tar is being disposed of to the best advantage and also the ammonia. A general change will be gradually effected by which the cyanogen will be saved—usually 12 to 16 oz. of  $(CN)_2$  per ton of American coals—as well as the sulphur and benzole. This latter will average approximately 1.5 gals. per ton of coal carbonised. This will be accomplished more from necessity through larger demands for gas than from new processes. The one thing which needs a radical change is the quality of the coke. This is caused by the ever increasing demand for a metallurgical coke with the gradual diminishing beds of ideal coking coals for bee-hive ovens, also the diminishing of the anthracite deposits, whose substitute must be crushed coke of suitable hardness; added to this the fact that the increasing demand for gas requires a better coke in order to extend the market, which, with ordinary gas house coke, is very limited.

With the above conditions in existence it is no wonder that the by-product oven has lately received such prominence as to make it appear, erroneously, in a class by itself. This view has been strengthened by the great secrecy maintained by several of the by-product oven promoters as regards their machinery for, and methods of, handling the gas. It seems to the writer that the by-product oven is only to be an improvement in one of the departments of coal gas manufacture, *viz.*, the retort house.

Once the gas is made and delivered to the hydraulic main it has entered wholly into the domain of the coal gas manufacturer, and no one, I think, will successfully contradict this fact. If the by-product coke oven can replace the retort by making a better and more saleable coke, as good a gas and as great in quantity with as much tar and ammonia at a less cost of labour and repairs, then the retort must be largely replaced by the oven, and this one disadvantage in coal-gas manufacture will have been brought abreast of the requirements of the times. This is now practically an accomplished fact. There are ovens now in operation which are as tight as the average gas retort, yielding a coke that is lower in volatile matter than bee-hive oven coke made from the same coal, and is very hard and thoroughly adapted to metallurgical purposes, while the gas is of excellent quality, analysing as follows:—

	Per Cent.
CO <sub>2</sub> .....	3.0
Illuminants.....	2.6
O <sub>2</sub> .....	0.2
CO.....	7.0
CH <sub>4</sub> .....	30.0
H <sub>2</sub> .....	52.6
N <sub>2</sub> .....	4.6

The great drawback in the use of the by-product oven has been some means of economically heating them, as the ovens require gas firing to produce a good quality of coke. This, however, is most satisfactorily accomplished by producer gas (preferably the Mond type, which will be mentioned below). Only a limited amount of recuperation is required. One of the best types for recuperation is the one employed by Carvès. The system of regeneration does not seem to produce as good coke on account of regular fluctuations in the temperature of the oven during coking, producing a more unevenly porous coke, and forming a

larger percentage of higher decomposing hydrocarbons, thus making a higher percentage of volatile matter in the coke.

Assuming the by-product oven in place of the retort, the products of one ton of coal, at a reasonable cost of manufacture, are—

	Lb.
Metallurgical coke.....	1,409
Crude tar.....	100
Ammonia (NH <sub>3</sub> ).....	5
Cyanogen (CN) <sub>2</sub> .....	0.75
10,000 cb. ft. gas, 600 B.T.U. = 6,000,000 B.T.U.	
One ton of bituminous coal averages 10,000,000 B.T.U.	

In assuming 600 B.T.U. per cb. ft. for coal gas, I have taken a very conservative average, and one that can always be maintained in practice, as the following analysis, made while making a test of Dominion coal with ordinary retorts, will show:—

#### The coal analysed—

	Per Cent.
Moisture.....	1.13
Combined volatile matter.....	40.25
Fixed carbon.....	53.76
Ash.....	4.86
Sulphur.....	1.50
Nitrogen.....	1.39

#### The coke analysed—

##### No. 1.

	Per Cent.
Moisture.....	0.41
Combined volatile matter.....	2.1
Fixed carbon.....	86.52
Ash.....	8.7
Sulphur.....	2.24

##### No. 2.

	Per Cent.
Moisture.....	1.31
Combined volatile matter.....	2.89
Fixed carbon.....	87.27
Ash.....	6.62
Sulphur.....	1.91

The analyses of the gas from this coal is a good average coal gas. The heat unit determinations were made with a Junker's calorimeter between the gas analyses and represent, not the same gas as that analysed, but give an average of the same gas and show the slight fluctuations during carbonisation.

	1st.	2nd.	3rd.	Heat Unit Tests (Made between Analyses Gas per Cb. Ft.)
CO <sub>2</sub> .....	Per Cent. 2.6	Per Cent. 3.0	Per Cent. 1.4	1st 617.9 B.T.U.
Illuminants..	5.2	5.0	6.2	2nd 644.9 "
O <sub>2</sub> .....	0.8	0.4	0.6	3rd 617.0 "
CO.....	5.8	5.8	4.5	Avg. 626.6 "
CH <sub>4</sub> .....	33.7	35.1	39.2	
H <sub>2</sub> .....	50.4	44.6	44.8	
N <sub>2</sub> .....	1.5	6.1	3.3	

A sample of gas, taken when the same works were running on Westmoreland (Pennsylvania) coal, gave, on analysis, the following:—

	Per Cent.
CO <sub>2</sub> .....	1.8
Illuminants.....	5.9
O <sub>2</sub> .....	1.1
CH <sub>4</sub> .....	42.8
CO.....	3.6
H <sub>2</sub> .....	40.9
N <sub>2</sub> .....	3.9

The candle power was 17.78.

Calorimeter gave 690 B.T.U. per cb. ft.

This, with the other analysis given above, shows that there is no difficulty in producing at least a 600 H.U. gas and maintaining it in daily manufacture.

**Second: Bituminous Coal Water Gas Producers.**—Under this type are classed such apparatus as manufacture gas from bituminous coals by means of first heating a large body and depth of fuel with an air-blast, burning the coal at bottom to coke, then admitting steam and producing water gas, the water gas formed passing up through the undecomposed coal, thus distilling off a part of the volatile matter as coal gas. The best developed machines of this type are the Hastings and Loomis. The regular water gas machines are not considered here, as they use only expensive fuel and produce a lower heating value gas.

An analysis of blue water gas made from gas house coke in the Granger machine gave—

	Per Cent.
CO <sub>2</sub> .....	4.8
CO.....	11.5
H <sub>2</sub> .....	52.41
CH <sub>4</sub> .....	0.2
N <sub>2</sub> .....	0.47

A heat unit determination of the same gas with Junker's calorimeter gave—

B.T.U. per cb. ft.....	331.5
------------------------	-------

The ideal of this class of gas machine would be a *machine which would remove all of the volatile matter from the coal as coal gas and convert all carbon into water gas, i.e., H<sub>2</sub> + CO*. This would be accomplished in part by either getting the necessary heat from outside sources to maintain incandescence, or when blasting up to allow the blast gases to pass only through the carbonised portion of the coal. Numerous patents have been taken out to accomplish this in the different ways mentioned, but as yet this field is open to very marked improvements.

The process which is the best developed in this class is the Hastings, or, as the European patents read, the "Hastings and Haak process." The writer had occasion to examine this process, which is in operation as an auxiliary to the natural gas plant at Louisville, Ky. The test extended over a period of 10 days. Jellico coal was used, analysing as follows:—

	Per Cent.
Carbon.....	63.10
Volatile matter.....	32.53
Moisture.....	1.90
Ash.....	2.4
Sulphur.....	0.07

In this process they work with a mass of fuel from 10 ft. to 12 ft. deep. In heating up by means of the air-blast, the gases produced rise up through the whole mass of fuel, thus destroying a part of the volatile matter of the coal. An analysis of these blast gases taken at the outlet of the machine gave—

	Per Cent.
CO <sub>2</sub> .....	13.15
O <sub>2</sub> .....	2.90
CO.....	9.90
N <sub>2</sub> .....	76.15

The volume of this gas produced per blast was 12,085 cb. ft. corrected to atmospheric pressure. It was found afterward that there was an extra air-blast over the coal, which destroyed all traces of CH<sub>4</sub> and H<sub>2</sub>. The blast gas was then completely burned in an unright tubular boiler recuperating nearly 10 per cent. of the heat generated in the process of manufacture. It is, however, safe to assume that quite as much of the volatile matter is distilled with the blast gases as by the water gas, as the heat range is necessarily exactly the same in each. The coal gas in the coal should be in volume approximately one-fifth, or as one is to four, hence the following calculated mixture should represent the resultant gas in this process. The two actual analyses made from two different runs show that this deduction is practically accurate.

	Water Gas (Typical).	Coal Gas (Typical).	Mixture (Calculated).	Analysis (No. 1 Found).	Analysis (No. 2 Found).
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
CO <sub>2</sub> .....	2.2	2.0	2.16	8.2	5.4
N <sub>2</sub> .....	3.4	2.0	3.12	5.2	9.2
O <sub>2</sub> .....	0.4	1.0	0.52	0.6	1.1
H <sub>2</sub> .....	57.5	49.0	55.8	43.8	41.9

B.T.U. .... 363.3 ..... 342

Specific gravity of gas ..... 0.576

The large percentage of non-combustibles is caused by poor construction of the machine used, there being leaky valves which allowed air to work in during gas making, as a constant air pressure was maintained against these valves.

The average yield of the 363 B.T.U. gas per ton of 2,000 lb. of coal was 51,250 cb. ft. (corrected).

There was some considerable tar produced, and 8.03 lb. of ammonia per ton of coal, calculated as sulphate.

The gas indicated five-candle power (approximately).

Taking the first analysis in the above table, which gave 363.3 B.T.U. per cb. ft., multiply by 51,250, the number of cubic feet of gas from a ton of coal gives an efficiency of 9,309 B.T.U. in gas from each lb. of coal used. 1 lb. of Jellico coal gives 15.105 (calculated). This, therefore, shows a fuel efficiency of 61.63 per cent. of the coal used, without considering the coal used to produce steam. It was impossible to obtain this last data, on account of the construction of the plant and other uses of the steam.

I have received from the company who operate the plant the following as the average of their winter's operation. They are making, I understand, about 2,500,000 cb. ft. per day.

Each 1,000 cb. ft. required to produce—

	Lb.
Coal.....	23
Coke.....	5
Coal under boiler.....	10
Total.....	38

The time of admitting the steam, or of gas making, was eight minutes. On one of these normal runs the gas was sampled every two minutes, and analysed, with the following results:—

	End of First Two Minutes.	End of Fourth Minute.	End of Sixth Minute.	End of Eighth Minute.
	Per Cent.	Lost	Per Cent.	Per Cent.
CO <sub>2</sub> .....	4.4		9.0	9.5
Illuminants....	1.0	"	0.8	0.7
O <sub>2</sub> .....	1.0	"	2.2	3.8
CO.....	33.0	"	28.8	23.5
H <sub>2</sub> .....	44.2	"	45.24	45.1
CH <sub>4</sub> .....	7.8	"	4.2	6.2
N <sub>2</sub> .....	8.6	"	9.76	11.2

The analyses show that the hotter the gas the greater the amount of volatile matter carried off. This type of apparatus, with some few changes in construction, should produce a 400 B.T.U. gas. This has been corroborated in part by some recent analyses made on a new plant, in which some of the errors noted in the first had been corrected.

The coal used was ordinary slack, mined near Greensburg, Pa., and analysed as follows:—

	Per Cent.
Moisture.....	1.00
Volatile matter.....	31.93
Fixed carbon.....	59.99
Ash.....	7.08

No oil was used, and the sample of gas for first analysis was taken from the large holder. The second was taken from a second holderful and a different run.

	First.	Second.
	Per Cent.	Per Cent.
CO <sub>2</sub> .....	7.9	8.1
Illuminants.....	1.4	1.1
O <sub>2</sub> .....	0.1	0.3
CO.....	28.5	28.1
H <sub>2</sub> .....	48.4	49.65
CH <sub>4</sub> .....	8.2	9.82
N <sub>2</sub> .....	5.2	3.95

Calorimeter test gave 390 B.T.U. per cb. ft., which shows that by a more careful exclusion of nitrogen and a proper reduction of the CO<sub>2</sub> there will be no difficulty in making and maintaining a 400 B.T.U. gas.

With proper appliances for utilising the producer gas formed in blasting up and the saving of the waste heat in the gas made, the net actual efficiency should be raised to at least 70 per cent. of the fuel charged, while any class of fuel can be used.

The net results at a very moderate cost of manufacture per ton of coal would be (approximately)—

8.0 lb. ammonia sulphate.

52.500 cb. ft. of 400 B.T.U. gas = 21,000,000 B.T.U.

One (1) ton of coal = 30,000,000 B.T.U. (Appx.)

Third:—*Producers or Continuous Gas Machines.*—This type is represented by the Siemens and Mond producers. The inventions of these two gentlemen represent the two steps of real progress made in continuous gas machines, i.e., the manufacture of gas by partial combustion with the recuperation of waste heat and saving of by-products. Dr. Siemens so constructed his producer as to get the very largest percentage of decomposition of CO<sub>2</sub>, admixing eventually with the air a small percentage of steam in order to reduce his temperature, at the same time forming H<sub>2</sub> and CO from same. The following analysis by Ritchie is a typical one, and gives the practical working limit of this machine:

	Per Cent.
CO <sub>2</sub> .....	5.2
CO.....	24.4
C <sub>2</sub> H <sub>4</sub> .....	..
CH <sub>4</sub> .....	2.4
H <sub>2</sub> .....	8.6
N <sub>2</sub> .....	59.4

Caloric value in B.T.U. per cb. ft., 137.28.

The amount of gas produced usually represents, in heating efficiency, from 60 per cent. to 65 per cent. of the coal charged in the producer. This type of machine practically supplied the demands for producer-gas from 1861 to 1889. True, there were many modifications, but no great progress was made in the art during this time.

The advent of Dr. Mond's invention marked the second epoch in this branch of gas making. His apparatus produces a higher heat unit gas per cb. ft., gives approximately a 20 per cent. better yield per ton, or over 80 per cent. fuel efficiency of the coal charged in the producer. The gas is clean and cold, and can be piped any distance, burning readily cold, as it is very high in hydrogen, and is adaptable to all purposes where fuel gas can be used. Added to this, about 100 lb. of sulphate of ammonia are produced and recovered per ton of coal, or, putting it more exactly, at least 70 per cent. of the fixed nitrogen in the coal is recovered as NH<sub>3</sub>. The machine is nearly automatic, and the composition of the gas changes very little. An average of many analyses from several months' operation gives—

	Per Cent.
CO <sub>2</sub> .....	17.0
CO.....	11.0
C <sub>2</sub> H <sub>4</sub> .....	0.4
CH <sub>4</sub> .....	1.8
H <sub>2</sub> .....	27.2
N <sub>2</sub> .....	42.5
	100.0

Calorific value in B.T.U. per cb. ft. = 156.9.

The coal used to produce this is a very poor quality of slack.

The first installation of these producers on this continent was at Halifax, Nova Scotia, and are being worked successfully with Dominion Coal Co.'s slack, the average analysis of the gas being—

	Per Cent.
CO <sub>2</sub> .....	18.0
O <sub>2</sub> .....	..
CO.....	9.9
H <sub>2</sub> .....	27.0
CH <sub>4</sub> .....	2.7

Taking the Mond producer as the type of this class, one ton of coal yields, with a very moderate expenditure in labour—

160,000 cb. ft. of 156.9 B.T.U. gas = 25,105,000 B.T.U.)

100 lb. of ammonium sulphate.)

(One ton of coal equalling, approximately, 30,000,000 B.T.U.)

Tabulating the results obtained in the different classes we have, as the products of one ton of coal—

	Cb. ft. of	B.T.U. of Total Gas.	Coke.
Coal gas.....	10,000	6,000,000	1,400
Bituminous water gas.	52,500	21,000,000	..
Producer gas (Mond).	160,000	25,105,000	..

	Ammonia (NH <sub>3</sub> ).	Tar.	Benzol.	Cyanogen.
Coal gas.....	5 lb.	100	1.5 gal.	0.75
Bituminous water gas.	2 lb.	..	..	..
Producer gas (Mond).	100 lb. sulphate.	..	..	..

The cost of producing a thousand feet of gas by these different processes, not taking either the coal used or the products sold into consideration, using only the cost of labour. The interest on the capital investment and cost of materials in the operation is—

	Cost per 1,000 cb. ft.
Coal gas.....	5.0 c.
Bituminous water gas.....	0.9 c.
Producer gas (Mond).....	0.62 c.

This gives only the cost value of producing a given volume of gas with its accompanying by-products, as given above. The cost of coal with the price obtainable for the different by-products all combine to change these values. These conditions, however, are different in each different locality and cannot be given here, but can be easily calculated for any locality from the above tables.

The last and one of the most important considerations is the real comparative value of the different gases, with each other, to the consumer; in other words, taking natural gas as a unit, its comparative value as coal is so thoroughly established in practice that it certainly makes a very accurate standard. Gas is found to be less economical in the generation of steam than for any other purpose. The average of a large number of tests show that it requires 80 per cent. of the heating value of the coal in natural gas in order to get the same results, labour, repairs, &c. considered. In one test of two months' duration, the heating efficiency of the gas used was 81.67 per cent. of that of the coal in order to obtain the same results under the same boilers. This is also true of Mond gas, as tests already made give the same evaporation from the gas produced from one ton of coal as burning direct under the same boiler. (It has been noted above that the fuel efficiency of the Mond producer is a little over 80 per cent.)

In all other branches of industry, especially iron, steel, and glass there is required only 40 per cent. to 45 per cent. of the actual heat units as gaseous fuel as compared with bituminous coal.

In domestic use, i.e., cooking and the heating of houses, the economy is still greater. It is proven by long practice

that 15 per cent. to 20 per cent. of the actual heating efficiency of a ton of coal delivered as gas will compete successfully with coal. The above calculations are based on the prices obtained for natural gas and coal in Pittsburgh, and the difference in value unit for unit includes all advantages and savings connected with the burning of gas as compared with coal. These results tabulated, give—

	1 Ton of Coal, including all Costs, Firing, Repairs, &c.	Gas Equiva- lent, including all Costs of Burning.	Percentage Equivalent of Gas necessary to equal Coal= 100 per Cent.
Generation of Steam.	B.T.U. 30,000,000	B.T.U. 24,000,000	Per Cent. 80
General mill use	"	12,000,000 to 15,500,000	40 to 45
Domestic use ...	"	4,500,000 to 6,000,000	15 to 20

In supplying and consuming gas it is very advantageous from the manufacturers' standpoint, to have as high a heat unit gas as possible on account of capital investment in mains; while from the consumers point of view it does not make as much difference, as the higher heating value gases require more air to accomplish complete combustion. The different percentages of air are therefore given below.

In the calculations given below a definite composition of each of the different gases considered had to be assumed in order to find the exact amount of air necessary for combustion, as well as the temperature of combustion.

The following analyses have been selected as representative average analyses of each gas considered:—

Natural Gas (PGH) (Analysis made April 1897).	Coal Gas.	Bituminous Water Gas.	Mond Gas.
Per Cent.	Per Cent.	Per Cent.	Per Cent.
CH <sub>4</sub> ..... 36.9	CO <sub>2</sub> ... 2.2	CO <sub>2</sub> ... 6.83	CO <sub>2</sub> .... 17.0
C <sub>2</sub> H <sub>6</sub> ... 0.8	Ilumi. 5.2	Ilumi. 1.24	CO ... 11.0
CO <sub>2</sub> ..... 0.3	nants.	nants.	Ilumi. 0.4
N <sub>2</sub> ..... 1.2	O <sub>2</sub> ..... 0.6	O <sub>2</sub> ..... 0.2	nants.
	CO <sub>2</sub> .... 3.8	CO ... 29.46	CH <sub>4</sub> ... 1.9
	C <sub>2</sub> H <sub>6</sub> ... 36.5	H <sub>2</sub> ... 48.95	H <sub>2</sub> ..... 27.2
	H <sub>2</sub> ..... 45.4	CH <sub>4</sub> ... 8.68	N <sub>2</sub> ..... 42.5
	N <sub>2</sub> ..... 0.3	N <sub>2</sub> ..... 4.64	
	100.00	100.00	100.00

Air necessary to burn completely 1 cb. ft. of each of the above gases is as follows:—

Natural gas .....	9.80 cb. ft. air for complete combustion.
Coal gas .....	5.65 " "
Bituminous water gas ....	2.97 " "
Mond gas .....	1.25 " "

Before closing, I wish to acknowledge the able assistance rendered by C. S. Lomax, who has had charge, under my direction, of all the different examinations from which extracts have been made for this article.

*Meeting held on Friday, March 19th, 1897.*

PROF. C. F. CHANDLER IN THE CHAIR.

## ON THE ANALYSIS OF ASPHALTUM.

BY S. E. AND D. E. PECKHAM.

Dr. H. ENDERMANN, in the Journal of the Society of Chemical Industry for December 1896, has proposed a new scheme for the technical analysis of asphalts, which may be characterised as wholly radical. We shall not attempt to discuss all of the points that he makes. A few will be sufficient.

One of us has been at work on asphaltums of various sorts since 1865. We fully agree with the inference that

may be fairly drawn from what Dr. Endemann says, that we can all plead considerable ignorance of the subject; still, something has been learned in the 60 years since Boussingault attempted to separate the maltha of Pechelbrunn into its constitutional principles. We think that Dr. Endemann has overlooked some of the facts, of which it may be said we are pretty sure. Of these facts let us mention a few as pertinent to this discussion; that bitumeus, from natural gas to asphaltum, include compounds and mixtures of compounds belonging to all of the known series of hydrocarbons; that of the more dense petroleum, malthas, and asphaltums these compounds have been very little investigated; and that no one has pretended to determine the series present in any asphaltum. Consequently, to talk about *petroleum* and *asphaltene* as entities, as chemical compounds, is no more rational than to speak of kerosene and naphtha as constituents of petroleum.

Dr. Endemann deals with refined asphalts as if they were quite independent of the crude materials from which they were derived. As a chemist we think he has made a great mistake at the outset. He says that asphalt is asphaltene dissolved in petroleum. He might, with equal propriety, say that petroleum is petroleum tar dissolved in kerosene. Neither the word *petroleum* nor *asphaltene* has any meaning as a name for a chemical compound.

While at Trinidad we were impressed with the large amount of strong mineral water that saturated the crude pitch, and the important rôle that it must play in the technology of that substance. The water itself is of no consequence, it is the salts that the water holds in solution. If the water is all evaporated the salts may act only with greater energy. We therefore determined to study the pitch with reference to this question. The pitch, when taken out of the lake is completely saturated with this water, some of it is dripping wet. When it is refined the water dries out, and the salts, particularly the sulphates, react with the bitumen. Every refiner knows that vast quantities of hydrogen sulphide escapes. Does Dr. Endemann think that this gas exists entangled in the pitch ready formed, and is simply driven off by heat? If so, he is greatly mistaken.

We have carefully examined pitch procured from both within and without the lake. Their action was identically the same. About 100 grms. were placed in an iron casserole and heated very carefully, with a thermometer as a stirrer. They softened at about 140° F., and continued to grow softer, until at 200° F. they were quite plastic, and began to give off little puffs of vapour. On testing these puffs with lead paper the reaction was strong for hydrogen sulphide. As the heat increased the reaction became more energetic, until at 300° F. the melted pitch boiled from escape of gas, a large part of which was hydrogen sulphide. The temperature was maintained at about 400° F. for about three hours, until the fused pitch became quiet and gave off very little gas. The gases given off from start to finish consisted largely of hydrogen sulphide.

In order to further test this matter, 100 grms. of crude commercial lake pitch, from near the tramway, was coarsely pulverised, suspended in distilled water in a flask, placed on a steam bath, and heated at from 140° to 150° F. At that temperature the pitch was not adhesive, and remained suspended in the water. It was digested in successive portions of water for about a week, until the water no longer gave a reaction for sulphuric acid, the whole amount of water being about 5 litres. The first portion of water used contained a notable quantity of ferrous sulphate, which, on standing, became ferric sulphate, with deposition of ferric oxide. The 5 litres were concentrated to one, and portions of 100 c.c. each were evaporated in duplicate on a water-bath for total solids. The amount obtained equalled an average of 1.355 per cent. of the pitch. In two other portions the sulphur existing as soluble sulphates was determined. It amounted to 0.1483 per cent. of the pitch. The residue from which the aqueous solution had been made, when dried, was without cohesion at ordinary temperatures, and when rubbed up in a mortar resembled in appearance a rich garden soil. Duplicate determinations of the sulphur in this extracted pitch gave an average of 3.3425 per cent. of the pitch originally taken. Duplicate

portions were then extracted with petroleum ether, with petroleum ether followed by boiling spirits of turpentine, and with the same followed by chloroform, and the sulphur determined in the several pairs of solutions. The values obtained were as follows:—

	Per Cent.
Sulphur in the aqueous solution.....	0.1483
"    "    petroleum ether solution .....	1.1450
"    "    spirits of turpentine solution.....	0.7818
"    "    chloroform solution.....	0.5313
"    "    residuum solution .....	0.8844
Total sulphur in pitch .....	3.4908

When Miss Linton analysed the 27 specimens for the Persia trial, the chloroform extract accumulated to the amount of about 2 galls. The excess of chloroform was distilled off on a water-bath, the residue evaporated nearly to dryness and allowed to become quite dry by exposure to the air of the laboratory. The dry residue was repeatedly washed in 95 per cent. ethylic alcohol until the alcohol was no longer coloured; when a very light, dry, brown, and incoherent powder remained, which contained 5.871 per cent. of sulphur. When carefully heated in a platinum crucible, it became black, intermixed, gave off, first, hydrogen sulphide, then dense vapours, which took fire and burned with a smoky flame, leaving a mass of coke that soon burned off, leaving a very light ash that retained the form of the intermixed mass. This ash consisted almost wholly of ferric oxide that dissolved in hydrochloric acid with difficulty. The amount was 5.016 per cent. of the powder = 3.5112 per cent. of iron, which, with the 5.871 per cent. of sulphur amounted to 9.3822 per cent. that was neither carbon, hydrogen, nor oxygen. We believe, however, that the sulphur and iron are inorganic combination with the other three elements.

This chloroform-soluble part is the only constituent of Trinidad pitch that has been isolated in such form as to approach the requirements demanded of a chemical compound. Of course if it contains nearly 6 per cent. of sulphur, which Dr. Endemann did not know was there, his determination of the carbon and hydrogen are probably valueless. We have not made any combustions for several reasons, chief among which is the fact, that the material, while all obtained from Trinidad pitch, was not all from the same specimen. We have concluded that the brown powder is a sulpho-salt of iron, in which ferrous sulphide is linked by sulphur to an organic radical. It is properly to be considered a part of the bitumen. Before we know anything about the compound, if it be a compound, it has got to be treated as suggested by Miss Linton in her first paper—a suggestion that Dr. Endemann appears to have overlooked. She says "a review of the results here given suggests the query, have the methods heretofore employed for the technical analysis of asphaltum really been analytical at all. Would not a method and process suggested by the results of the qualitative analyses given in this paper, and based on the successive application of different solvents and yielding results similar to those of fractional distillation, really become analytical, especially if the separate portions dissolved by the different solvents were subjected to such treatment by oxidising agents as would enable us to determine to what groups of hydrocarbons the different substances dissolved respectively belong"?\* The colossal magnitude of this problem deters any chemist who knows anything about it from attempting its solution.

There are few substances in nature more complex than crude Trinidad pitch. It consists of crude bitumen, mineral salts, sulphates, chlorides, &c., partially decayed wood, humus, humic acid, &c., sand and clay, ferric disulphide in such a minute state of division that it may almost be said to be molecular, and sulphur; some of it no doubt free, and the remainder in various forms of organic combination. No chemist has yet attempted to show what the varied reactions of these materials upon each other

produces as a resultant in the crude pitch, nor has any attempt been made to show what the chemical effects of refining are. It is obvious that a part of the sulphur escapes as hydrogen sulphide. It is quite certain the amount so removed depends upon the temperature and the length of time the pitch is heated; but what becomes of the sulphur that remains, what new combinations follow; what part, if any, those remarkable humus compounds play in the new arrangement; how much, if any, of the compounds of iron and sulphur are removed, and many other problems, are those that the chemists of the future have got to solve.

We know already that refined Trinidad pitch may consist of a good quality of crude pitch carefully melted, containing, after being refined, about the same percentage of sulphur as the crude; but, as a large proportion of the pitch is removed in the process of refining, so a correspondingly large proportion of the sulphur has disappeared. There is nothing in the treatment by solvents to change the condition of the mineral matter. If, however, the pitch has been oiled in the still, as Mr. Richardson says in one of his reports is the custom of the Barber Co., the problem of comparison of results becomes infinitely complicated; for, as the pitch is made more fluid, more or less sulphur may burn out more or less hydrogen, and a variety of combinations and recombinations follow. Dr. Endemann seems to think that oiling simply adds to the petroleum and makes it capable of dissolving more asphaltene. If that is the case it destroys the validity of the comparison and increases the apparent value of the oiled specimen. It may do more: it may menace the volatility as well as solubility of the so-called asphaltene, and thus augment the apparent value of the specimen. It also makes a specimen apparently require less residuum oil to soften it, when in reality it does not, the oil having been added in two portions.

Again, the pitch may have been blown with air in refining. Blowing bitumen with air at 400° F. burns out the hydrogen. The Blyerite process proves it in the same manner that the Dubb's process proves the burning out of hydrogen by sulphur. A large amount of personal experience, which we are not at liberty to further explain, has proved to us years ago that both air and sulphur will at high temperatures remove hydrogen from asphaltum, making it hard and brittle.

If the pitch is oiled in the kettle, the increased fluidity of the refined pitch makes a barrel of pitch extremely irregular in its composition. Much of the organic matter, not bitumen, and a part of the chloroform soluble will rise to the top, while a part of the mineral matter sinks to the bottom, thus leaving the middle of the barrel much richer in desirable qualities than the average of the barrel. Those who are posted take their samples from the middle of the barrel.

Now Dr. Endemann has proposed to take a sample of one or the other of these refined pitches and heat the bitumen extracted by chloroform for 29 hours in a stream of carbonic acid gas, at a temperature of 200° C.—220° C.—392° F.—428° F., and weigh the residue as asphaltene. He says, "the loss should be called water and light petrolines." Why? It should be called exactly what is. If the chloroform is dry, as it should be, where does the water come from? At that temperature the distillates are not light unless they are cracked products of decomposition, as they might be in this case. If they are not decomposition products they are heavy oils. As long as any volatile matter is driven off, hydrogen sulphide will form a part of it, until nothing but coke is left; why, then, shall we name it until we know what it is?

He says that "asphalt is mainly asphaltene dissolved in petroleum, like turpentine." What kind of asphalt does he mean? Is it one containing  $7\frac{1}{2}$  per cent. of sulphur or one half of one per cent. of sulphur? Is it one with a large per cent. of pyridin bases, that on distillation will not yield a trace of paraffin, or is it one that contains only a trace of nitrogen and yields largely of paraffin? Is it one that forms substitution compounds with great readiness with nitric acid, or is it one that is simply oxidised into water and oxides of carbon, without a trace of nitro-substitution compounds? We satisfied ourselves 30 years ago that nothing but decomposition products can be obtained

\* Journal of the Amer. Chem. Soc. 16, p. 809; Chem. News; Analyst; Chem. Centr. Blatt.

from the distillation of solid asphaltums. Why, then, should we attempt to go back to Boussingault's early research, which he himself admitted was unsatisfactory?

We have lately had two specimens of refined Trinidad pitch submitted to us by members. They were so nearly alike in colour that when powdered and placed in the sun in a window sent to dry, they were both black and coherent in 10 minutes, and if not carefully labelled could not have been distinguished.

The results of analysis were reported as given below:—

	I.	II.
Soluble in petroleum ether .....	Per Cent. 39.340	Per Cent. 38.485
" turpentine, after .....	19.270	21.705
" chloroform " .....	0.713	1.133
Total bitumen .....	59.250	61.323
Organic and volatile .....	8.507	7.460
Mineral matter .....	32.243	31.217
	100.000	100.000
Sulphur .....	3.633	3.372
Silica .....	19.182	20.005
Oxides of iron and alumina .....	21.168	19.377
Total bitumen—		
Soluble in petroleum ether .....	66.409	62.743
" turpentine, after .....	32.417	35.394
" chloroform " .....	1.174	1.863
	100.000	100.000
Proportion of total bitumen soluble in boiling turpentine .....	98.854	98.137

Upon these results we pronounced these two specimens, samples of practically the same thing. Such an examination involves a considerable amount of careful analytical labour, but the results are not without value. If anyone has anything really better to offer, no one would be more glad than ourselves to hear the report.

#### DISCUSSION.

Mr. CLIFFORD RICHARDSON, in reply to a question whether the silica and the oxides of iron and aluminium were given on the total or on the percentage in the ash, said that they were the percentages in the ash. Adding together the 19 and 21 made 32. The silica and oxide of iron made up the total. The silica was the much larger constituent of the ash.

Dr. ENDEMANN said it seemed evident that the author looked upon the sulphur as a necessary constituent, not only of asphalt, but also of asphaltene, or of the substance which remained behind after distillation. Without intending to deny the presence of a certain amount of sulphur in bitumen prepared by the author's method, he (Dr. Endemann) denied the conclusions which the author had drawn from the work he has done. Sulphur was present in most asphalts, but the sulphur was not a constituent of asphaltene. His own investigation of asphalt was with a view of isolating those substances which really gave asphalt its peculiar properties, and the substances which he had isolated did not contain sulphur. He consequently left out all such substances which he knew did not belong to the bituminous material. He separated the sulphur on the same principle that he separated the ashes. If Texan asphalt, alluded to in his second paper (this Journal, 1897, 122), were distilled, sulphur compounds, as well as some sulphuretted hydrogen, were obtained in the distillate. The residue, dissolved in a little chloroform and evaporated, contained in the average about 0.4 per cent. of sulphur. Of this 0.4 per cent. of sulphur, however, he had been able to eliminate during the whole process described in the paper still more, leaving only a little over 0.1 per cent. of sulphur behind. Asphaltic oxide ( $C_{20}H_{20}O_2$ ) contained 16 per cent. of oxygen. One atom of oxygen therein would correspond to 4 per cent. of oxygen; one atom of sulphur in such compound would

correspond to 8 per cent. of sulphur. Assuming the material to contain 0.4 per cent., the formula must be multiplied by  $\frac{8}{0.4} = 20$ , in order to insert one atom of sulphur; that is, they would have a formula for asphaltic oxide like the following:  $C_{520}H_{520}O_{20}S$ , which was quite preposterous. But since more than half this sulphur could be removed by further treatment, it was clear that sulphur was simply a slight impurity, owing to an imperfect method of extraction. There were thus asphalts where sulphur played no part whatever. Admitting that Trinidad asphalts contain a very large amount of sulphur, he had not analysed for it, not wanting sulphur in his product; and he had done his best to exclude it during the purification described in his former papers. The author implied that the asphaltogen or asphaltene contained sulphur of constitution, and that it was this sulphur which linked the metals to the organic portion; that is, he looked upon the solution of the iron as due to the formation of a thio salt. Now, apart from the fact that the chloroform-soluble inorganic material consisted mainly of alumina with only small quantities of iron and lime, and that aluminium sulphide could never exist in a mass often containing 10 per cent. of water, if bitumen of refined Trinidad asphalt were extracted by means of a little chloroform, a considerable amount of sulphur dissolved. But if that solution were diluted with more chloroform, as stated in his previous paper, a precipitate was obtained, which, on being examined, gave far more sulphur than the pitch which remained in solution. Further dilution gave a further precipitate. If that were filtered off and the solution allowed to stand a day or two, the apparently clear liquid deposited a third precipitate, and thus within a few days the 10 or 6 per cent. of sulphur which the author found in his asphalt came down to about 1 per cent. Of course the removal afterwards of the petroleum would still more reduce the sulphur in the residue. Now, according to his theory, the sulphides were soluble in a chloroform solution of asphaltene and more soluble in concentrated solution than in dilute solution. This was nothing so very extraordinary. They could not dissolve resins in water, yet they knew that they could dissolve resins in water containing other substances in solution. Those who had had anything to do with the poorer grades of logwood extract would know that logwood extract diluted with water gave a heavy precipitate, insoluble on washing; but it was in perfectly clear solution before. Refined asphalt contained, like nearly all carboniferous minerals, pyrites, and later, after exposure, perhaps also sulphates; so it might contain arsenical pyrites. That these substances might have influence on the two asphalt constituents during application was possible, and certainly worth the study; but everybody must admit that this was a secondary matter.

Now as to the reaction accompanied by the formation of sulphuretted hydrogen. For many years his hydrogen sulphide apparatus consisted of a flask filled with paraffin, to which a certain amount of sulphur had been added. Heating alone produced sulphuretted hydrogen. But if iron pyrites instead of sulphur were taken and heated with paraffin they would find that, instead of all sulphur passing over, with formation of an unsaturated hydrocarbon, in the case of iron pyrites,  $FeS_2$ , only half the sulphur passed over, while half remained behind with the iron. The petroleums contained paraffins. In Texas asphalt, at least, the petroleum contained about 25 per cent. of paraffins. The other substances or substance seemed to be a diterpene or perhaps a mixture of several diterpenes, as far as he had been able to determine. Boussingault made an analysis of petroleums obtained from the asphalt of Pechelbronn, and he found it had the composition of spirits of turpentine. However, it had a very much higher boiling point, and the vapour density was found to be about 9, which would indicate that he had not a terpene but a diterpene in his hands.

His reasons for believing that there was a diterpene present were: concentrated sulphuric acid acted upon the material very energetically, developing sulphurous acid, and producing, besides a sulpho acid, a solid black condensation compound, looking like asphaltene, but which was not asphaltene; also the boiling point of the sub-

stance, the peculiar fluorescence, and the artificial musk odour on treatment with nitric acid. Artificial musk is trinitrocymene. The products which he obtained could not be chemically pure. The nature of these substances did not permit it. He had stated repeatedly that his formulae were only approximate, and to be used simply as guides in chemical analysis, and in this case they held good. By whichever of his methods the chemical analysis was carried out he generally obtained concordant results.

The author's references to his paper as to how asphalt should be treated, &c., were not always correct. He stated that Boussingault's process was unsatisfactory, and that he had said himself it was unsatisfactory. The reason he (Dr. Endemann) had never dwelt upon it before was this: Boussingault had found that when he made a combustion of his original asphalt, that he could find in it only 2 to 3 per cent. of oxygen. When afterwards he examined his so-called asphaltene he found it contained 15 per cent., and when he developed the relation between the two, then he found out he got a good deal more of asphaltic oxide than would correspond to that small quantity of oxygen which he found in the original asphalt. In this special case he had asphalt which contained very likely asphaltogen as well as asphaltene.

The CHAIRMAN said he understood from the paper that the author seemed at issue with Dr. Endemann, because he understood Prof. Endemann to intimate that asphaltum was a combination of two or three simple definite compounds, while his opinion was that asphaltum was a mixture of an indefinite number of definite compounds.

Dr. ENDEMANN said, as the result of his last investigation, he started with an asphaltogen containing less than 0.2 per cent. of sulphur, and being, therefore, a practically pure hydrocarbon. This substance oxidised to asphaltene, then to asphaltic acid, and finally to asphaltulmic acid. Commencing with a pure hydrocarbon, he obtained all these substances. Of these substances the asphaltogen and asphaltene and asphaltic oxide might be found in one single specimen of asphaltum. The asphaltic oxide, however, was not a substance which possessed bitumen properties, so that the solid hydrocarbon or the solid bitumen consisted of two substances—*asphaltogen* and *asphaltene*; the volatile substances consisted of a series of hydrocarbons belonging to the paraffin series and also one or more hydrocarbons belonging apparently to the diterpene series. This investigation was not concluded, but at any rate there were a number of substances present. Mr. Peckham based his remarks on his first paper which treated simply of the hard asphalts used for paving. Those contained mainly asphaltene. At that time he did not yet know asphaltogen. He did not get asphaltogen until he commenced to work with the malthas. His first paper was on the hard paving asphalt after being refined, while the second paper treated of the malthas, which reached them also refined; that was, so far refined that the water was driven off before they were sent out, and probably the very lightest petrolenes. There were a great variety of asphalts, both hard and soft, but he had invariably been able to get asphaltic oxide from any and all asphalts which he had examined. That is, they contained a hydrocarbon or an oxygen compound which oxidised at a temperature of between 220° and 250° C., and might finally be converted into the substance asphaltic oxide.

Dr. SCHWEITZER asked if every asphalt contained asphaltogen.

Dr. ENDEMANN said that every one which he had seen contained asphaltene; even the petroleum residuum oil used as a dilutant in case of fluxing for cement contained about 25 per cent. of asphaltogen, which might be obtained as asphaltic oxide.

The CHAIRMAN asked what were the characteristic properties of asphaltene generally.

Dr. ENDEMANN, in reply, said that asphaltene was, at ordinary temperature, solid. Its melting point was at about 210° C. When melted it soon became covered with a wrinkled skin, and this skin, when pushed aside, became quite elastic, and another skin formed, all of which skins finally were converted into asphaltic oxide of the formula

$C_{20}H_{26}O_4$ . If mixed with real petroleum, obtained by the distillation of asphalt, it gave a mixture with the properties of asphaltum.

In reply to further questions, Dr. Endemann went on to say that asphaltogen was not very good for varnish purposes; asphaltene was better. A certain quantity of asphaltogen would make an asphaltene more elastic. In the case of varnish gum, the petrolenes were nearly all driven out, and a small quantity of asphaltogen was of great value as taking the place of the petroleum, and producing elasticity, with the additional advantage that it was far more stable than the more volatile petroleum. The asphaltogen had a very high boiling point. Asphaltogen was separated from asphalt as follows:—In the first place, the amount of asphaltogen present was determined by the quantity of asphaltic oxide which can be obtained from it. Guided by this, the asphalt was distilled in a partial vacuum; it being necessary not to overheat the material, because the temperature for the distillation of petrolenes and the destruction of the asphaltene lay very near together. A member present had tried distillation in an absolute vacuum, and perhaps would give his experience.

A MEMBER stated that in his hands distillation in a partial vacuum was not a success; but a vacuum of about 711 mm. gave a very good result. By distilling in a half vacuum, he obtained a peculiar decomposition and a sulphurous odour, and on this account he decided to get a perfect vacuum with a pump working with about 42 ft. water pressure. With this pump he got a splendid result, but distilled about  $\frac{1}{2}$  oz. only. The first trial in a vacuum was not a success; his half-gallon retort collapsed. With a sand-bath it distilled very easily and very quickly. The liquid was perfectly transparent. He used Trinidad asphalt, but did not know to what extent it would be of use to Dr. Endemann.

Dr. ENDEMANN said the Trinidad asphalt did not contain much petroleum. He had used an asphalt containing about 25 per cent. of petroleum, and with this he was able to obtain a sufficient yield of material.

Mr. S. F. PECKHAM wrote, in reply, that Dr. Endemann's paper in the December issue of the Society's Journal was the only paper of his relating to asphalts that he had seen. He did not recollect having said that sulphur was a necessary constituent of asphalt or asphaltene, of which latter substance he had no knowledge. The statements made were the result of careful research, extending over many months on his own part and that of his son. They were intended to refer to Trinidad pitch solely, and not to bitumens in general, asphaltene, asphaltogen, or any other substance. After having an opportunity to study the discussion in print, and the paper on the same subject promised by Mr. Richardson, he might possibly prepare some further notes on the subject.

### PATENTS.

*Superheating Steam, Impts. in Apparatus for.* G. Sinclair, Albion Boiler Works, Leith, N.B. Eng. Pat. 7819, April 14, 1896.

THE "apparatus for superheating steam, comprises two vessels provided with steam inlet and outlet branches, and connected together by rows of tubes, the tubes being arranged in the main flue or equivalent part of a boiler or set of boilers," so that they are heated "by the outgoing gases."—R. A.

*Highly Superheated Steam or Vapours, Improved Method of Apparatus for Producing.* D. Adorján, Budapest, Hungary. Eng. Pat. 6377, March 23, 1896.

THE heating gases are conducted between a system of continuous tubes, through which the steam or vapour is passed in a direction opposite to the direction of the gases. The tubes are tapered or reduced in diameter from the place at which the steam or vapour enters from the generator to the place at which it leaves the tubes, this construction giving a greater area of passage to the heating gases at the place where they enter the system of tubing. The heating gases are deflected by plates disposed between the tubes, to distribute the gases uniformly, and heat-conducting bodies may also be placed within the tubes to transmit the heat to the steam or vapour. A draft regulator, automatically adjusted by means of a "cataract," is employed to regulate the passage of the heating gases in exact proportion to the quantity of steam or vapour passing through the tubes.—R. A.

*Oil-Presses, Filter-Presses, and the like; Impts. in or relating to Cloths for.* A. J. Boulton, 111, Hatton Garden, Middlesex. From H. W. J. Van Otterbeek Bastiaans, Cleve, Germany. Eng. Pat. 7718, April 11, 1896.

To avoid unequal wear, the cloths employed are in the form of folded or flattened tubes, which, after one or more operations in the press, are refolded so that the parts of the opposed sides occupy new relative positions. The cloths may be used as ordinary flat fabrics, or their edges may be thickened by folding them.—R. A.

*Asbestos [Filtering, &c.] Fabric, Impts. in and relating to.* J. Germain, L. Boissne, and H. Boissne, Condé-sur-Noireau, Calvados, France. Eng. Pat. 8078, April 16, 1896.

THE warp or weft threads of the fabric, or both, are each formed of a core of one or more twisted asbestos threads, around which a number of strands or slubs of untwisted or slightly twisted asbestos are wound. After the weaving operation, the untwisted or slightly twisted fibres or strands

adhere to one another, so that no interstitial spaces or openings are left through which liquids or gases can escape unfiltered.—R. A.

*Fluid Extracts and Solutions, Impts. in the Method of and Means for Preparing.* J. Longshaw, Burlington Street, Liverpool. Eng. Pat. 9085, April 30, 1896.

THE material is placed in one or more tanks, in which it is treated with the extracting liquid or solvent. The liquid is withdrawn from the tanks through a steam heater, and again returned, this process being continued until the required degree of strength is obtained. A pump may be employed to effect the circulation of the liquid.—R. A.

*Evaporating Apparatus, Impts. in and relating to, chiefly designed for obtaining Salt from Brine.* W. Shedlock, Clapham, Surrey. Eng. Pat. 7997, April 15, 1896.

APPARATUS is claimed of the kind described in the Specification of Eng. Pat. 7796 of 1896. The brine or other liquid is fed into one or more externally heated tubes or troughs, which extend through the steam space of a steam generator, and the salt or other deposited substance is automatically and continuously conveyed (by screw conveyors) from the said troughs into a chamber or casing connected therewith, from which it is elevated by an additional conveyor, through an inclined casing, and is discharged at a higher level than that of the liquid in the tubes or troughs.—R. A.

*Metallic Surfaces, A Process for Protecting, against Chemical and Atmospheric Action.* B. Politzer, Vienna. Eng. Pat. 10,864, May 19, 1896.

THE metallic surface is coated with a thin layer of a drying oil or mixture of drying oils to which a siccativ has been added, and when thus coated is exposed to a temperature of from 200° to 400° C. for from half an hour to one hour. The adhesion of the drying oil to the surface is increased by the addition of a little resin, before the heat is applied.

—C. A. M.

*Furnaces, Impts. in.* J. Wagner, Paris. Eng. Pat. 16,061, July 20, 1896.

AIR is distributed to the under side of the furnace grate by a series of louvres, movable on a horizontal axis, and jointed at the ends of the rods. By this arrangement the rate of combustion is regulated by acting upon the admission of air. The furnace is provided with side combustion chambers above the grate and fuel bed. The walls are furnished internally with flues for the circulation of air, opening into the furnace through holes in a specially prepared perforated brick. The fireclay blocks also have angles, which cause the hot air to produce whirls, whereby a perfect mixture of the gases is obtained. The furnace is provided with two bridges at a distance apart, the first permitting the entrance of hot air by the side flues to the bed, the two bridges forming really a combustion chamber in the furnace. Mechanical raking is performed; it is based on the imparting of a series of shocks or movements to the grate. The mouth of a blower or ventilator, or the blast pipe of a steam injector, is arranged in the ash pit. To delay the flame and the gaseous current, and to change their direction, thereby allowing for the deposition of ashes, there is arranged a series of flame directors, fixed at a certain distance behind the bridge and distant from one another by a space proportional to the size of the furnace. Air is supplied by side flues in the fire blocks or the lateral masonry. The combustion chambers behind the bridge are closed by movable louvres working on an axis, to allow removal of cinders without interruption.—R. S.

*Earthenware Still-Worm Pipes, Impts. in.* E. Edwards, London. From L. Rohrmann, Krauschwitz, near Muskau, Germany. Eng. Pat. 29,345, Dec. 21, 1896.

IN order to make framing or other supports unnecessary the separate pipes are provided with projecting parts, in which openings or passages are formed for the circulation of the cooling water, the pipes being laid helically, directly one above the other, the interior of the pipes being strengthened,

if necessary, by ribs or stays. A bottom stand or support, the inclination of which is made to correspond with that of the worm pipes, and provided with openings, serves to carry the entire apparatus.—E. S.

*Millstones and Milling-Rollers, Impts. in Artificial.* S. Theiner, Pilsen, Bohemia. Eng. Pat. 3458, Feb. 9, 1897.

The inventor claims the use of carborundum along with material such as quartz, &c., as an ingredient of artificial millstones.—V. C.

*Retorts for the Distillation of Shale and other Bituminous Substances, or for the Calcining of Ironstone, Lime, or other Substances; also applicable to Gas Producers; Impts. in or relating to.* J. Bryson, Pimphers-ton, Midlothian. Eng. Pat. 4249, Feb. 17, 1897.

In retorts of the kind mentioned above, each retort or pair of retorts is provided with one lower hopper leading to a discharge door, the door being operated by one of four methods illustrated: (1) a chain and hydraulic or other ram direct; (2) a chain and hand-lever; (3) a chain, spur gearing, and hand-wheel; and (4) a chain and ram, and a horizontal shaft connecting the two.—R. S.

*Compressed or Liquefied Gas [Carbonic Acid Gas, &c.], Impts. in Capsules for Containing, and Apparatus for Charging them.* T. A. Calderwood, Canonbury, London. Eng. Pat. 5008, Feb. 24, 1897.

One end of the capsule is formed with a cylindrical mouth, which is closed by a plug, and the other end is formed with a hole provided with a check valve through which the capsule can be charged and emptied. In charging the capsule, it is pressed lengthwise between two dies, the lower die being formed with two valve-controlled duets, one to supply the gas to the capsule, and the other to permit the escape of superfluous gas, &c. after the capsule is charged.—R. A.

## II.—FUEL, GAS, AND LIGHT.

*Gases from Coke Furnaces, Treatment of.* Stahl u. Eisen, 1896, 17, 90; Chem. Zeit. 21, 38.

*Separation of Cyanogen.*—The gases, previously freed from ammonia, are passed through scrubbers containing a solution of soda or potash, in which is suspended carbonate or oxide of iron. A ferrocyanide is formed, which may be purified by crystallisation. The amount of cyanogen formed depends on the temperature of the furnace. Thus, at 800°—900°, 1 cb. m. of gas gave 8 grms. of sodium ferrocyanide, whilst at 950°, and above this, 56—95 grms. were obtained.

*The Use of the above Gas for Lighting Purposes.*—The gas itself has only half the illuminating power of ordinary coal-gas, but it can be easily enriched with benzol. The lighting power of the gas may, by this means, be raised to that of 16 candles.

*The Application of Benzol for Enriching Coal-Gas.*—The benzol may be used for enriching inferior coal-gas. Judiciously admixed, it does not condense in the gas pipes, even in very cold weather. At present, about 5 per cent. of the coal-gas produced in Germany is thus enriched.—W. P. S.

*Coal-Gas, The Use of "Manjak" [Barbados Bituminous Pitch] in the Manufacture of.* J. H. Pye. J. Gas Lighting, 1897, 69, 882.

"MANJAK" is a natural bituminous pitch, and is found in Barbados, very near and sometimes upon the surface of the ground, in seams varying from 1 to 2 feet in thickness, running usually at an angle of about 45°, and in close proximity to rocks. Petroleum oil occurs in abundance in the same localities, and is often seen oozing out of the ground or floating down the streams. "Manjak" is black, has a high lustre and a bright conchoidal fracture, in appearance closely resembling newly broken pitch. It gave on analysis: moisture, 2.00 per cent.; volatile organic matter, 70.85 per cent.; non-volatile organic matter, 26.97 per cent.; and mineral matter, 0.18 per cent. "Manjak" has, under different names, been used in the insulation of

electric wires, in the manufacture of varnishes, a bituminous concrete in asphalt roads and pavements, and as patent fuel, when mixed with peat or other organic matter.

The gas-producing power of "manjak" was compared with that of Wigan Arley coal, which latter, owing to the defective state of the plant, gave only 9,000 cb. ft. of 17 candle-power gas per ton. The "manjak" was carefully hand-picked so as to remove all stuff and dust, and preserve the stokers from the intense heat produced when charging with very fine material, and small charges of 80 lb. each were carbonised for 6 hours, before being completely burned off. The gas-holder was practically emptied before commencing the test, and six tests of the illuminating power of the gas at the outlet of the holder were made during the day, their average being taken. The coke was water-slaked and dried before weighing. The tar and liquor were not measured, but a larger quantity of tar was apparently formed than was the case with coal. The rapidity with which the gas was evolved during the first three hours of the charge, necessitated regulating the exhauster to draw  $\frac{3}{4}$ -in. vacuum, instead of working with a level gauge as usual, and this caused a slight suction of air through the leaky condensers, which somewhat reduced the illuminating power of the gas. One ton of "manjak" yielded 13,324 cb. ft. of 43.85 candle-power gas, and 9 cwt. of friable and porous coke.

The author considers that "manjak" is eminently suitable as an enricher of coal-gas, since, when well mixed in small quantities with the retort charges, it is very easily handled by the retort men.—A. S.

*Monazite Sands, Examination of the Earths contained in.* Schützenberger and Boudouard. Comptes Rend. 1897, 124, 481—486.

By treating monazite sands with sulphuric acid, and precipitating the earths of the cerium group as double sulphates by the addition of potassium sulphate and further purification, the authors have obtained:—

(1.) A cerium metal having an atomic weight of about 138, the solution of which is not precipitated by copper oxide.

(2.) A substance which can be precipitated by copper oxide and by sodium sulphate, with an atomic weight of about 148.

(3.) A substance of atomic weight, 157, the sulphate of which is precipitated by copper oxide, but not by sodium sulphate.—J. S.

*Thorium Nitrate, Crystallised.* O. Fuhse. Zeits. angew. Chem. 1897, 115—117.

THORIUM salts, as is well known, form the principal material for impregnating mantles for incandescent gas lighting. The nitrate is the most suitable salt for this purpose, because it is easily soluble, and is converted into oxide without producing a troublesome amount of smoke. As sent out from the chemical works it is known as "calcined" thorium, and forms white fragments, obtained by drying an aqueous solution of the nitrate. In this condition it contains 48 to 50 per cent. of oxide, the anhydrous nitrate,  $\text{Th}(\text{NO}_3)_4$ , representing 55 per cent. Thorium nitrate decomposes on evaporation, so that it is not concentrated beyond the point where a nitrate of the above oxide content results, and which still dissolves easily in water to a clear solution.

With regard to this behaviour the question arises, Why is not crystallised thorium nitrate produced, which, like every crystalline salt, would offer a certain guarantee of purity and uniformity in percentage of oxide? Earlier authorities considered thorium nitrate as uncrystallisable, or as crystallisable with extreme difficulty. Clève, in 1871, prepared large, well-formed crystals in the form of six-sided plates, containing 12 mols. of water of crystallisation—

These, however, quickly lose 18 per cent. of water, or about 8 mols. of water of crystallisation, when dried over sulphuric acid. But if an aqueous solution of the nitrate be evaporated and allowed to crystallise hot, large, well-formed crystals are easily obtained, essentially different

from those of Clève. The salt contains 6 mols. of water of crystallisation, loses none of this over sulphuric acid, and, when well dried, is only slightly hygroscopic. Its formula is  $\text{ThO}_2 \cdot 2\text{N}_2\text{O}_5 + 6\text{H}_2\text{O}$ , and the crystals belong to the quadratic system.—L. J. de W.

*Free Nitrogen in Purified Coal-Gas, Apparatus for the Determination of the.* G. Arth. Bull. Soc. Chim. 1897, 17, 427.

See under XXIII., page 470.

*Thoria, Behaviour of, with Oxalic Acid and Ammonium Oxalate, and the Estimation of.* C. Glaser. Zeits. anal. Chem. 36, 213.

See under XXIII., page 468.

## PATENTS.

*Illuminating Gas [Acetylene, &c.], Impts. in the Manufacture or Production of.* V. B. Lewes, Greenwich. Eng. Pat. 6922, March 30, 1896.

To obtain illuminating gas containing acetylene, which can be used in ordinary burners without smoking, mixed carbides are manufactured in an electric furnace, using such compounds in their production as will by double decomposition give rise to a high temperature, whereby the carbides are produced with less expenditure of electrical energy than heretofore. Such metals are chosen that the carbides formed can be decomposed by the action of water, liberating a mixture of acetylene and other hydrocarbon gases. For example, 261 parts of manganese peroxide, 56 parts of lime, and 72 parts of carbon are mixed and heated in the electric furnace in the ordinary way. The oxygen liberated from the oxide of manganese burns violently with some of the carbon, the heat of the combustion, together with the heat of the electric arc, producing a fused mass of the carbides of calcium and manganese. On treating this substance with water, the gas evolved, consists of acetylene diluted with methane and hydrogen, which can be burnt with very great illuminating effect and without smoking.—II. B.

*Acetylene Gas for Illuminating Purposes, Impts. in Apparatus for the Production and Storage of.* E. Clansolles, Barcelona, Spain. Eng. Pat. 11,737, May 29, 1896. (Under International Convention, Jan. 24, 1896.)

THE admission of water to a receiver containing carbide of calcium is controlled by the rise and fall of the bell of a gas-holder, which automatically moves a cock on the water-supply pipe. The gas-holder may be a storage reservoir, or may merely receive gas temporarily when the production exceeds the consumption. When the bell has fallen a certain distance, it closes the circuit of an electrical signalling apparatus, and thus the attendant is notified that recharging is necessary.—J. A. B.

*Acetylene, Impts. in or relating to the Generation and Storage of.* R. R. Gibbs, Egremont. Eng. Pat. 12,788, June 10, 1896.

WITHIN a gasometer bell floating in a tank is a perforated diaphragm for the support of carbide of calcium. A thick layer of oil on the water in the tank is provided, with the object of preventing moisture acting on the carbide when the latter is drawn up by the rise of the bell from the tank. A pipe from the base of the tank telescopes within a wider pipe attached to the crown of the bell. The latter pipe is perforated near the gasometer crown, and thus the acetylene generated may be withdrawn from, or other gas for admixture admitted to, the gasometer by either pipe. Fresh supplies of carbide are admitted through a sliding chamber with mercurial seal attached to the crown of the gasometer, or by hand through a siphon filled with oil.—J. A. B.

*Acetylene Gas Generators, Impts. in.* D. Whalley and J. Hacking, Blackburn. Eng. Pat. 15,654, July 15, 1896.

THE generator is preferably a cylindrical metal vessel with a detachable lid secured tightly thereto by a screw or clamp.

Within the upper part of the generator is a perforated metal receptacle for carbide. Water-inlets with separate taps are provided at three different levels, and a gauge shows the height of the water in the generator. The gas passes from near the top of the latter through a cooler to the burners or a gasometer.—J. A. B.

*Acetylene, Impts. in and in Apparatus for the Production of.* G. S. T. Gastine, Marseilles. Eng. Pat. 20,529, Sept. 16, 1896.

THE apparatus comprises a generator or generators and a bell gasometer. Each generator consists of a vertical tank, with discharge cock at its base, in which is supported a perforated basket containing calcium carbide. A bell-shaped cover, having a protruding spout near its rim, passes over the basket. Beneath the dome of the cover is the mouth of a pipe which rises vertically through the generator. When the tank is filled with water, the gas generated collects under the cover and normally passes by this pipe to the gasometer, whence the burners are fed. A vertical groove allows the passage of the spout when the cover is being affixed or removed; by turning the cover when it is in the lowermost position about its vertical axis, the spout is brought beneath an overflow chamber, and at the same time retains the cover in that position. The movement of the gasometer bell is made to operate the spindle of a tap on the pipe which conveys the gas from the generator to the gasometer in such a manner that the tap closes when the bell is charged to about one-fifth of its total capacity. The pressure of the gas then accumulating in the generator depresses the level of the water below the carbide, but gas continues to be slowly evolved through the action of the aqueous vapour, and further depresses the water until the spout becomes unsealed and the gas escapes into the overflow chamber. A pipe from the top of the latter conveys it to the gasometer.

—J. A. B.

*Acetylene Gas, Impts. in Apparatus for Producing and Storing.* G. Trouvé, Paris. Eng. Pat. 23,591, Oct. 23, 1896. (Under International Convention.)

THIS relates to improvements in the apparatus described in Eng. Pat. 23,521, 1895 (this Journal, 1896, 892). In the generator the stopper is dispensed with and the vessel permanently closed by a heavy lead top, and the wire cage is supported by a stand at a convenient height, instead of being suspended. The vessel is now provided with a removable bottom. In place of a condenser, for cooling and drying the gas prior to consumption, it is now stated that a more favourable result is obtained by coupling together two gas-holders which are supplied alternately by one or more generators. One holder delivers while the other is filling. Suitable taps and connections between the generators and holders are described. The whole apparatus is arranged so that the gas is under the pressure of a very small (10 to 30 cm.) head of water.—J. A. B.

*Acetylene Gas, Improved Apparatus for Producing and Utilising.* G. Trouvé, Paris. Eng. Pat. 23,592, Oct. 23, 1896. (Under International Convention.)

THIS, like the preceding, relates to improvements in the apparatus described in Eng. Pat. 23,521, 1895. They comprise a condenser, packed with glass beads or absorbent material, attached to the top of the generator, and a safety siphon tube, by which, when the pressure in the generator rises, the excess gas passes direct to the gas-outlet pipe, or to a point above a burner, instead of escaping into the atmosphere.—J. A. B.

[*Acetylene.*] *Generation of Gas, Impts. in or relating to Apparatus for the.* A. J. Boulton, London. From H. F. Fuller, Chicago. Eng. Pat. 1440, Jan. 19, 1897.

WITHIN an outer tank, containing water, is a bell, supported by counter-weights and guide-rods. In the lower part of the tank is a cylindrical chamber surrounded by the water and fitted internally with diaphragms so arranged that the gas entering at one point pursues a tortuous course before passing out at the opposite point, the object being to cool it and thus condense any water present. The gas passes from

the upper part of the bell by a pipe, which passes downwards and telescopes over a stand pipe which rises from the bottom of the tank. The stand pipe being in communication with the condensing chamber, the gas from the bell can always pass into the condensing chamber whatever the height of the bell. The calcium carbide holder is fixed in the upper part of the bell. Three forms of holder are described, the object of each being to bring a single isolated portion of the charge into contact with the water at a time. In each form, as the bell descends, fresh portions of carbide come into contact with the water as required. The generator is fitted with a safety vent.—H. B.

*Acetylene Gas, Improved Apparatus for the Production and Storage of.* R. F. Carter, Niagara Falls, Canada. Eng. Pat. 2284, Jan. 28, 1897.

THE generator consists of a cylindrical bell, the base of which stands in a water lute. Within the bell is a cylindrical carbide receptacle centrally divided by a perforated diaphragm, preferably of hemispherical form. The carbide is put in the space above the diaphragm, and the lime formed falls through the latter. The carbide receptacle is provided with an agitator worked by a crank outside the generator. The water is sprayed on to the carbide from a pipe fed through a funnel and siphon. The gas passes from the generator to a bell gas-holder, whence the burners are supplied. A lever, attached at one end to the gas-holder bell and at the other to a cord connected to a valve spindle in a water receptacle, controls the supply of water thence to the funnel mentioned above, by the rise and fall of the bell. The water receptacle, of which the capacity is regulated by the position of a movable overflow pipe, is filled from a cistern through a cock actuated by a float within the receptacle. The water flows very slowly through this cock, but escapes rapidly through the exit valve when it is open, and thus the water receptacle serves as an automatic measuring and feeding apparatus, which limits the amount of water admitted each time to the generator.—J. A. B.

*Carbides, Process for the Agglomeration of.* G. de R. de Sales, Lyons. Eng. Pat. 1653, Jan. 21, 1897.

SO-CALLED "cartridges" are formed by filling carbides into cylindrical cases made of cardboard, paper, or metal, which are provided, if desired, with a longitudinal slot or slots. The interstices are filled up with tar, bitumen, or sand, according to the rapidity of action required when generating gas. The ends of the cartridges and the slits are covered, till required for use, by impervious paper or waterproof fabric.—R. S.

*Fire-lighters, Impts. in.* P. R. de F. d'Humy, Liverpool. Eng. Pat. 5795, March 16, 1896.

THE fire-lighters are formed principally of fine shavings, or sawdust, which is first immersed in a caustic soda solution, and, after drying, is plunged into petroleum or other mineral oil. It is afterwards again dried, pressed into a mass, and then reduced to powder. A second powder is formed by grinding the product obtained by mixing and heating together powdered resin, fine shavings or sawdust, and an oxidiser, as saltpetre, sodium nitrate, or other nitrate or chlorate. The first powder is mixed with the second and heated, a little dust of charcoal and lime being added. The material is afterwards moulded under pressure.—R. S.

*Chambers for the Combustion of Gases [Waste and Blast-Furnace Gases, &c.], Impts. in or relating to.* J. Hartmann, Paris. Eng. Pat. 8679, April 21, 1896.

THE apparatus, serving for heating steam-generators or other furnaces, by the combustion of waste gases from blast furnaces or the like, is composed of three, or sometimes of two, chambers so arranged as to obtain at least one reversal of the flame. To avoid loss of heat by radiation, all the walls which are externally in contact with the atmosphere, are entirely hollow or provided with flues in which the air supply for the combustion of the gas circulates. A pressure gauge is fixed at the point where the gas enters the chamber, indicating the pressure of the gas, and to this pressure correspond certain bars and numbers

marked upon the valves of the air- and gas supply pipes, in such a manner that when the valves are opened to the scales, the proper proportions of air and gas flow into the chamber.—H. B.

*Hydrocarbon Mist, Gas for Illuminating and other Purposes, Impts. in and relating to the Treatment of.* C. E. and C. F. Botley, Hastings. Eng. Pat. 9316, May 2, 1896.

TO prevent the formation of naphthalene and other deposits from the gas and to increase its illuminating power, it is passed through a horizontal cylindrical metallic vessel, at one end of which are atomisers producing a mist of any suitable liquid hydrocarbon, from 0.680 to 0.980 sp. gr. The atomisers may be operated by either compressed air, gas, or superheated steam, and each consists of a tubular body provided with inlet branches, one of which communicates with a smaller tube arranged within, to convey the oil, whilst the other communicates with the annular space between the said tube and the outer body, and forms a passage for the compressed air, &c. The combined oil and air, &c., then enter an expansion chamber and finally pass through a nozzle covered with a perforated plate to complete the "atomisation" of the oil. "The gas will thus carry a certain amount of oil in mechanical suspension."—H. B.

*Pure Hydrogen Gas, Impts. in the Production of.* L. V. Prati and P. Marengo, Turin, Italy. Eng. Pat. 16,277, July 22, 1896.

HYDROGEN gas is obtained by acting upon iron filings and water by gradual additions of sulphuric acid of 50° B., equal parts by weight being taken of each. The hydrogen produced is conducted first through water, then through solution of a lead salt, then through a device containing diaphragms of wire gauze, to a gasometer, whence the gas traverses an insulating water valve, an elastic chamber, and a second device similar to the first, when it is taken by branch pipes to the place of utilisation. The arrangements described, permit of the gas being produced under considerable pressure.—E. S.

*Combustible Gas, including Illuminating Gas; Impts. in and in connection with the Manufacture of, and in Apparatus or Plant for the Purpose.* J. C. Mewburn, London. From F. G. Bates, Philadelphia. Eng. Pat. 26,261, Nov. 20, 1896.

THE 15 pages of text, with 26 claims and 23 drawings, describe improvements upon Lorois's Eng. Pat. 16,413 of 1892. For producing combustible gas, heated air and superheated steam, either or both, carburetted with hydrocarbon vapours, are passed through a producer containing incandescent fuel, wherein combustion is maintained under a pressure of over 42 lb. per square inch. For producing illuminating gas the pressure is maintained at over 50 lb. per square inch, whereby the hydrocarbons are partly oxidised and partly fixed as illuminants; and for gas of high illuminating power the proportion of hydrocarbon is increased, and the pressure is maintained at about 100 lb. per square inch. In one modification for making combustible gas, the incandescent fuel in the producer is disposed with. Means are described for utilising the heat of the waste and other gases for heating the boiler feed-water, injecting the same into the boiler, for heating the compressed air and for utilising the heat disengaged by the compression of the air, &c.—H. B.

*Water-Gas, Impts. in the Production of, and in Apparatus therefor.* C. Dellwik, Stockholm. Eng. Pat. 29,863, Dec. 28, 1896.

DURING the air-supply period, such a quantity of air is admitted to the fuel as to produce chiefly carbon dioxide instead of carbon monoxide, the combustion to carbon dioxide producing a greater amount of heat, and thus shortening the necessary air-supply period as compared with combustion to carbon monoxide, the patentee's object being to have as small a proportion as possible of producer gas in the gas finally obtained. In a suitable generator

described and claimed, the air is supplied from an upright pipe into the fuel at various levels, and the fuel is kept at a definite level which a trial has shown to result in the production of the maximum of carbon dioxide. The height of the fuel is automatically kept at the required level by using a coal receptacle, consisting, say, of a cast-iron pipe passing down through the top of the generator. The lower extremity of this pipe is fixed at the required level, and the coal is fed down the pipe, the upper end of which is closed after each charging to prevent the gases from passing up. The generator is fitted with usual steam pipes, &c., for producing the water-gas.—H. B.

*Brown Coal and Lignite Coke, A New or Improved Process for Making.* D. Nagy, Budapest. Eng. Pat. 29,202, Dec. 19, 1896.

LIGNITE or brown coal is placed in closed vessels or piles, mixed with 65 per cent. of calcium chloride, 2 per cent. of magnesium carbonate, and 5 per cent. of boric acid. The mixture is then distilled under atmospheric pressure. The residue is a substance between charcoal and coke, and can be used for all purposes for which charcoal has hitherto been used.—R. S.

*Combustion Products under Pressure, and utilising the same for Operating Heat Engines and for Propelling Ships: Impts. in and connected with Means for Generating.* D. Cook, Queen Victoria Street, London. Eng. Pat. 6073, March 18, 1896.

THE products are produced under pressure in a chamber A, leading to a receiver B, the whole of the chamber and receiver being lined with non-conducting material C, as a

thick lining of fireclay. Outside the plates is a space D, and then comes the outer shell. Air enters the space D at a, and passes to a ring of perforations L, leading to the combustion chamber. Fuel (as powdered coal) and air are forced in measured quantities into the chamber through an opening M, a special device for this purpose being illustrated. The fuel is ignited by an incandescence tube, or grid, or wire, or electric spark, or, as shown, by a tube E, capable of being rendered red hot by a blow-pipe flame, applied internally, and afterwards of being withdrawn. The hot products under pressure escape through an expansion nozzle lined with fireclay, and provided with a valve or valves.—R. S.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*Benzene, Recovery from Coke-Oven Gas.* C. Heinzelting. Chem. Rundschau, 1897, 82 and 102.

IS the author's method of separating benzene from coke-oven gas by cooling the compressed gas by a counter current of that from the expansion cylinder, a temperature of  $-70^{\circ}$  to  $-80^{\circ}$  C. is obtained, the benzene being deposited in the condensing tubes, which are duplicated so that one set is always available while the other is being freed from the solid deposit. In an experimental installation in Upper Silesia, about 10,000 cb. m. of gas were treated daily; they

contained 20 grms. of benzene per cubic metre. For treating 60,000 cb. m. a pressure of about 240 lb. is required, working day and night, to produce 1,200 kilos. of benzene. The working expenses may be reduced by utilising the excess of gas, over and above that required for heating the coke ovens, as a source of motive power in gas engines; and, since the excess from 60 Otto coke ovens is 24,000 cb. m. per diem, there is an ample margin for this purpose, only 3,600 cb. m. being needed daily for the amount of power in question. It is found more advantageous to dispense with an expansion cylinder in working the apparatus, and to allow the gas to expand in a chamber instead, the increased power requisite being obtained from the waste gas, without much expense.

Before the coke-oven gas is compressed, it is advisable to dry it by passing it through a Rohrmann-Lunge sulphuric acid tower, or by means of calcium chloride, to prevent the formation of ice in the tubes, economise power, and enable the residual ammonia to be recovered. Filtration for the removal of traces of coke-dust is also expedient.

For estimating the benzene content of the gas, a modification of Deville's method, by substituting liquid carbon dioxide for methyl chloride in the final cooling, is recommended. A simpler but less accurate method is to absorb the benzene by passing the gas through cumene in a cooling mixture, distilling off the fractions below  $140^{\circ}$ – $145^{\circ}$  C., and submitting the distillate to fractional distillation.—C. S.

*Asphalt and Petroleum, The Crédo Deposit of.* Boulanger. Comptes Rend. Mens. de la Soc. de l'Ind. Minérale, 1896, 14.

THE deposit recently discovered at Crédo, which lies midway between two important asphalt mines—that of Seyssel, in France, and that of Val-de-Travers, in Switzerland,—contains beds of sand impregnated with a viscous petroleum, rich in paraffin, running from the sand as soon as the beds are cut and flowing at and from an altitude of 2,952 ft. Asphalt has also just been discovered.—A. S.

See under XXIII., page 471.

### IV.—COLOURING MATTERS AND DYES.

*Indigo Salt, Action of Light on Kalle's.* E. Kopp. Bull. Soc. Ind. Mulhouse, 1897, 87–89.

IN some of the early dyeing experiments with Kalle's indigo salt, *o*-nitrophenyl-lactylmethylketone—

it was noticed that the goods had a patchy appearance after developing in caustic soda, which was found to be due to the action of light previous to development. The cotton was printed with the following mixture: 100 c.c. of gum-water, 1 gm. of sodium carbonate, 29 (4 + 25) c.c. of water, 7.5 grms. of indigo salt, and 10 c.c. of sodium bisulphite solution ( $40^{\circ}$  B.), and then passed through a caustic soda bath ( $15^{\circ}$  B.) at  $62^{\circ}$  C., washed, soaped, and dried. On exposing samples to sunlight it was noticed that after 2 minutes a distinct effect was produced, whilst in 5 minutes the shade was reduced to one-half. The yellow rays of the spectrum produced no effect, whilst the action gradually increased from the green, through red, to blue. This method has been applied for obtaining photographic prints by employing the solution as above with three times the quantity of gum-water, for coating a suitable medium and drying the plates in the dark. The exposure varies from 1 to 12 hours, the image appearing in yellow and brown shades, and is then developed. It would appear that light effects a partial decomposition of the indigo salt. Indigo salt was formerly sold in the form of its bisulphite compound, but owing to the readiness with which it decomposes, even in diffused light, it is now supplied as the free ketone.

—T. A. L.

*Diphthalylethane, An Analogue of Indigo in the Indene Series.* V. Kaufmann. Ber. 30, 382—387.

In the course of a research on the cause of colour in organic substances, the author has prepared an analogue of indigo, in which the imido groups are replaced by carbonyl groups. The action of potash and hydrogen peroxide on diketohydrindene (indandion)—

(obtained by the action of sodium on a mixture of phthalic acid diethyl ether and acetic ether, and decomposition of the product with dilute sulphuric acid. Wislicenus and Kötze, *Annalen*, 252, 72), gives, according to the conditions of the experiment, four well characterised substances:—

1. A green substance, which is the potassium salt of the analogue of indigo white, and having the following constitution:—

2. A red substance, which is also obtained by the action of sodium or molecular silver on dibromodiketohydrindene in benzene or toluene, which is the analogue of indigo, has the formula—

and is termed diphthalylethylene or indenigo.

3. A brownish-yellow substance, triketohydrindene (indandion), probably—

4. An acid, which is the final product of the oxidation, and apparently identical with—

The first of these, termed diphthalylethane, is in many respects similar to indigo as regards its solubility in aniline and sulphuric acid, its stability, and faculty of sublimation. Since, however, its alkali salts are practically insoluble in water, it is, unlike indigo, unsuitable for employment in the reducing vat, and hitherto it has not been possible to obtain in quantity a soluble sulphonic acid of diphthalylethylene. From a boiling bath, the alkali salts of this latter, dye animal fibres a greenish shade. For the preparation of the potassium salt of diphthalylethane, 5 grms. of diketohydrindene and 2.25 grms. of potash are dissolved in 50 c.c. of 0.5 to 0.75 per cent. hydrogen peroxide, and heated for half an hour on the water-bath. The precipitate is washed with dilute potash and extracted with alcohol, which, on concentration, deposits the potassium salt as a

greenish powder. On boiling with glacial acetic acid, diphthalylethane is obtained as an amorphous yellow powder, which crystallises from alcohol or aniline in microscopic needles, melting at over 200° C. The best yield of indenigo (about 10 per cent.) was obtained by dissolving 5 grms. of diketohydrindene with 2.2 grms. of potash in 50 c.c. of water, and gradually adding 11.25 grms. of 80 per cent. potassium persulphate, neutralised with ammonia. The sulphuric acid formed is gradually neutralised with the calculated amount of potash, and the precipitate is washed with hot dilute potash. The product is extracted with glacial acetic acid, and crystallised from aniline, forming red needles, which sublime with partial decomposition, and form a sparingly soluble sulphonic acid. Indandion is obtained, together with diphthalylethylene, when the oxidation is effected with 3—3.5 per cent. hydrogen peroxide. It is dissolved out with glacial acetic acid, forms brownish-yellow plates melting at 190°—206° C., and is insoluble in dilute acids and alkalis.—T. A. L.

*Nitronaphthalene, α-Naphthylamine, p-Phenylene Diamine, and Phenylene Blue, Preparation of.* L. Paul. Zeits. f. angew. Chem. 1897, 145—152

The author describes a number of experiments for the preparation of the various products mentioned, the following quantities giving the best results:—

*Nitronaphthalene.*—1.5 kilos. of naphthalene are gradually stirred into a mixture of 1.1 kilos. of nitric acid (43° B.) and the same weight of sulphuric acid (66° B.) at a temperature below 45°—50° C. Towards the end of the operation the temperature is allowed to rise for about half an hour to 50° C. The nitronaphthalene is then allowed to solidify, separated from the acid, washed with hot water, and dried at 140° C. The yield was 1.91 kilos., and the product melted at 50°—55° C. Although no appreciable quantity of naphthalene was obtained on steaming, the solidifying point after this treatment rose to 50°—55° C. For further purification, 2.73 kilos. of the crude by-product were dissolved in 0.68 kilos. of solvent naphtha, filtered, and cooled to 30° C. About half the nitronaphthalene crystallises out and is filter-pressed, the press cakes being steamed to remove the last traces of naphtha. The nitronaphthalene, after drying at 130°—140° C., solidifies at 54°—55° C. and weighs 1.17 kilos. If required still purer, 100 grms. of this product are recrystallised from 500—750 c.c. of alcohol, when the solidifying point rises to 55°—75° C.

*α-Naphthylamine.*—A cast-iron vessel which can be closed, provided with an agitator, and containing 800 grms. of ground iron borings, 40 grms. of hydrochloric acid (20° B.), and 400 c.c. of water, is heated in an oil-bath to 70° C., when 656 grms. of nitronaphthalene (91.5 per cent., m.p. 50°—55° C.) are gradually added in portions of 20—25 grms. every 5 minutes, and stirred for 7—8 hours. The melt weighs 1.84 kilos.; half of it is neutralised with 50 grms. of slaked lime in an iron vessel and distilled with steam heated to 150°—265° C.

Fig. 1.

In Fig. 1, B is the superheater, and D represents the still containing the neutralised melt. The flame under D is so adjusted that the temperature of the thermometer is approximately the same as that in C. At the commencement, about 250 c.c. of water pass over; the temperature in D is then raised to 150° C., when *α*-naphthylamine begins to come over. The temperature gradually rises to 260°—265° C., the whole operation lasting 5 hours, and about 4 litres of water passing over, the quantity of *α*-naphthylamine varying from 406—418 grms. The product, after drying, is distilled *in vacuo* at a temperature from 240°—290° C., the largest fraction distilling at 248°—252° C. 3.9 grms. were obtained from 400 grms. of crude base, but no details are given as to the pressure.

***p*-Phenylene Diamine.**—A mixture of 4.67 kilos. of amino-azobenzene hydrochloride (=6.7 kilos. of a 90 per cent. paste), 13 litres of water, and 2 kilos. of spirit, is placed in a wrought-iron vessel provided with a water jacket and an agitator. The temperature is raised to about 60° C., and 3—5 kilos. of zinc dust in quantities of 75 grms. are added every 5 minutes. The melt is finally heated to 90° C., and maintained at this temperature for half an hour. One kilo. of sodium carbonate is then added, and by means of a current of steam, first the alcohol and then the aniline is blown off. The alcoholic distillate measures about 3 litres, has a sp. gr. 40° Tralles, and is used for the next operation. In order to recover the aniline, 25 litres are distilled off, and the aniline is salted out. The residue remaining in the redneig still consists of an aqueous solution of *p*-phenylene diamine (about 40—50 litres), which, after filtering from the zinc hydrate, is evaporated under reduced pressure in a current of carbonic acid to about 6 litres. The *p*-phenylene diamine crystallises out and is hydro-extracted. The yield is 2.0 kilos., equal to about 90 per cent. of the theoretical. The addition of 0.5 to 0.75 kilo. of hydrochloric acid to the mother-liquor gives about 150 grms. of *p*-phenylene diamine hydrochloride more. The base so obtained is sufficiently pure for the preparation of water-soluble indulines, but for further purification it is extracted with benzene. A diagrammatic representation of an apparatus for this purpose is given in the accompanying Fig. 2.

Fig. 2

A is a jacketed, leaden, cylindrical vessel provided with a sieve plate covered with cloth. The vessel is filled about two-thirds with crude base and is then closed with a well-fitting cover by means of a red-lead and glycerin joint. The cock *c* being closed and *b* open, benzene is poured into the apparatus through B. After closing *b* the water in *d* is heated by means of the steam-pipe in order to bring the benzene to gentle ebullition. When the extraction has been carried on for a sufficient time, *c* is opened, and the benzene charged with *p*-phenylene diamine is allowed to flow into C, whence it is distilled through the condenser D into A, and the operation is again repeated. After several extractions, A is charged with fresh base, and in the end C contains pure *p*-phenylene diamine, which is removed through the man-hole *h*.

**Phenylene Blue.**—100 grms. of crude *p*-phenylene diamine and 35 grms. of its hydrochloride are heated to 150° C., and 36 grms. of *α*-nitronaphthalene are slowly added, the temperature during this operation being kept below 170° C. The melt is then heated to 180°—190° C. for three hours, when, after cooling, it is ground, dissolved in 4 litres of water and 200 grms. of hydrochloric acid, and precipitated with 5 kilos. of salt. The dyestuff so obtained weighs 150 grms., and is in no way different from commercial Paraphenylene blue. The mother-liquor contains about 15—18 grms. of a redder dyestuff, which can be separated by the addition of more salt or by caustic soda, but it is also contaminated with *α*-naphthylamine, due to reduction of the *α*-nitronaphthalene.—T. A. L.

#### Yellow Dyestuff derived from Dinitrofluorescein.

F. Reverdin. Bull. Soc. Chim. 1897, 17, 416—419.

By the action of ammonia on dinitrofluorescein at the ordinary temperature, a yellow dyestuff is obtained which dyes wool in an acid bath a yellow shade, similar to that obtained with tartrazine. The following is the method of preparation:—To a paste of 100 grms. of dinitrofluorescein and 100 grms. of water, in a flask kept in ice-cold water, 75 c.c. of 21 per cent. ammonia are added. The mixture dissolves, and, after some hours, is changed into a solid mass. This is triturated with 125 c.c. of brine and filtered, and after well draining, the ammonium salt is converted into the acid by the addition of dilute hydrochloric acid. The acid is filtered, and digested with 10 parts of acetone to remove impurities; it is then converted for use into the easily soluble sodium salt.

On leading a current of hydrochloric acid gas into the boiling alcoholic solution of the acid, a yellow crystalline ether is formed, the sodium salt of which crystallises well.

The composition of the yellow dyestuff is probably represented by the formula—

an oxygen atom of dinitrofluorescein being replaced by the imido group.

Caustic soda in excess does not change the yellowish-red solution of the new dyestuff, but turns the pure yellow solution of dinitrofluorescein to a deep violet. The effects obtained on wool with the new colour are distinguished from those given by dinitrofluorescein by their level shade and by their much greater fastness to light, which is, however, not quite equal to that of tartrazine.

A similar dyestuff is obtained by the action of aniline on dinitrofluorescein at 120° C., removal of excess of aniline by hydrochloric acid, solution in sodium carbonate, and salting out; this colour dyes wool reddish-yellow. The product of the action of ethylamine on dinitrofluorescein colours wool orange; the *p*-toluidine compound produces a brownish-yellow.

Similar dyestuffs have been obtained by the action of ammonia on other nitrofluoresceins, such as the products of the nitration of dichloro- and tetrachloro-fluorescein,

and the substance produced by fusing resorcinol with the naphthalic acid—

—A. C. W.

#### Azonium Bases, Relations of the, to the Safranines.

O. Fischer and E. Hepp. Ber. 30, 391—402.

The ammonium compounds obtained by the action of methyl iodide on phenazine, naphthazine, or naphthophenazine (Ber. 26, 179), are easily converted by the action of potash into other bases. Thus the iodomethylate of naphthophenazine yields *ms*-methyl rosindone. By the action of ammonia instead of potash, these addition products yield rosindulines, as Kehrman (Ber. 29, 2316; this Journal, 1896, 802) and Fischer and Hepp (Ber. 29, 2752; this Journal, 1897, 132) have shown. The iodide of *ms*-methyl naphthophenazonium is obtained by heating naphthophenazine with an excess of methyl iodide to 100—120° C. The product is extracted with benzene, and is sparingly soluble in water. The chloride obtained by treating a warm alcoholic solution of the iodide with silver chloride is easily soluble, but can be salted out. When dissolved in 20 parts of 70 per cent. alcohol and treated with an excess of ammonia, it yields, after standing about two days and separation from some tar formed, dark red needles of *ms*-methyl rosinduline hydrochloride.

The aqueous solution is a fiery orange-red, and does not fluoresce, whilst the alcoholic solution exhibits a fine yellow fluorescence. The base is very similar to rosinduline, and dissolves with a greenish colour in sulphuric acid, which becomes yellowish-red on dilution. When heated with hydrochloric acid and acetic acid to 180° C. under pressure, or else with dilute sulphuric acid at 170° C., the product is converted into the corresponding indone, the imido group being replaced by oxygen. As already mentioned, the action of potash on an alcoholic solution of a salt of naphthophenazonium yields the same substance. It crystallises from dilute alcohol in golden yellow matted needles, and dissolves in concentrated sulphuric acid with a cherry-red colour and slight greenish-yellow dichroism, the solution on dilution becoming yellow. Continuing the discussion on the relations between the azonium bases and the safranines, and in reply to Kehrman and Nietzki (Ber. 29, 2316 and 2771; this Journal, 1896, 802, and 1897, 132), the authors point out that Kehrman adopts the paraquinone formula for the safranine bases, and that whereas the anhydride of *m*-diazobenzoic acid is formed in an acid solution, Nietzki's proposed 5-ring anhydride is decomposed by acids and re-formed by alkalis.

With regard to the fact of the diazotisability of aposafranine, &c., the authors maintain that this does not affect their previous views, and they again refer to their remarks on the conversion of different nitroso bases, such as nitroso-phenol, *p*-nitroso-aniline, and *p*-nitrosodiphenylamine, into diazophenol, diazo-aniline, and diazodiphenylamine. All these quinone imides are converted by the action of nitrous acid into another configuration, and a similar change would appear to take place in the case of aposafranine salts, that is to say, that the normal red and not the abnormal green salts are diazotisable. The concentrated sulphuric acid necessary in order to produce the change, causes the acid to attach itself to a nitrogen of the phenazine ring. The salts are represented by the following formulae:—

By the action of nitrous acid the substance assumes the *o*-quinonoid form—

and diazotisation follows. It appears more probable that a transformation such as this, should take place under the action of concentrated sulphuric acid and nitrous acid, rather than that this change should be brought about by cold water, which is in effect Kehrman's view, the bases according to him being paraquinones and the salts *o*-quinones. Safranil hydrochloride, for instance, according to Kehrman and Nietzki, has the formula—

By washing with cold water it yields safranil, and it more probably has the constitution of a *p*-quinone like the base—

since, on heating with acetic anhydride under pressure, only a mono-acetyl derivative is obtained, which is also the case with safraninone. Further proofs are afforded by the behaviour of methylphenosafranine (from methyl-*p*-phenylene diamine + 2 anilines).

**Safraninone.**—This substance, having the formula—

has been obtained by the action of alcoholic potash on phenosafranine (Annalen, 286, 211; this Journal, 1895, 797), and synthetically by Jaubert (Ber. 28, 274; this Journal, 1895, 564). Neither method is satisfactory, but one giving better results, consists in heating 1 part of phenosafranine hydrochloride, 1 part of crystallised sodium acetate, and 100 parts of water under pressure to 150° C. The product forms bluish-green prisms, which dissolve to a red solution fluorescing brownish-yellow. The solubility of the base in water is noteworthy, as also its relatively high tinctorial value. The substance contains one primary amido group, which can be diazotised, and it also unites with aldehydes with liberation of water. When heated with dilute alkalis under pressure, it is converted, like phenosafranine, into safranil. Methylphenosafranine, obtained by oxidising *p*-methylphenylene diamine, together with two molecules of aniline, yields a hydrochloride crystallising in green prisms. The solutions are somewhat bluer than those of phenosafranine. Mineral acids cause a change to bluish-violet or blue. The solution in concentrated sulphuric acid is bluish-green, whilst the solutions fluoresce similarly to those of phenosafranine. The substance contains one primary amido group and can be diazotised. From reactions described, the authors conclude

that methyl phenosafraanine only contains one nitrogen group capable of acetylation, and they ascribe the following formula to the compound:—

—T. A. L.

*Azo Dye-stuffs, Dynamical Investigations on the Formation of.* H. Goldschmidt and A. Merz. Ber. 30, 671—687.

With a view of studying the course of the reaction in the formation of azo dye-stuffs, the authors have investigated the rate of formation of certain amido-azo and hydroxyazo dye-stuffs under various conditions by combining diazobenzene sulphonic acid with dimethylaniline hydrochloride and with phenol, and have arrived at the following conclusions:—1. On combining the hydrochloride of a tertiary aromatic amine with diazobenzene sulphonic acid, the base, itself liberated by hydrolysis, combines with this latter. 2. An excess of hydrochloric acid diminishes the rate of combination. 3. The rate of combination is unaffected by the concentration of the solutions. 4. In the formation of hydroxyazo derivatives from phenols and diazo compounds, the reacting substances are the free phenol (liberated by hydrolysis) and the syn-diazo compound. 5. An excess of alkali diminishes the rate. 6. The time requisite for the combination increases with the concentration of the solutions.—T. A. L.

*The "Shinia" Leaves of Cyprus.* Imp. Inst. J., May, 155. See under XXIV., page 474.

#### PATENTS.

*New Colouring Matter [Violet-Blue] from Dinitronaphthalene, The Manufacture and Production of.* J. Y. Johnson, London. From "The Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 7766, April 13, 1896.

According to Eng. Pat. 10,596 of 1893 (this Journal, 1894, 630), a dye-stuff termed A, was obtained by reducing dinitronaphthalene with grape-sugar. It had, however, the disadvantage of being very insoluble, and could only be used for dyeing purposes by producing it on the fibre. If, however, the dinitronaphthalene be reduced, in presence of a sulphite or a bisulphite, with grape or milk sugar, sodium sulphide or stannite, or with zinc dust, a dye-stuff is obtained which is completely soluble in water and dyes unmordanted wool deep violet-blue shades. About 10 kilos. of finely powdered 1,4-dinitronaphthalene, 10 kilos. of grape sugar, 20 kilos. of a sodium bisulphite solution (40 per cent. NaHSO<sub>3</sub>), 20 kilos. of caustic soda lye (24 per cent. NaOH), and 800 litres of water, are heated for about 2 hours to 80° C. until no unaltered dinitronaphthalene can be detected. The solution, which is blue, is mixed with 30 kilos. of hydrochloric acid (32 per cent. HCl) and boiled so long as sulphurous acid gas is given off. The dye-stuff is then precipitated with salt or potassium chloride, and after drying has the appearance of a violet-black powder with a metallic lustre, and is readily soluble in hot water.

—T. A. L.

*Dye-stuffs and Tanning Extracts, Impts. in and relating to the Manufacture of.* H. H. Lake, London. From Lepetit, Dollfus, and Gausser, Milan and Susa (Piedmont), Italy. Eng. Pat. 5582, April 23, 1896.

The action of bisulphite or neutral sulphite of soda on certain vegetable colouring or tanning extracts gives new products having valuable properties. Thus, 300 kilos. of old fustic extract (28° B.) and 100 kilos. of sodium bisulphite solution (35° B.) are mixed and heated for 8 hours in an autoclave to 110—115° C. A magma of microscopic crystals of so-called sulphomine is thus obtained, which is sparingly soluble even in hot water. This dye-stuff gives bright yellow shades on alum, chrome, and tin mordants, quite differ from those given by

ordinary fustic extract. Young fustic treated in the same way, but heated to 140—150° C. gives a product dyeing very pure yellow shades. By heating 300 kilos. of quercitron bark extract (28° B.) with 100 kilos. of sodium bisulphite for 8 hours in a closed vessel to 140—145° C., a product is obtained of much greater solubility than the original extract and giving much stronger shades on mordanted cotton. The products obtained from quebracho and hemlock extracts are perfectly soluble in cold water, and give a pink colour to hides similar to that produced by mimosa bark. These tanning extracts keep the leather perfectly soft, and act more quickly than the quebracho extracts generally used.—T. A. L.

*Colouring Matters of the Rosinduline Series, Impts. in the Manufacture of.* C. D. Abel, London. From "The Actien Gesellschaft für Anilin Fabrikation," Berlin, Germany. Eng. Pat. 8857, April 27, 1896.

PHENYL- or tolyl-rosinduline sulphonic acids are obtained by the action of aniline or *o*- or *p*-toluidine on the rosinduline derivatives described in Eng. Pat. 16,217 of 1895 (this Journal, 1896, 587). By the further sulphonation of these products, trisulphonic acids are formed. The following working quantities are given:—10 kilos. of the rosinduline sulphonic acid of the aforementioned specification, 30 kilos. of aniline, and 5 kilos. of aniline hydrochloride are heated for two hours to 165—170° C. The phenyl rosinduline sulphonic acid separates as a greenish crystalline powder, the excess of aniline being removed in the usual manner. The new acid is almost insoluble in water, whilst its sodium salt is sparingly soluble. It dyes wool bluish-red shades from an acid bath, and when treated in the following manner yields a trisulphonic acid. 10 kilos. of the product are stirred into 30 kilos. of fuming sulphuric acid (32 per cent. SO<sub>3</sub>) at 30—35° C., after which the temperature is raised to 65—70° C. for four hours. The melt, when cold, is poured on to 3—4 times its weight of ice, the trisulphonic acid filtered off, converted into its sodium salt, and the dye-stuff salted out. It dyes very level bluish-red shades on wool, which are distinguished for their fastness to light and alkalis. The following characteristics distinguish it from the phenyl rosinduline sulphonic acids of Eng. Pat. 19,167 of 1890 (this Journal, 1891, 831). The free acid is readily soluble in water and forms well-characterised salts. Its disodium salt crystallises in brown lamellae, is insoluble in alcohol, sparingly soluble in cold but easily in hot water, and can be completely precipitated by salt. The acid barium and calcium salts are nearly insoluble in water.

—T. A. L.

*Basic Disazo Dye-stuffs, Manufacture of.* O. Imray, London. From "The Farbwerke vorm. Meister, Lucius, and Brüning," Hoechst a. M., Germany. Eng. Pat. 9343, May 2, 1896.

THE amido ammonium bases produced according to Eng. Pat. 14,494 of 1895 (this Journal, 1896, 587), when utilised as dye-stuff components, yield basic disazo dye-stuffs, which dye cotton not only when mordanted with tannin, but also unmordanted cotton from an acid bath. The dye-stuffs may be obtained according to three methods: either by diazotising amido dye-stuffs produced by the action of diazotised amido ammonium bases on primary amines and combining them with other components, such as resorcinol, naphthol, *m*-phenylene diamine or *β*-naphthylamine, or by combining monazo dye-stuffs with diazotised amido ammonium bases, or by treating azo dye-stuffs capable of being combined, and containing an amido ammonium base as component, with diazo compounds. The following method gives the quantities employed in one of the processes:—3.77 kilos. of *m*-trimethyl ammonium phenyl-azo-*α*-naphthylamine, obtained by the action of diazotised *m*-amidophenyltrimethyl ammonium, on *α*-naphthylamine, are dissolved in 150 litres of water and diazotised by means of 2.4 kilos. of hydrochloric acid, and 0.69 kilo. of sodium nitrite. The diazo solution is run into a solution containing 11 kilos. of resorcinol and 3 kilos. of sodium acetate. After standing some time it is boiled and salted out, when it forms a blackish-brown powder.—T. A. L.

*Cinnamir Aldehyde, Impts. in the Manufacture or Production of.* C. F. Boehringer and Söhne, Waldhof, Germany. J. V. Johnson, London. Eng. Pat. 10,903, May 11, 1896.

*New Red Colouring Matters of the Triphenylmethane Group, and Method of Producing the Same.* J. J. M. Ville, Paris, France. Eng. Pat. 16,039, July 20, 1896.

THESE dyestuffs, which the patentee terms rhodazines, are obtained by heating under an inverted condenser for about 12 hours, one, two, or three molecular proportions of phenylhydrazine with one molecular proportion of rosolic acid, with or without the presence of alcohol. The melt forms a reddish-brown mass, and for use it is dissolved in concentrated acetic acid. The solution is added directly to the dye-bath, which is afterwards neutralised with sodium aluminate until only slightly acid.—T. A. L.

*Sulphuretted Colouring Matters [Black, Blackish-Brown], Impts. in the Manufacture of.* H. R. Vidal, Paris, France. Eng. Pat. 18,489, Aug. 20, 1896.

CERTAIN meta derivatives of benzene, when heated with sulphur or with sulphur and ammonia, either alone or together with alkaline sulphides, yield dyestuffs which give black or blackish-brown shades on vegetable fibres. The derivatives suitable are dihydroxyl, amidohydroxyl, diamido, triamido, and certain sulphur derivatives, such as sulphamintol (*m*-oxythiodiphenylamine) or thioresorcinol. Thus, 30 kilos. of resorcinol saturated with ammonia and 6.4 kilos. of sulphur are heated in a closed vessel to 260° C. for eight hours, when a brittle blackish mass is produced. According to another method, 25 kilos. of Chrysoidine or Bismarek brown are heated to 240° C. with 30 kilos. of sodium sulphide. When the reduction is finished, 6.4 kilos. of sulphur are added, and the reaction is complete when the mass has become too stiff to agitate.—T. A. L.

*New Colouring Matters [Blue-, Green-, and Brown-Blacks] from Benzidine Sulpho Acids, Manufacture of.* H. Imray, London. From F. Petersen and Co., Schweizerhalle, Bâle, Switzerland. Eng. Pat. 1145, Jan. 15, 1897.

ACCORDING to Eng. Pat. 13,713 of 1896 (this Journal, 1896, 647), certain intermediate products are obtained by combining the benzidine sulphonic acid of Griess with two molecular proportions of  $\gamma$ -amidonaphthol sulphonic acid. In the present specification, one or both of these latter is replaced by one or two molecular proportions of amidonaphthol disulphonic acid II, or by one molecular proportion of acid II and one of a phenol or amine. Polyazoic dyestuffs are thus obtained which show peculiar bluish shades on wool or half-wool and similar fibres. On further diazotising and combining with an amine or a phenol, or one of their derivatives, dyestuffs are produced which give bluish-black to brown-black shades on unmordanted vegetable fibres, fast to light and washing. A quantity of benzidine sulphonic acid corresponding to 10 kilos. of sodium nitrite is mixed in an alkaline solution with 17 kilos. of  $\gamma$ -amidonaphthol sulphonic acid, and immediately afterwards, with 25 kilos. of amidonaphthol disulphonic acid II. The mass is then further diazotised and combined with 23 kilos. of *m*-phenylenediamine. After making the solution alkaline, the dyestuff separates as a black precipitate, which dyes cotton or wool a deep blue-black, fast to light and washing.—T. A. L.

## V.—TEXTILES: COTTON, WOOL, SILK, Etc.

*Mercerised Cotton, Screeping.* H. Werner, Leipziger Färber- u. Zeugdrucker Zeit. 46, [5], 179–181.

To cotton which has been lusted by mercerisation whilst in a stretched condition (see this Journal, 1896, 801 and 898) a silk-like screep may be imparted by the following process.

Work the goods for 15 minutes at 40° C. in a solution of calcium acetate of 5–6 B. Squeeze lightly, and, without rinsing, work for 15 minutes at 50°–60° C. in a bath containing 40–60 per cent. of soap. Again squeeze lightly and pass through a cold bath consisting of 1 part of acetic acid to 10 parts of water, and dry without rinsing.

This process is generally applied after dyeing. Should the shade have undergone a slight change, this may be rectified by adding a suitable basic dyestuff to the acetic acid bath. For light shades it is preferable to pass the goods in the grey or bleached state through the calcium acetate, and to dye them by adding some substantive dyestuffs to the soap-bath, and to shade, if necessary, with basic colouring matters in the acetic acid bath.—I. S.

*Raw Fibres, A New Method for the Quantitative Estimation of.* Lebbin. Arch. Hyg. 1897, 28, 212.

See under XXIII., page 471.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

*Acetic Acid as an Assistant in Dyeing.* A. H. Wainright. (N. Dyers' Journal.) Leipziger Färber Zeit. 46, [4], 119–150.

THE author advocates the substitution of acetic acid for the stronger mineral acids in dyeing, on the ground that the dyes obtained with it are more level, the penetration of the dyestuff, in the case of heavy cloths or felts, much better, whilst yarns are less liable to felting than with the more active mineral acids.—I. S.

*Logwood Substitutes in Woollen Dyeing.* Leipziger Färber- u. Zeugdrucker Zeit. 46, [4], 155–157.

THIS is a review of the various artificial colouring matters which have been put on the market in competition with logwood for blacks on woollen cloth. The dyestuffs which the author considers as most suitable substitutes for logwood, are Diamond Black F, Naphthylamine Black R, and Naphthyl Blue-black N. The following methods of application are given. Diamond Black is dyed with 10 per cent. of Glauber's salt and 4 per cent. of acetic acid. Enter at "hand-heat," raise slowly to boiling, keep the bath at this temperature for half an hour, then add 1 per cent. of sulphuric acid, and boil again for half an hour. Add now 1 per cent. of potassium bichromate and boil half an hour longer.

Naphthylamine Black is dyed with 10 per cent. of Glauber's salt and 5 per cent. of acetic acid. Enter at 65° C., raise to boiling point, and maintain this temperature for half an hour; then add 3 per cent. of copper sulphate and 4 per cent. of acetic acid, and keep boiling until the bath becomes exhausted.

Both these colouring matters possess the advantage over logwood of being much faster to light and acids; whilst Naphthylamine Black R has the additional advantage that its tint is not altered in artificial light.—I. S.

*Pink on Cotton with p-Nitraniline.* M. Goldovsky. Färber Zeit. 8, [6], 89.

THE author aimed at finding a substitute for alizarin pinks that would not involve so many tedious manipulations as the latter, and he recommends the use of *p*-nitraniline for the purpose.

Equal molecules of *p*-nitraniline salt and hydrochloric acid, together with 15 per cent. of common salt (of the weight of material taken), are dissolved in boiling water. The yarn is impregnated with this solution, squeezed, passed through a nitrite bath, then through a solution of  $\beta$ -naphthol, and soaped. The resulting colour is yellowish rather than pink. But a good pink may be obtained if 2 mols. of sodium acetate are substituted for the 1 mol. of acid in the above formula.

Subsequently the author has modified this process by passing the impregnated yarn through a solution of a "lead salt" before entering the nitrite bath. Another method, which the author believes to be the most promising, is first to fix on the fibre a metallic oxide (preferably that of lead), and, after rinsing, to pass the goods through the diazo solution of *p*-nitraniline, and develop in  $\beta$ -naphthol. This process is said to give beautiful light pinks. For fuller and deeper shades the order of treatment is reversed. In either case the goods are subsequently to be soaped.—I. S.

*Discharging Para Nitraniline Red Fabrics White and Coloured, and Manufacture of a Discharging Colour therefor; Process for.* O. Imray, London. From "The Farbwerke vorm. Meister, Lucius, and Brüning," Höchst a M., Germany. Eng. Pat. 8860, April 27, 1896.

In discharging paranitraniline red it has been hitherto difficult to obtain pure whites, and the same objection also applies to the use of resists. The patentees have, however, discovered that satisfactory results are produced by employing in the resist, substances in which paranitraniline red is soluble. The products of reduction (*p*-phenylenediamine and amidonaphthol) are then removed by washing. A tin-salt discharge is printed on *p*-nitraniline red, containing 50–150 grms. per litre of a solvent such as glycerin, acetic, chlorhydrin, &c., together with the acetates and citrates of ammonium and a thickening such as wheat starch or gum. After printing and dyeing, the fabric is steamed for 10 minutes, passed through hot water, well washed, and then passed through a very dilute slightly acid solution of bleaching powder. By the addition of dyestuffs which are not affected by the treatment (such as Persian berries, with or without the addition of aniline colours, &c.), coloured discharges can be obtained.—T. A. L.

*Paranitraniline Red Discharge on Indigo, The Production of.* C. Kurz and E. Kunert. *Färber Zeit.* 8, 49–50.

THE only discharge suitable for this purpose is found to be the lead chromate and chlorine discharge, which depends on the fact that lead chromate precipitated on the fibre causes liberation of chlorine on passing through a bath of hydrochloric and oxalic acids, thereby discharging the indigo. Paranitraniline red is totally unaffected by chlorine. The method for producing a red on a dark vat-blue ground is as follows:—Pad the dyed cotton with 1 litre of water, 30 grms. of  $\beta$ -naphthol, 32 c.c. of caustic soda of 70° Tw., 60 grms. of Turkey-red oil, 2 grms. of tartar emetic, and 300 grms. of neutral potassium chromate. Dry in the hot-dye and print with 250 c.c. of starch-tragacanth thickening, 100 grms. of lead acetate, and 250 c.c. of a solution of diazotised paranitraniline containing 13 grms. of paranitraniline, and 30 grms. of sodium acetate in addition to sodium nitrite and hydrochloric acid. After printing, dry, pass through dilute ammonia, wash well, and pass rapidly through the discharging bath, which contains 40 c.c. of hydrochloric acid of 36° Tw., and 10 grms. of oxalic acid per litre; finally, wash thoroughly and dry.

If a white discharge be desired in addition to the red, a thickened lead acetate solution is also printed on the fabric before discharging in the acid bath.—R. B. B.

*Orange and Red Shades by Means of Nitrobenzidines on a  $\beta$ -Naphthol Ground, Production of.* T. Skawinski. *Bull. Soc. Ind. Mulhouse*, 1897, 90–94.

THE author has examined the shades obtained by combining the diazo compounds of 8 of the 10 possible nitrobenzidines with  $\beta$ -naphthol padded on a fabric, and arrives at the results given below. To prepare the diazo bath, dissolve

3.5 grms. of a nitraniline or 3.8 grms. of a nitrobenzidine in 50 c.c. of boiling water and 6 c.c. of hydrochloric acid (22° B.), cool, add 100 grms. of ice, diazotise with 25 c.c. of normal nitrite, allow to stand 15 minutes, then add 7.5 grms. of crystallised sodium acetate and make up to 250 c.c. The cotton fabric is prepared with  $\beta$ -naphthol in the usual manner.

*Resists and Coloured Designs on an Aniline Black by Printing on Resists with a Black containing Substantive Colours.* P. W. Pluzanski. *Bull. Soc. Ind. Mulhouse*, 1897, 98–103. Sealed Communication deposited May 10, 1885; opened Oct. 28, 1896.

THE method consists in printing an alkaline resist, either white or coloured, and printing on this with an aniline black containing a direct dyestuff. The black does not develop on the resist, whilst the dyestuff contained in it, does, thus giving its own colour if the resist used be white, and a different shade if it be coloured. A second communication gives details of the quantities employed, of which the following is an example:—On a diamine blue ground the following resist is printed: 218 grms. of tragacanth, 100 grms. of crystallised tartaric acid, 46 grms. of calcined potassium carbonate, 66 grms. of caustic soda lye (45° B.), and 100 c.c. of water; this must react neutral, and is mixed with 170 grms. of tragacanth and 120 grms. of tin salt, after which 60 grms. of sodium carbonate are added, and finally 100 grms. of crystallised sodium acetate, 10 grms. of olein, and 10 grms. of terebenthene. The black consists of 1 kilo. of black thickening, 520 grms. of Brilliant Green, 80 grms. of glycerin, 90 grms. of 97 per cent. aniline, and 90 grms. of hydrochloric acid (19° B.). The goods are then steamed for three minutes in a Mather-Platt steaming chamber well soaped (at 44° C.), dried, and finished. For obtaining discharges on coloured goods dyed with chromium acetate or with basic colours on tannin and tartar emetic, the fabric is printed with a mixture containing sodium chlorate, citrate, and acetate, citric acid, potassium ferrieyanide, and chromium acetate, then steamed, grounded with Aniline Black containing Rhodamine, Methylene Blue, &c., passed through the Mather-Platt steaming chamber, and finished as above.—T. A. L.

*Finishing Operations, The Influence of, on the Colour of Wool-Dyed Goods.* O. Walther. *Färber Zeit.* 8, 50–51.

IN the selection of colouring matters for the dyeing of loose wool, too much attention cannot be paid to the influence of the various finishing operations upon the colour of the cloth. Washing, milling, carbonising, raising, shearing, drying, steaming, and hot-pressing may each have an important influence upon the shade, these influences being partly chemical and partly mechanical. The operations of raising and shearing may considerably affect the depth of colour. It is usual in raising, to commence with already used and comparatively blunt teazles, and

gradually proceed to sharper ones; if this change is not sufficiently gradual there is a tendency to tear out fibres from the fabric; the resulting covering of hairs is then less thick than when the progression has been less rapid, and the colour appears paler. Shearing too close has also the effect of making the shade appear paler, especially when raising has been badly carried out. Too vigorous a steaming may readily change the tone of colour, and too strong a pressure forces the surface hairs down upon the body of the fabric, and in this case also, the colour will appear paler.—R. B. B.

*Leather Dyeing with Artificial Dyestuffs.* Leipziger Färber-u. Zengdrucker Zeit. 46, [4], 162—165.

*Steeping Method.*—The dyeing is most conveniently carried out in a wooden trough, with sloping sides, about 1 m. long, 0.5 m. wide, and 0.25 metre deep. Iron should be avoided in the interior of the trough. The water to be used should be free from lime and iron. When such water is not available, about 10 c.c. of acetic acid should be added to a bath of 5—6 litres.

Two skins about equal in size are laid with their flesh sides together, and are then pressed together on a plate of glass or zinc, by passing over them a blunt brass blade, which at the same time removes any adhering foreign matter. By this means only the grain side of the skin is dyed, leaving the inside white.

From 5—6 litres of water, at about 40° C., are poured into the trough, and the requisite dyestuff is added in solution. In order to obtain level dyeings, however, the dyestuff is distributed over three baths of varying strengths, the first being the weakest, and the last the strongest. The second pair of skins is first passed through the second, and then through the third old baths, and finally through a freshly-prepared third bath. For very delicate shades, two baths, one old and one new, are sufficient.

For basic colours, the leather is first mordanted with potassium bichromate for light, with iron acetate for medium, and with pyrolignite of iron ("Iron liquor") for dark shades. When very small quantities of potassium bichromate are sufficient, this may be added to the dye-bath direct; but when larger quantities are to be used, the bichrome is applied in a separate bath, in which the skins are worked for about 10 minutes. Iron mordants should be used of a strength of 15° B. for the pyrolignite, and 12° B. for the acetate.

After dyeing, the skins are well rinsed, and the surplus water is removed by laying them flat on an inclined plate of glass or zinc, and passing over them a blunt blade of brass or steel. Skins that are to be glazed receive now a coating of raw linseed oil, and are then dried in the air, or in a moderately heated room. Too slow drying may cause unevenness of shade. During the drying, creases are to be avoided.

*Brushing Method.*—To dye leather by this method, the dry skins are laid on a table and the tepid dye solution is applied with a long-haired brush. As it is difficult in this way to get an even colour free from streakiness, in one operation, the dye solution is used very weak and the skins receive several successive coats, allowing each one to dry before the next one is applied. When acid colours are used, some acetic acid, or a correspondingly smaller quantity of sulphuric acid, is added to the dye-bath.

Finally, the skins receive a dressing of milk, or of a mucilage of Flea-wort (Floh-samen), *Plantago Psyllium-L.*, or linseed, in order to impart to the leather, softness and a dull finish, not otherwise obtainable. The first of these dressings is used for light, the second for medium, and the third for dark shades. The two last are prepared by boiling the Flea-wort or linseed with water and straining off the mucilage, which is then diluted to the proper strength. These dressings are applied to the dry skins with a sponge, and after allowing to dry, the skins are rubbed with a hair brush or coarse flannel, which produces the required dull finish.—I. S.

## PATENTS.

*Bleaching, Dyeing, Washing, and similarly Treating of Spun Fibres and Stuffs of every kind; Process of and*

*Apparatus for.* B. Thies, Ochtrup, Germany. Eng. Pat. 8491, April 22, 1896.

A NUMBER of vessels, which serve as receptacles for the materials to be dyed, &c., are mounted near one another and connected with liquor-supply and -collecting vessels, the latter of which receive the liquors after use, for conveyance back to the supply vessels. All the vessels are closed when in use, and by means of arrangements of pumps, exhaust vessels, valves, and two- and four-way cocks, the flow of the liquors through the materials under treatment, is caused to take place alternately in opposite directions. The materials may also be treated with gases, air, and steam, if desired.

Numerous modifications in the construction and arrangement of the apparatus, and in the methods of working it, are described in the original specification, which is illustrated with eight sheets of drawings.—E. B.

*Colouring Photographs, Improved Means for, suitable also for Dyeing and Printing.* J. A. Michel-Dansac and J. Chassagne, Paris. Eng. Pat. 18,131, Aug. 15, 1896.

See under XXI., page 161.

*Bleaching Cotton and other Vegetable Textile Materials, An Improved Method or Process of.* J. Kent, London. Eng. Pat. 22,823, Oct. 14, 1896.

CORROX and other vegetable textile fibres are "bleached" or "half-bleached" by steeping them in a solution prepared by treating a finely ground mixture of lime and soda with water. The fibres may afterwards be treated with bleaching powder and acid in the usual way.—E. B.

## VII.—ACIDS, ALKALIS, AND SALTS.

*Sulphur, The Extraction of, in Sicily.* Eng. and Mining J., April 24, 1897.

IN a recent paper in the *Rassegna Mineraria*, Sr. Aichino says that by far the greater portion of the sulphur raised from the mines of Sicily is extracted from the accompanying limestones by liqumtion in kilns, the necessary heat being produced by the combustion of part of the sulphur in the rock. In other cases the fuel used is coal or wood, or superheated steam, or the liqumtion is effected by a solution of calcium chloride, whose boiling point is slightly higher than the melting point of sulphur. The preponderating method is still that of using large kilns, originally introduced in 1860. The only difference now noticeable is the increased dimensions of the kilns. The kiln consists merely of a circular pit, surrounded by a wall. The bed slopes at an angle of 10° to 15° toward a rectangular aperture in front, 4 ft. high and 9 in. wide. The burning lasts, for kilns holding 250 to 2,500 cb. m., from a month to three months. The consumption of sulphur as fuel amounts to one-third or even more of the sulphur contained in the rock, a proportion notably greater than that theoretically necessary. In practice it is not found expedient to treat rock containing less than 10 per cent. The cost of treatment averages 18 c. per ton. In order to obviate the great loss of sulphur numerous modifications have been proposed. In 1880 Robert Gill patented a regenerative furnace for the purpose, which has been largely adopted. The chambers have a capacity of 10 to 30 cb. m., and a kiln with two chambers can be used for 45 to 90 operations in the year. The steam extractor, which was introduced 25 years ago, has gradually come into more general use. It consists of an iron vessel filled with mineral into which steam is conducted. The cylinder holds 5 to 5½ tons, and the operation lasts 24 hours. In a recent installation with a horizontal cylinder holding 4½ tons it has been found possible to complete 15 to 16 operations in 24 hours.

The relative importance of the three types of apparatus is shown by the statement that of the sulphur produced in Sicily in 1891 about 74.5 per cent. was from the old kilns, 17 per cent. from regenerative furnaces, and 8.5 per cent. by steam extractors. In 1895 the proportions were 56.3 per cent., 31 per cent., and 12.7 per cent. respectively.

*Chlorine by Mond's Process. Preparation of.* G. Lange and E. Marmier. *Zeits. f. angew. Chem.* 1897, 137—138.

ALTHOUGH in this method the loss of nickel is said to be considerable and the chlorine obtained not pure, investigation has been undertaken with the view of a comparison with the Deacon process, with which it has certain points in common. The process consists in passing air and hydrochloric acid gas over pumice soaked in nickel chloride, and heated to a temperature of about 650° C. In the first experiments, the gases were first mixed, whilst subsequently they were passed over the hot pumice in succession. When employing the former method, the best result, *viz.*, 54 per cent. of the theoretical amount of chlorine, was obtained by passing 25 volumes of hydrochloric acid and 75 volumes of air over the pumice heated to 650° C. At this temperature, however, the sublimation of the nickel chloride was very considerable, and resulted in the exit tube soon becoming choked. According to the alternative method the pumice soaked in nickel chloride was heated in a current of air at 400° C., the temperature being gradually raised to 650° C. in order to convert the nickel chloride into nickel oxide. A known quantity of hydrochloric acid gas was then passed through the apparatus, that unabsorbed by the nickel oxide being retained by caustic soda and titrated, so that an approximate idea was obtained of the amount remaining in the apparatus. Air was then passed through the apparatus, the temperature being raised, and the chlorine and hydrochloric acid were estimated in the issuing gas. The following conclusions were arrived at from the experiments:—1. The best temperature for the absorption of hydrochloric acid by nickel oxide is between 450° and 500° C. 2. The freshly prepared catalytic absorbs hydrochloric acid well, but soon loses its absorptive power, so that frequent renewal is necessary. 3. The best temperature for the formation of chlorine by passing air over, appears to be between 600° and 650° C. The ratio of Cl:HCl during the whole process is, on an average, 80:20, but at certain periods the proportion of chlorine rises to 91 per cent. The decomposition proceeds best when the pumice, after treatment with hydrochloric acid gas, is quickly and not gradually raised to the higher temperature. It is to be observed with regard to the purity of the chlorine, that this method was patented with a view to utilising it in the Ammonia-soda process. Even for this, however, the method, it is said, has been abandoned, since volatilisation of the nickel soon chokes the tubes. (See also this Journal, 1893, 146.)—T. A. L.

*Chlorine and Steam, Action of a Mixture of, on Glowing Charcoal.* A. Naumann and F. G. Mudford. *Ber.* 1897, 30, 347—354.

THE authors have investigated the action of a mixture of chlorine and steam on glowing charcoal, and, in contradistinction to the results of Lorenz (*Zeits. anorg. Chem.* 1895, 10, 74—77), have arrived at the following conclusions.

(1.) The action of a mixture of steam and chlorine on glowing charcoal takes place in accordance with the equation—

at the temperatures attained in an ordinary combustion furnace, and not quantitatively, according to the equation—

as maintained by Lorenz.

In proof of this, they point out that the ratio of carbon monoxide to carbon dioxide increases with increased length of the layer of glowing charcoal, which indicates that the carbon dioxide first formed is afterwards reduced in passing over the glowing carbon.

(2.) The increase of carbon monoxide is, in presence of a sufficient quantity of chlorine, limited by the following process, which takes place even at low temperatures and which may be of technical value:—

(3.) The formation of hydrochloric acid as the result of the combined processes takes place with an evolution of heat, so that if the proper conditions are fulfilled, and especially if an excess of steam be avoided, the continued application of heat on the large scale would be unnecessary.

—J. S.

*Chlorate, On the Conversion of Hypochlorite into.* J. Bhaduri. *Zeits. anorg. Chem.* 1897, 13, 385.

THE author has carried out a series of experiments to find the exact conditions under which the above conversion takes place. Sodium hypochlorite was prepared by conducting washed chlorine gas through a caustic soda solution made from metallic sodium. The content of the solutions varied in the different experiments, from 1.5 to 25 per cent. The temperatures at which the absorption took place, lay between 25°—33° C., and the gas current was continued in some experiments for 4 or 5 hours. It was found that the amount of chlorate formed was inappreciable in solutions below 7 per cent. strength, and that in such solutions the reaction proceeded according to the equation—

In solutions of 10 per cent. and upwards, the secondary reaction—that is, the conversion into chlorate—became more marked, and when the percentage strength rose above 20, it was found that time played an important part in the decomposition.

In one series of experiments a solution kept in the dark, showed a decomposition of only 6 per cent. after 24 hours. By conducting chlorine through another portion of the solution for 1 hour, decomposition proceeded up to 1.5 per cent.; free alkali hindered the change. Further experiment showed that a solution of sodium hypochlorite underwent change even in the dark, and that the amount of decomposition increased with the refrangibility of the light rays; the yellow rays were far more active than the red. The decomposition gave rise to chlorate and oxygen, and proceeded more rapidly under diminished pressure.

The author has also studied the change occurring in the dark at 100°, and he finds that with dilution, the decomposition diminishes to a certain point, where it possesses a minimum value. With further decrease in the concentration, the decomposition again increases. The most stable aqueous solution is one containing approximately 0.4 per cent. of salt molecules.—J. T. C.

*Salts, Action of Free Bases on.* A. Colson. *Comptes Rend.* 1897, 124, 502—504.

THE author has proved that the displacement of ammonia in ammonium chloride by the free bases di-isobutylamine and piperidine is a case of heterogeneous dissociation similar to the action of a fixed acid on the salt of a volatile acid, *e.g.*, sulphuric acid on lead chloride.—J. S.

*Ammonium Cyanide, Note on the Formation and on the Manufacture of.* D. Lance. *Comptes Rend.* 124, 819—821.

ACCORDING to Langlois and Kuhlmann, ammonia gas, when passed over carbon, always yields ammonium cyanide; on the other hand, Buch and Bergmann assert that at 1,000° C. and temperatures above this, only hydrocyanic acid is formed, and the residual ammonia is all dissociated into nitrogen and hydrogen. The author has caused dry ammonia gas to pass through a column of wood charcoal, 0.2 m. high by 0.02 m. in diameter, contained in a porcelain tube. The gas was passed at the rate of 4 litres per hour, and the temperature of the charcoal, as determined by the Le Chatelier pyrometer, in a series of experiments, varied from 1,000° C. to 1,100° C. The products of the reaction were collected in a series of washing vessels containing distilled water, and the liquors obtained were titrated—1st, by Buignet's method; 2nd, by Liebig's method. Liebig's process being only applicable in the presence of an alkaline cyanide, the difference or the identity of the results obtained by the two methods at once showed whether a liquid containing free hydrocyanic acid or ammonium cyanide only, had been produced. In every case the tests by Liebig's method were identical with those by Buignet's, showing that under the conditions above described, ammonium cyanide was always formed. The author found that the temperature employed (1,000°—1,100° C.) was that which yielded a maximum amount of cyanogen, and that the nitrogen converted into cyanogen was equal to 25 per cent. of the nitrogen contained in the ammonia used.

When, however, a mixture of ammonia, hydrogen, and nitrogen was passed through the charcoal heated to the same temperature, a much larger yield of cyanogen was obtained. A mixture in the proportion of 1 litre of ammonia gas, 1 litre of nitrogen, and 8 litres of hydrogen raised the percentage of nitrogen converted into cyanogen to 30.6 per cent. of the nitrogen of the ammonia, and by decreasing the proportion of ammonia relatively to the two other gases, and also increasing the proportion of hydrogen relatively to the nitrogen, the yield of cyanogen was still further increased. Thus, a mixture in the proportion of 200 c.c. of ammonia gas, with 5 litres of hydrogen and 500 c.c. of nitrogen, yielded an amount of cyanogen containing nitrogen equal to an average of 85 per cent. of the nitrogen contained in the ammonia used. As this amount of cyanogen was combined with an equivalent of ammonia containing the same percentage of nitrogen, it was evident that at least 70 per cent. of the nitrogen in the recovered ammonium cyanide had been derived from the free nitrogen in the mixture.—H. S. P.

*Salt from Brine, Impts. in and relating to Apparatus for obtaining, and for similar Purposes.* W. Shedlock, Clapham, Surrey. Eng. Pat. 7796, April 13, 1896.

A PAN, with a circular brim and flat bottom, is continuously fed with brine, led into a circular vessel mounted upon a vertical central revolving shaft, which also carries a series of scrapers. One or more perforated pipes, extending from the receiving vessel, distribute the brine as they revolve. Flat chambers or pipes, having the form of incomplete rings, to admit of passage downwards of the salt scraped off their upper surfaces, are provided as heaters, and the heat of the water of condensation (when steam is used as the heating agent) is utilised for raising the temperature of the brine before it enters the pan. The pan is preferably steam-jacketed at the bottom. A trough or channel is arranged below for the reception of the salt, which, by the action of the scrapers, is continuously driven towards an aperture in the bottom of the pan; and the salt is carried by a screw-conveyor in the trough to an inclined casing, from which it is delivered by a suitable elevator, in a drained condition, into moulds or other receptacles. Alternative modifications of the apparatus are described.

—E. S.

*Evaporating Apparatus, Impts. in and relating to, chiefly designed for obtaining Salt from Brine.* W. Shedlock, Clapham, Surrey. Eng. Pat. 7997, April 15, 1896.

See under I., page 428.

#### VIII.—GLASS, POTTERY, ENAMELS.

*Glass coloured by Copper.* P. Zulkowski. Chem. Ind. 20, [6], 134—139.

THREE kinds of glass coloured by means of copper were examined by the author, viz.:—*Copper-ruby*—an alkali-

lead glass containing 64.8 per cent. of silica, 1.63 of cuprous oxide, 2.16 of stannous oxide, 10.71 of lead oxide, 9.11 of potassium oxide, and 5.13 per cent. of sodium oxide; "*Aventurin*"—an alkali-lime glass with 4.9 per cent. of copper, 3.07 of lead oxide, 8.74 of calcium oxide, 1.46 of potassium oxide, and 10.22 per cent. of sodium oxide; and "*Porpora*"—an alkali-lime-lead glass with only 35.8 per cent. of silica, but 39.06 of lead oxide, 7.89 of cuprous oxide, 4.31 of calcium oxide, 2.6 of potassium oxide, and 6.31 per cent. of sodium oxide, this latter glass resembling the ancient *hematimone*.

The *Aventurin* exhibited, under the microscope, innumerable crystals resembling those of metallic copper, the presence of which in the free state was proved by the decoloration, effected by the pulverised glass, of an ammoniacal solution of cupric oxide when heated in a sealed tube, thus confirming Wöhler's view that the peculiar appearance of this glass is due to metallic copper in suspension.

On the other hand, neither the *Copper-ruby* nor *Porpora* glass exerted any reducing action on cupric oxide solution, even after three years' exposure in sealed tubes, and this circumstance, coupled with their appearance, leads the author to conclude that their colour is due to cuprous oxide, in solution in the first-named, and as dark red crystalline ramifications, branching in all directions, in the *Porpora*.

Experiments on the devitrification of slags that have been forced to dissolve or combine loosely with extraneous substances, showed that though the mass remains homogeneous when cooled suddenly, yet, when the internal friction is diminished by reheating, molecular rearrangements impairing the homogeneity of the mass are easily occasioned, and, as this phenomenon is on a parallel with the behaviour of glass coloured by copper, it is assumed as probable that the cuprous oxide forms an unstable compound, which, on reheating, is broken up, the oxide remaining in solution (*Copper-ruby*), or, finally, after prolonged heating, separating out as crystals (*Porpora*) in a manner analogous to devitrification. This view is also held to apply to glazes, glasses and enamels coloured by metallic oxides, Seger (Jahresber. f. Chem. Tech. 1896, 762) having disproved the "dissolved metal" theory in the case of copper-red glazes by showing the necessity for an alternate reducing and oxidising atmosphere in the kiln during their preparation, whereby glaze containing cupric oxide and fritted at 400° to 500° C. in an atmosphere of hydrogen, assumes a red colour, which it loses at a higher temperature (1,000° C.), and only regains when fused again with a glaze free from copper, containing some oxidising agent. This reaction explains the previously unknown rôle of the tin and iron oxide always used in making these glazes, their function being to at first reduce the cupric oxide, and subsequently oxidise the metal. An excess of tin may reduce, not only the copper oxide, but also any sulphates present, as was found by Witt in a glass slag composed almost entirely of cuprous sulphide, and containing, in the centre, a regulus of tin and copper.

With regard to the production of gold colouring, which should be on a par with copper if the foregoing assumptions be correct, the author points out that the non-existence in a free state of a fire-resisting red oxide of the former metal, does not disprove the hypothesis; and, from the dyeing properties of the ammoniacal solution of "gold purple," he considers it not impossible that this metal may form in molten glass an unknown compound, which, in subsequent stages of decomposition, produces gold-red, and also gold *Aventurin* glass.—C. S.

#### PATENTS.

*Coloured Glass Lights for Lenses, Impts. in the Methods of Producing; also applicable for other suitable Purposes.* J. Davis and A. J. Davis, West Bromwich, Stafford. Eng. Pat. 15,804, July 17, 1896.

THE invention relates to the manufacture of lenses and dioptric lights of plain and coloured glass combined, as well as to coloured glass lights for use on ships, light-houses, railways, &c., and may also be applied in the production of table glasses of various kinds. To produce

a plano-convex lens, of ruby colour for instance, a flat piece of ruby glass, cut to the required size, is heated and bent to fit a thin concave heated iron mould. The formed glass is transferred to the concave bed of a massive mould, and a mass of white molten glass is pressed upon it by a flat plate or cover. The mould, with its contents, is then placed in a heated kiln, and the lens thus formed is afterwards ground on the plane surface. In forming a dioptric lens, the piece of coloured glass is bent to the convex surface of a plano-convex-shaped mould, called the "combiner and compressor," and is retained in its place by clips; white molten glass "metal" is then placed in a mould of the form required for the outside face of the lens, and the compressor, with its adhering plate of coloured glass, is applied. The lens is then heated and annealed. The methods of producing other forms of combined coloured and white glass are similar.—E. S.

*Stoneware and the like, Improved Method of Manufacturing.* F. S. Wincer, London. Eng. Pat. 2791, Feb. 2, 1897.

SELECTED fireclays are incorporated with flint, Cornwall stone, or china clay, finely ground and sifted, and "mellowed" in the clay shed. The material is then worked on plaster slabs, before being placed in plaster of Paris moulds, in which it is left for 24 hours. The moulded articles are then dried, finished off, and glazed with a compost of 4 parts of Cornwall stone, 2 parts of whiting, and 1 part of calcium sulphate; and, after again drying, are fired at a slowly increasing temperature. The name of "Siennow" is given to the stoneware thus made.—E. S.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

*Stone [Artificial] capable of resisting Fused Alkalies, Alkali Sulphides, and Hydrochloric Acid.* W. Hempel and W. Seiner-ski. Bayerisches Ind. u. Gewerbe Blatt: Thonwaren Ind. 11, 148.

The natural soap-stone (steatite) occurring in Norway, the Tyrol, and North America is mainly composed of  $\text{SiO}_2$  (44.3 per cent.),  $\text{MgO}$  (20.7),  $\text{CaO}$  (3.4), and  $\text{Al}_2\text{O}_3$  (4.3 per cent.), and when fired, resists the action of fused alkalis and alkali sulphides, the loss in weight not exceeding 0.4 per cent., whereas in the case of ordinary fire-brick it amounts to about 54 per cent.

In an attempt to imitate this stone for lining alkali furnaces, the authors selected a brick-earth containing  $\text{SiO}_2$ , 72.82 per cent.;  $\text{Al}_2\text{O}_3$ , 10.18;  $\text{MgO}$ , 0.31; and  $\text{CaO}$ , 0.63 per cent., differing from the natural stone chiefly in the inverted ratio of silica and alumina. To approximate to the constitution of the latter, they employed the calcined magnesite, formed as a by-product in the hydrochloric acid works at Stassfurt, and containing 83.76 per cent. of  $\text{MgO}$ , and 3.42 per cent. of  $\text{SiO}_2$ ; also a dolomite from Ostrau, with 16.84 per cent. of  $\text{MgO}$ , 27.86 of  $\text{CaO}$ , and 5.13 per cent. of  $\text{SiO}_2$ . Two classes of mixtures (which follow) were made, the one forming a product agreeing in silica-content and the other in magnesite-content with the natural stone; these gave, on examination, the following results:—

*Mixture I.* (44.2 per cent.  $\text{SiO}_2$ ).—Clay, 142 parts; magnesite, 100 parts. Fusing point same as steel. Loss of weight on exposure to fused alkali and alkali sulphides, 0.02 and 0.12 per cent. respectively.

*Mixture II.* (20.7 per cent.  $\text{MgO}$ ).—Clay, 300 parts; magnesite, 100 parts. Fused concurrently with I.; lost 0.18 per cent. under the action of fused alkali sulphide, but decomposed in presence of fused alkali (soda).

*Mixture III.* (44.3 per cent.  $\text{SiO}_2$ ).—Clay, 57.83 per cent.; dolomite, 12.17 per cent. This mixture forms a hard stone corroded by fused alkali to the extent of 0.5, and 0.04 per cent. by sulphides; it also resists concentrated hydrochloric acid, and, being more refractory than the natural stone, forms the best substitute for the latter. Both the component materials are plentiful in nature, and it is therefore advisable to employ the product for furnace

linings, those parts not in contact with the fused alkalis being constructed of fireclay, with an intermediate zone of pure magnesite when high temperatures are in question.

—C. S.

*Cement, New Quick-Setting Resistent.* Monit. Ceramique, 28, [4], 39.

THE Société métallurgique de Champignenilles employs hot blast-furnace slag—containing 32 to 36 per cent. of silica, 39 to 45 per cent. of lime, 15 to 22 per cent. of alumina, 0.5 to 1.5 per cent. of iron oxide, and 0 to 8.5 per cent. of manganese oxide—quenched in cold water, and thoroughly mixed with slaked lime in the following proportions:—

(1.) Strong lime, 25 to 30 parts; slag sand, 75 to 70 parts (dry).

(2.) Hydraulic lime, 35 to 50 parts; slag, 65 to 50 parts; together with sufficient water to form a stiff mortar. On leaving the mixer, the mass is formed into slabs, and exposed to the air until dry enough to break into large pieces, and it is then roasted in furnaces at a temperature ranging from dull to bright red heat, according to the degree of quick setting to be produced. It is finally ground to fine powder.

To prepare less rapid setting cements, the calcined mass is ground with dry, quenched furnace slag (as above) and slaked lime in suitable proportions.—C. S.

## PATENTS.

*Insulating Material for Underground Electric Wires, Cables, or the like; New or Improved Manufacture of.* P. R. de Fauchaux d'Humy, Liverpool. Eng. Pat. 5794, March 16, 1896.

The substance of this invention is the use of cellulose material, such as cotton disintegrated by beating in petroleum or other hydrocarbon. Shale oil and refined petroleum are mixed, and ozokerite and fine sawdust or like vegetable material introduced. A certain quantity of paraffin wax is then added, together with waste cotton or refuse fibre, and grease—in preference, linseed or cotton-seed oil. After the addition of water the whole is boiled, and when the cotton is entirely amalgamated and the water evaporated, fresh waste cotton or cotton wool is added, with a small quantity of ozokerite. The cotton wool is allowed to soak, and when cool, the material is pressed between cylinders and converted into sheets. Or it can be applied direct in a hot state, to the wire to be insulated.—C. A. M.

*Bricks and the like, Impts. in Insulating.* S. Pollak, Klausenburg, Hungary, and N. Zwiliogier, Egeres, Hungary. Eng. Pat. 8281, April 20, 1896.

The inventors claim the method of making insulating bricks by impregnation, immediately on leaving the kiln, with a hot solution of asphalt, tar, paraffin, or pitch, and the use of such bricks for building purposes, electric insulators, and for rendering floors and walls damp-proof.

—V. C.

*Wood [Waterproofing for Carvings], Impts. in the Method of Preparing or Treating, for the Purpose of Waterproofing the same, or for making it more applicable for the Formation of Permanent Pressed Designs.* W. P. Thompson, Liverpool. Eng. Pat. 11,182, May 22, 1896.

The wood is impregnated with a solution of cellulose, and, it is stated that it can be moulded under heavy pressure without disintegration, so that it is applicable for the preparation of "pressed wood carvings."—V. C.

*[Plaster.] Process for the Production of a Material for making Floors, Plastering Ceilings, Walls, Roofs, and the like without Joints or Chinks.* O. Krauer, Einsiedel, near Chemnitz, Saxony. Eng. Pat. 23,654, Dec. 24, 1896.

A solution of magnesium chloride is mixed with paper pulp "residue," filling matter is added, then carbonate of

magnesia, and lastly water. The usual proportion is 60 per cent. of magnesium chloride, 10 per cent. of "paper or asbestos leavings or residue," and 30 per cent. of water.

—V. C.

*Wood, An Improved Process for Increasing the Density of.* C. A. Allison, London. From F. P. Stone, Chicago. Eng. Pat. 2085, Jan. 26, 1897.

"A HARD, compressed, water-proof, wooden block, consisting of an integral structure composed of solidified cotton-seed oil, and the naturally united fibres of the wood transversely flattened and compacted, and having their natural length and direction, the flattened fibres and their intermixed cotton-seed oil being substantially as set forth."—V. C.

*Glazed Bricks, and Manufacture of the same; Impts. in.* W. D. Cliff, Leeds. Eng. Pat. 2402, Jan. 29, 1897.

In addition to the glaze on the face, a glaze about  $\frac{1}{4}$  to  $\frac{1}{2}$  in. wide is formed on the edges or sides of the beds and ends adjoining the coloured and glazed face.

The face of the brick is first dipped in a colouring body, the body being then scraped "off the adjoining edges of the beds and ends." Afterwards the face of the brick is dipped "from about  $\frac{1}{4}$  to  $\frac{1}{2}$  in. below the surface of the glaze bath, so as to leave a coating of glaze of this width on the adjoining sides of the beds and ends."—V. C.

*Cement and Concrete, Impts. in.* W. S. Robinson, Hants, Nova Scotia, and S. M. Brookfield, Halifax, Nova Scotia. Eng. Pat. 4018, Feb. 15, 1897.

To earth, gravel, broken rock, or the like, are added metallic iron or ferrous salt, alum, Epsom salts, and silicate of soda. A hydraulic cement is thus said to be formed, capable of setting under either salt or fresh water.—V. C.

*Bricks, Tiles, Earthenware Pipes, Pottery-Ware, Cement, Lime, Gypsum, and Similar Materials; Impts. in Kilns for Burning.* John West, Didsbury, and W. J. Jenkins, Manchester. Eng. Pat. 7270, April 23, 1897.

THE inventors claim an arrangement (described in the specification with reference to drawings) "of flues and dampers, whereby fires are maintained and regulated along both sides of the kiln," and "conveying the gases from the top of the chambers to the chimney."—V. C.

## X.—METALLURGY.

*Gold Mining in Burma, Notes upon.* A. H. Bromly. Trans. North of England Inst. of Mining and Mech. Engineers, 1897, 46, [2], 122–129.

THE principal gold-mining property is that held by the Choukpazat Gold-mining Company, in the Wuntho district. Upper Burma. The lode is a bedded lenticular body in clay-slate, varying from 8 ft. in thickness downwards, the average being about 3 ft.; it is about 200 ft. deep. The country rock of clay-slate is much impregnated with chlorite, and also, in places, the quartz itself. The quartz is often heavily mineralised, containing iron and copper pyrites, arsenical pyrites, galena, blende, and a tin-white mineral, stated by Saville Shaw to be tellurium or a telluride. This latter is always associated with gold, and consequently enriches the stone. Schistose filling sometimes replaces the quartz.

A ten-stamp, 800-lb., high mill is used, with bins at the back, grizzly, spalling-floor, &c., and the power is furnished by a 40 horse portable Robey engine. The drop is 7 in.; depth of discharge, 8 to 10 in.; number of drops, 90; mesh 30, "or hole 0.021 in. square." The output is about 2.2 tons per stamp per 24 hours, and duty of stamps about 1.5 cwt. per effective horse-power per hour. These conditions of milling gave the best results with a decidedly refractory ore. From the plates, the pulp passes over two 6-ft. corrugated belt Frue-vanners. The concentrates consist mainly of iron pyrites, containing about 0.7 per cent. of copper, a little antimony, and about 2 to 2½ oz. each of gold and silver. Milling returns give an average of 5 per cent. of sulphurets, value as above. Some coated non-

amalgamable gold also escapes the battery. Returns over about 3,000 tons milled, shows the value of the ore to be about 10 dwt. of fine gold, or a little over 11 dwt. of bullion per ton. The tailings vary from 2 to 1½ dwt., and may be averaged at 3 dwt.; they are amenable to cyanidation. The average percentage recovered by amalgamation is 51 per cent.; locked up in concentrates, 20 per cent., and in tailings, 29 per cent. It is probable that concentrating may be dispensed with and direct cyaniding of tailings adopted.

The total working costs are: mining, 7.15 rupees; transport, 0.75; milling, 4.00 rupees per ton. Total, about 12 rupees or 14s. per ton.

The output from this mine is at present only 300 tons per month, but it is hoped that an output of 200 tons per month will shortly be attained.—A. S.

*Gold-Gravel Washing in Eastern Siberia.* E. D. Levat. Eng. and Mining J. 1897, 63, [14], 329.

THE introduction of the sluice for washing gold-bearing gravels is gradually proceeding in Eastern Siberia. In the Trans-Baikal it is little employed, but in the Amour province it is quite common, and in the placers worked by the Zeya Company, it is used to the exclusion of other appliances.

In the placers worked by the Zeya Company, the sluices are 29.82 m. in length, of which 21.3 m. are enclosed in a kind of cage to prevent the stealing of gold, nearly all the metal being obtained from the riffles of the upper part. The bottom of the sluice is furnished with riffles of iron, where the gravel is coarse; when the alluvium is of fine gravel or sand, the bottom is of iron, perforated with holes 15 to 20 mm. in diameter. The average fall is 6". A sluice of this kind, 0.71 m. in width, washes about 600 cb. m. in 10 hours, and the water required is about eight times the bulk of the gravel washed. If much clay be mixed with the gravel, lumps not broken up and dissolved are carried away with the stones and pebbles, and the gold contained in them is lost. The author suggests as improvements: an increase of the length of the sluice, use of a larger quantity of water, and the introduction of mercury in the riffles or boxes near the tail of the sluice. A washer used in the Amour region is also described. It is driven by a water-wheel, which imparts a rotary motion to the washer itself. This washer is used to treat the gravel directly from the placer and also for a second treatment of the tailings. It treats about 160 c.m. in 10 hours. The author suggests that the washer would be improved by the addition of riffles and mercury to the sluice, to catch the fine gold.—A. S.

*Uranium, Preparation and Properties of.* H. Moissan. Bull. Soc. Chim. 1897, 17, 266–271.

URANIUM may be obtained readily from the double chloride of uranium and sodium, either by electrolysis or by reaction with sodium; but it is best prepared by the reduction of the oxide with carbon in the electric furnace. In the pure state its properties resemble those of iron: it may be filed, it combines with carbon, and may be hardened by quenching. It is, however, more oxidisable than iron, finely powdered uranium slowly decomposing water even in the cold. It may be obtained crystalline, and, if pure, it is quite white. A yellowish shade indicates the presence of nitrogen, with which it combines so readily that special precautions must be taken in preparing the metal in order to avoid the action of this element. Uranium, when free from iron, exerts no influence upon the magnetic needle, and as a metal it is more volatile than is iron in the electric furnace.—W. G. M.

*Metals, Precipitation of.* J. B. Senderens. Bull. Soc. Chim. 1897, 17, 271–286.

THIS is a continuation of the author's previous work with nitrate solutions (Bull. Soc. Chim. 15, 208, 691, 991; this Journal, 1893, 761, and 1895, 370), the action of metals upon solutions of sulphates, chlorides, and acetates of silver, copper, and lead being now examined. It has hitherto been stated in general terms that a certain metal is capable of precipitating certain other metals from their solutions; but it is now shown that such generalisations are unsafe, as the possibility of precipitation depends upon the

acid of the dissolved salt. Thus, neither tin nor iron will reduce the acetates of silver or copper; bismuth will act upon the acetate, but not upon the sulphate, of silver; aluminium precipitates silver sulphate completely, but is almost without action upon the acetate; and again, it precipitates cupric chloride very rapidly, whilst it attacks the sulphate very slowly, and the acetate even more slowly. The degree of dilution also causes similar variations in the behaviour of the metals: a metal which precipitates another very rapidly from a solution of a certain strength may react slowly, or even be quite inactive, with another of different strength; lead in cupric chloride, and zinc and aluminium in lead acetate, are cases in point. It has been previously shown that when metals were precipitated from their nitrates a variable amount of nitric acid was decomposed, and, as a result, Richter's law was never found to be verified. With the salts now tried, the acid remains unchanged, but the water is in some cases split up, hydrogen being evolved and a portion of the precipitating metal being oxidised and forming basic salts. Zinc and aluminium afford good examples of this action. Occasionally (*e.g.*, in the case of tin and bismuth) an acid salt is formed and remains in solution, whilst a basic salt or an oxide is precipitated.

It would seem that if this action of the acid on the water were eliminated, Richter's law should hold good; but account must be taken of the tendency, in some cases, to form alloys. Cadmium, placed in solutions of silver or copper, gives precipitates which absorb a considerable proportion of the precipitating metal. Other metals also form alloys, but in very small proportions. Zinc, alone, acting upon lead acetate, gives a precipitate of pure lead. It is found that out of 90 cases examined, Richter's law is only approximately true in about 10 cases, and true in one. In the other 80 cases either the weight of deposit was incorrect, or else no deposition took place at all, or not after the first instant. Richter's law is, therefore, not generally applicable, being affected by more or less complex reactions.

It may be specially noted that the author, confirming and extending his earlier work, shows that whilst annealed iron and steel readily attack silver nitrate solution, cold-worked iron and quenched steel are without action, which tends to indicate the existence of allotropic modifications of iron. This is observed with all specimens, whether roughly cleaned or smooth polished with rouge. Slight action is sometimes observed in the case of worked specimens, if the cut ends of the bar be exposed to the solution, as though the inner portions of the metal were different from the exterior; but if the ends of such bars be coated with vaseline no action will be apparent. The action of the annealed iron upon the solution varies with the temperature and duration of the annealing. With silver sulphate both kinds of iron can react, but the annealed bars act more vigorously. With silver acetate and cupric chloride or sulphate both classes of iron behave alike.—W. G. M.

#### Aluminium Bronze. The Use of. Imp. Inst. J., May, 1895.

UNTIL quite recently aluminium bronze was used chiefly in the manufacture of cheap jewellery, for which purposes its capacity for taking a good polish and of retaining its colour, render it peculiarly suitable. In a paper communicated to the American Institute of Mechanical Engineers (*Engineering*, January 29th, 1897), Dr. Wahl points out that it is a very suitable material for the manufacture of the seamless tubes for water-tube boilers, for which brass and steel are now commonly used. The author has examined a series of alloys of aluminium and copper, and he has obtained evidence of the existence of the following definite chemical compounds:—

$\text{Cu}_2\text{Al}$	$\text{Cu}_3\text{Al}$	$\text{Cu}_{10}\text{Al}$	$\text{Cu}_{16}\text{Al}$
$\text{Cu}_4\text{Al}$	$\text{Cu}_7\text{Al}$	$\text{Cu}_{12}\text{Al}$	$\text{Cu}_{18}\text{Al}$
$\text{Cu}_9\text{Al}$	$\text{Cu}_{11}\text{Al}$	$\text{Cu}_{13}\text{Al}$	$\text{Cu}_{22}\text{Al}$

The evidence which Dr. Wahl adduces as proof of this may be summarised as follows:—

1. A rise of temperature occurs when the molten metals are mixed.
- II. The alloys are crystalline when carefully made.

III. Chemical analysis and microscopical examination show them to be homogeneous.

IV. There is no "sweating out" of either metal when the alloys are worked at a red heat.

Of these alloys he recommends those having the composition  $\text{Cu}_3\text{Al}$  or  $\text{Cu}_{10}\text{Al}$  as most suitable for industrial use.

A comparison of the tensile strengths of aluminium bronze with those of Swedish open-hearth steel and brass, at different temperatures, gave the following results:—

Temperature of Experiment.	Aluminium Bronze.	Brass.	Swedish Open-Hearth Steel.
15° C. ....	96,000	81,000	79,300
980° C. to 1,010° C. ....	6,100	2,770	17,500
1,300° C. to 1,400° C. ....	4,100	250	1,350

From this table it will be seen that the tensile strength of aluminium bronze is very high, and this, taken with the fact that it stands great strains without undergoing molecular rearrangement, ought to gain for it an extensive application in the arts.

*Tungsten-Iron, Alloy of.* T. H. Norton. J. Amer. Chem. Soc. 1897, 19, 110.

THE author describes an alloy which, when analysed according to Ziegler's method (Dingler's Polyt. J. 274, 513) was found to contain 93.4 per cent. of tungsten and 6.18 per cent. of iron. The specimen had a lustrous appearance, a hardness of 7, and, when powdered, a specific gravity of 14.55.—J. L. B.

#### PATENTS.

*Steel or Alloys of Iron, Impts. in the Manufacture of.* R. A. Hadfield, Sheffield. Eng. Pat. 7422, April 7, 1896. (Under International Convention.)

NON-MAGNETIC alloys of iron, nickel, manganese, and carbon, of high electrical and thermal resistance, tough, and of great tensile strength, which can be forged, rolled, or cast, are prepared by adding to pig-iron, cast or wrought iron, steel or iron scrap, or a mixture of these, either direct or by means of previously prepared alloys or mixtures, from 3 to 11 per cent. of manganese, 8 to 25 per cent. of nickel, and carbon up to  $1\frac{1}{2}$  per cent.—J. H. C.

*Gold, Silver, and other Precious Metals, Impts. in Apparatus for the Recovery of.* S. Vivian, Southall. Eng. Pat. 8967, April 28, 1896.

REVOLVING drums or barrels of hexagonal or polygonal section, and furnished upon their inner circumference with radial partitions lined with flat or corrugated plates, preferably of copper, are used as amalgamators instead of the usual drums with curved plates.—J. H. C.

*Zinc, Impts. in the Extraction of, from Ferruginous Liquors, specially applicable to the Treatment of the Spent Liquors of Copper Works.* J. R. Wyld, J. W. Kynaston, and J. Brock, Liverpool. Eng. Pat. 10,494, May 15, 1896.

THE ferruginous spent liquor is taken hot from the copper precipitating tanks into a series of cisterns similar to Weldon chlorine stills, and calcium carbonate is added sufficient to

neutralise the free acid, and then in further proportion equivalent to the zinc present in the liquor. Hydrogen sulphide is passed through the series of eisterns (which are provided with agitators) in such a manner as to make the process continuous. When a batch of the liquor has been saturated with the gas, sufficient spent liquor is added to react with the excess of hydrogen sulphide, and, after subsidence, the precipitate of zinc sulphide and calcium sulphate is drained and washed free from iron salts, and is then heated in a Weldon still with hydrochloric acid, the hydrogen sulphide evolved being utilised in the first-described process. The contents of the still are then filtered from the undissolved calcium sulphate, and heated with milk of lime to obtain zinc hydroxide, which may be treated in any desired way. If iron be present in the zinc chloride solution, bleaching-powder solution may be added to peroxidise the iron, and then calcium carbonate in slight excess. The solution, after filtering off the ferric hydroxide, may then be precipitated as before.—E. S.

*Sulphide of Aluminium, which may or may not be combined with other Sulphides (or Sulphurets). A Process of Manufacture of.* [Obtaining Aluminium.] D. A. Peniakoff, Huy, Belgium. Eng. Pat. 11,555, May 27, 1896.

A SINGLE or double anhydrous aluminium salt, such as a fluoride or chloride, fused with the sulphide of an alkali or alkaline earth, together with a chloride or fluoride as a flux, yields a mixture containing aluminium sulphide, from which, in the same crucible, aluminium may be reduced, "either by the action of an electric current or by means of reducing gases (such as hydrocarbons, for example)."

The following formulae present examples of the preparation of aluminium sulphide:—

When the bath is constituted according to the reactions (1) or (2), if aluminium be reduced from the fused mass, the supply of aluminium sulphide is kept up by additions of aluminium sulphate and carbon; aluminium fluoride and sodium sulphate are first formed, according to the equation  $\text{Al}_2\text{SO}_4 + 6\text{NaF} = \text{Al}_2\text{F}_6 + 3\text{Na}_2\text{SO}_4$ , and the sodium sulphate is reduced to sulphide by the carbon, with subsequent production of aluminium sulphide according to equations (1) and (2). It is stated that "even where the sulphide of aluminium produced in the bath is subjected to electrolysis, the sulphide alone may undergo the electrolytic action, and not the fluoride, as the latter requires for its electrolytic decomposition, a far greater electro-motive force than that which suffices to bring about the decomposition of the sulphide of aluminium. Besides, where electrolysis is resorted to, the sulphur separated from the aluminium serves, for the most part, to reduce the alkaline sulphate to the condition of alkaline sulphide, thus adding its effect to the action of the carbon."—E. S.

*Aluminium and Aluminium Alloys, Impts. in the Manufacture of Rods and Tubes mainly from.* A. G. Brown, Manchester. Eng. Pat. 14,330A, June 29, 1896.

THE molten metal is poured into the chamber of a press and allowed to cool until it has attained a temperature of about  $650^\circ\text{C}$ ., when it is forced through a die of the required form by means of a plunger. This system of treatment is claimed.—J. H. C.

*Blast Furnaces, Impts. in, and in the Mode and Means for Charging the same.* T. Lewis, Shifnal. Eng. Pat. 10,061, May 12, 1896.

THIS invention is intended to lessen the escape of gases or heat while charging, and to prevent the entrance of cold air; also to reduce the chances of explosion, and to prevent injury to the furnace lining, bell, and ring, and irregular charging, by the swaying of the bell.—J. H. C.

*Sheet Iron and Steel, Impts. in the Treatment of, in the Manufacture of Polished Sheets.* J. D. Grey, Bridgend, and T. Gwynne, Briton Ferry. Eng. Pat. 91, Jan. 1, 1897.

THE sheets, after leaving the pickling and washing tanks, are dipped into lime water and passed through a drying stove; they are then cold-rolled and annealed, and finally passed slowly through a furnace heated to dark cherry-redness to produce a thin film of oxide, which prevents rust.—J. H. C.

*Ore-Briquettes, Process of Treating Granular or Pulverulent Iron Ores and Slag or other Residues containing Iron to facilitate the Extraction of the same.* S. Neffgen, Mühlheim-on-the-Rhine. Eng. Pat. 4309, Feb. 17, 1897.

THE materials are moistened with calcium oxide or mixed dry with calcium hydroxide, pressed in moulds, and heated in a moist atmosphere for 4 to 6 days to a temperature of  $90$  to  $100^\circ\text{C}$ .—J. H. C.

## XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

### (A).—ELECTRO-CHEMISTRY.

#### PATENTS.

*Carbon [Electro-Deposition of], Impts. relating to the Use and Treatment of, in Electro-Chemical or Electrolytic Processes, and to Apparatus therefor.* Dr. A. Coehn, Göttingen, Germany. Eng. Pat. 5584, March 12, 1896.

ADVANTAGE is taken of the discovery that carbon dissolves when used as an anode in strong hot solutions of sulphuric and other acids which give off oxygen at the anode during electrolysis, to employ such solutions as baths for the electro-deposition of carbon on suitable cathodes. Under these conditions also, carbon may be employed as a soluble electrode in a battery, peroxide of lead or other suitable substance forming the negative element, and such battery is reversible and capable of being recharged.—G. H. R.

*Secondary Voltaic Batteries, Active Material for [Lead-Antimony Backing], An Impt. in.* G. A. Gridle, Prestwich. Eng. Pat. 10,472, May 15, 1896.

THE claim is for "active material for secondary voltaic batteries in form of strips, sheets, rods, or other pieces of composite metal, each consisting of a layer of lead and a layer or core of alloy of lead and antimony."—J. C. R.

*Galvanic Batteries, Dry Cells for, Impts. in.* T. Clark, Greenwich. Eng. Pat. 11,212, May 22, 1896.

THE inventor claims the employment in galvanic batteries (Leclanché type described) of a mixture of gum tragacanth (3 parts) and (1 part) sawdust or the like.—J. C. R.

*Electrical Batteries [Leclanché], Impts. in.* D. Mathieu, Buckfastleigh. Eng. Pat. 20,035, Sept. 10, 1896.

IN lieu of the ordinary porous pot in the Leclanché cell, the inventor illustrates and claims "a carbon pole composed of a number of carbon pencils clamped between recessed carbon discs [forming a "cage"] and containing manganese and gas carbon in the approximately cylindrical space between such pencils and discs."—J. C. R.

*Primary Electric Battery, An Improved.* O. Rothmund and E. von Burgwall, Vienna, and L. Ofenschüssl, Prag, Austria. Eng. Pat. 27,262, Dec. 1, 1896.

THE electrodes are peroxide of lead, of any form, and amalgamated zinc, aluminium, magnesium, or iron . . . "to carry the element dry to the place of use, and not to carry corrosive liquids or salts, the positive electrode is saturated in a liquid (like concentrated sulphuric acid, potash, soda, or chromic acid), so that the electrolyte is produced by the positive plate (electrode) by the application of pure water." To protect these plates against moisture of the air, they are

wrapped in gutta-percha paper or lead foil. The plates being regenerated electrolytically or in a chemical way, they are freed from moisture in drying chambers by chloride of calcium or other hygroscopic substance before being saturated with the aforementioned concentrated solutions.

—J. C. R.

*Batteries, Secondary: Impts. in.* A. Heil, Fränkisch Crumbach, Germany. Eng. Pat. 29,306, Dec. 21, 1896.

The claim is for "A secondary battery cell in which a reduced and chlorinated peroxide of manganese and carbon electrode is placed in a chlorine-containing electrolyte opposite to a lead electrode that is covered with powdered lead, the arrangement being such that the two electrodes alternately give out and take up electrical energy by their chlorination and reduction, according as they are discharged or charged."—J. C. R.

*Batteries, Galvanic: Impts. in.* W. S. Doe, Brooklyn, U.S.A. Eng. Pat. 995, Jan. 12, 1897.

This zinc-carbon battery is designed mainly for lighting bicycle lamps, being readily rechargeable. "The invention consists principally of a perforated tube [hard-rubber], adapted to extend into the exciting fluid [sulphuric acid], and adapted to receive a depolariser" [fused sodium nitrate "cartridges"], and "of certain parts, and details and combinations of the same," fully described.—J. C. R.

*Electric Accumulators, Impts. in the Manufacture of Positive Lead Electrodes for.* [Improved Planté.] H. O. Tülor, Luxembourg. Eng. Pat. 10,718, May 18, 1896.

The plates are placed as positives in very weak sulphuric acid of 2° B., and charged at first with intervals of rest, and then of discharge, until they are coated with a sufficiently thick and hard layer of mixed sulphate and peroxide of lead, the process occupying from 15 to 20 days. The plates are then arranged as negatives, and the coating reduced to spongy lead, after which they are placed as positives in strong acid and formed in the usual way.—G. H. R.

*Chlorine, Impts. relating to the Electrolysis of Soluble Salts, especially applicable for the Production of.* [Reduction of Oxylchlorides.] A. J. Outhenin-Chalandre, Paris, France. Eng. Pat. 15,834, July 17, 1896.

In order to prevent the formation of oxygen compounds, such as oxylchlorides, at the anode during the electrolysis of salt solutions, hydrogen or hydrochloric acid is added continuously to the bath, so that the hydrogen combines with the oxygen, with the formation of water and the evolution of pure chlorine.—G. H. R.

*Electric Accumulators [Planté Type]. Impts. in or connected with.* J. Julien, Brussels, Belgium. Eng. Pat. 21,956, Oct. 3, 1896.

The object is to produce accumulators of large surface and capacity. The claims are:—

"1. In a Planté accumulator, a positive electrode formed by the horizontal superposition of an indefinite series of finely grooved or corrugated rolled sheets of lead or lead alloys, having any suitable contours, with or without a fine coating of active material [waste from worn-out accumulators may be utilised], applied to assist the formation, and electrically connected together and with the terminal by bands of lead enclosing the block of superposed plates."

"2. In a Planté accumulator, a negative electrode consisting of cylinders or moulded prisms of litharge or other suitable plumbiferous compound perforated through their axis and strung on conducting rods so as to form unalterable electrodes for accumulators of great power."

3. Further, "the assembling of the electrodes in a single body by providing the positive electrode with a series of vertical channels or passages, and inserting in the latter a corresponding number of pencils of negative material connected in a group, with the object of reducing to a minimum the space occupied by the battery and the quantity of electrolyte in which it is immersed."—J. C. R.

## (B.)—ELECTRO-METALLURGY.

### PATENTS.

*Wire, Impts. in the Method of Electrically Coating, and Apparatus therefor.* [Continuous Deposition.] W. S. Rawson, London. Eng. Pat. 6069, March 18, 1896.

The apparatus consists of a roller formed of two end frames resting on insulated bearings, having centres for a number of longitudinal spindles carrying grooved pulleys made of porcelain or other insulating material, and placed side by side. In the upper parts of the frames are bearings for two grooved rollers, the lower one of which is metallic, and suitably connected to the negative terminal of a dynamo. The wire, which forms the cathode, is wound round the pulleys and the grooves of the metallic roller, against which it is pressed by caoutchouc rings on the upper roller, and as the rollers revolve, the wire is fed forward. This apparatus is immersed so that nearly the whole surface of the wire is covered by the electrolyte, and two anodes are employed, one of which is external and stationary, while the other, which is inside the pulleys, revolves, and may be formed with blades, or be a metallic basket containing scraps of the metal to be deposited. The anodes are so arranged that equal quantities of metal are deposited on both sides of the wire.—G. H. R.

*Copper, Impts. in Apparatus for Depositing on Printing Rollers and the like.* H. Wylie and J. Grant, Renton, Dunbarton. Eng. Pat. 8326, April 21, 1896.

A VERTICAL rotating anode of copper is placed centrally in the electrolytic vat, and surrounding it, and suspended from an annular frame, are the rollers which are to receive the deposit. By means of gearing, the rollers are caused to revolve on their own axes, and the annular frame may also rotate around the anode, and preferably in an opposite direction.—G. H. R.

*Metals, Impts. relating to the Coating, Covering, or Amalgamating of, with Metals, by the Aid of Electricity, and to Apparatus therefor.* [Plating Ships' Hulls.] F. H. Snyder, Westcombe Park, Kent. Eng. Pat. 25,360, Nov. 11, 1896.

The method is applicable to the coating of the interior and exterior of iron and steel ships, bridges, and other metallic structures with metals or alloys to protect them from oxidation and corrosion. It consists in connecting the object to be protected to the negative terminal of a dynamo, while applying to its surface, as in painting, a brush about 6 ins. wide and 1½ ins. deep, formed of asbestos or other suitable material, and provided with an insulating handle, through which connection is made to the positive terminal of the dynamo. The contact surface must be small, and the brush contains an anode of copper or the alloy which is to be deposited, and is saturated with an electrolyte of the same composition as would be used in ordinary electro-plating to deposit the metal or alloy. The electro-motive force employed is as high as practicable, and the brush must be kept constantly moving, or the deposit will be burnt and pulverulent. In the deposition of copper, an E.M.F. of 25 to 30 volts is employed, and a current of 10 to 15 amperes. The process can also be used for coating plates, electrodes, or cells for electric batteries with platinum or gold, or other suitable metal or alloy.

—G. H. R.

*Metallic Alloys [Ferromanganese, &c.] and Pure Metals, Process for the Extraction of, by Electric Heat.* [Sulphide of Antimony Flux.] H. Aschermann, Cassel, Germany. Eng. Pat. 859, Jan. 12, 1897.

This process consists in the extraction of metallic alloys and pure metals by electric heat from a mixture of the oxide of a metal and the sulphide of another metal or of a metalloid, or of the oxide of a metalloid and the sulphide of a metal, the object being to accelerate the reduction, and eliminate the carbon and other impurities. The metal is obtained in the form of an alloy, from which the more fusible metal can be separated by distillation if desired. Sulphide of antimony is preferably employed as the flux;

for instance, in the preparation of chromium, 10 parts of chromium oxide are mixed with 23 of sulphide of antimony and placed as cathode in an electric fusion furnace, and treated by a current of 20 to 25 amperes, and the antimony is driven from the resulting alloy by reheating. Similarly, aluminium may be obtained from a mixture of 10 parts of its oxide with 37 of sulphide of antimony; and directions are also given for the preparation of ferrochromium, ferromanganese, and ferrocerium.—G. H. R.

*Metals and Alloys. An Impt. in the Electro-Deposition of. [Phosphor Bronze.]* G. A. Webb and W. A. Thomas, London. Eng. Pat. 1657, Jan. 21, 1897.

According to this process, phosphorus is deposited electrolytically in combination with platinum, antimony, or their alloys, on metals or alloys of metals, or other suitable materials. The anode is formed of the phosphor metal or compound which it is desired to deposit, and the baths are composed of solutions of one or more of the metallic salts required to furnish the electro-deposit. Instructions for the preparation of these baths are given.—G. H. R.

## XII—FATS, OILS, AND SOAP.

*Wool-fat, The Action of Sulphuric Acid on some Alcohols occurring in.* E. v. Coehnenhausen. Dingler's Polyt. J. 1897, 78, [303], 283–285.

The action of concentrated sulphuric acid on cetyl alcohol, ceryl alcohol, and cholesterol was investigated. The cetyl alcohol was prepared from spermaceti, and had a melting point of  $49.3^{\circ}\text{C}$ ; the ceryl alcohol was prepared from Chinese wax, and melted at  $19^{\circ}\text{C}$ , whilst the cholesterol melted at  $143^{\circ}\text{C}$ . The alcohols were dissolved in petroleum spirit, and about five times the quantity of concentrated sulphuric acid added, with constant shaking, the mixture being kept cool by cold water. If the mixture be kept thoroughly cool, the reaction takes place without development of sulphur dioxide. After standing for 24 hours, the mass was poured into a large quantity of cold water, more petroleum spirit added, and the whole well mixed. The petroleum spirit solution of the alkyl sulphates, separated from the dilute acid, was neutralised with alcoholic soda, the petroleum spirit distilled off, and the residue dried in the water-bath and extracted with absolute alcohol to remove the sodium sulphate. The extract, after distilling off the alcohol, yielded by crystallisation from 50 per cent. alcohol, the pure sodium salts of the alkyl sulphuric acids. The calcium and barium salts were prepared by treating a solution of the sodium salt with calcium chloride or barium chloride. They separated in flocks, and were obtained pure by crystallisation from 50 per cent. alcohol.

*Cetyl Sulphuric Acid and its Salts.*—The acid, which is with difficulty soluble in water and dilute sulphuric acid, but more easily in dilute alcohol, was not prepared in the free state. On evaporation of its solution in the water-bath, decomposition occurs, a black wax like residue being left behind. The sodium, calcium, and barium salts form, on crystallisation from dilute alcohol, white needle-shaped crystals without water of crystallisation, which blacken at  $100^{\circ}\text{C}$ . with partial decomposition. The sodium salt is soluble in acetone, the calcium and barium salts insoluble. Analysis of the barium salt showed  $17.42$  per cent. of barium, corresponding to the formula  $\text{C}_{32}\text{H}_{66}\text{S}_2\text{O}_4\text{Ba}$ , which requires  $17.58$  per cent. of barium.

*Ceryl Sulphuric Acid and its Salts.*—The free acid behaves towards solvents, and on heating, like free cetyl sulphuric acid. The sodium salt forms a thick paste with boiling water, which, on cooling, becomes thin. From absolute alcohol, the salt separates in the form of a crystalline powder: from dilute alcohol, in a flocculent mass, consisting of fine needles. The sodium salt is also soluble in acetone. The calcium salt is but slightly soluble in water, but equally soluble in hot and cold absolute alcohol; from 50 per cent. alcohol, it separates in flocks, which consist of fine needle-shaped crystals. The barium salt is insoluble in cold and hot water, and is only slightly soluble in hot and cold absolute alcohol. The calcium and barium

salts are not soluble in acetone; they are converted by ether and petroleum spirit into pasty masses. Analysis of the sodium salt gave an average of  $6.255$  per cent. of  $\text{Na}_2\text{O}$ , corresponding to the formula  $\text{C}_{32}\text{H}_{66}\text{S}_2\text{O}_4\text{Na}$ , which requires  $6.23$  per cent. of  $\text{Na}_2\text{O}$ .

*Separation of the Cetyl and Ceryl Alcohols from the Sulphuric Acid Compounds.*—The alcohols were separated from the sulphuric acid compounds by boiling with dilute hydrochloric acid, and, after recrystallising, showed the correct melting points: cetyl alcohol,  $19.3^{\circ}\text{C}$ , and ceryl alcohol,  $79^{\circ}\text{C}$ . The decomposition takes place in a few minutes, if the acid compound be moistened with acetone before adding the hydrochloric acid.

*Action of Concentrated Sulphuric Acid on Cholesterol.*—Cholesterol does not form an acid compound by the action of sulphuric acid, but is probably converted into cholesterones (Zwenger, Beilstein's Handbuch, III. Aufl.; and Mauthner and Suida, Monatsh. für Chemie, 17, 29). These are easily soluble in alcohol, ether, petroleum spirit, and acetone.

The treatment of the alcohols of wool fat with concentrated sulphuric acid has not yet led to any definite results, except that saturated alcohols were obtained after removal of the cholesterones. The author is of the opinion that the treatment with sulphuric acid may be used as a means of separating the saturated alcohols from the unsaturated ones.—A. S.

*Wool Fat, Purification of.* [Lanolin Manufacture.]

C. Baron. Rev. Chim. Ind. 1897, 8, 111.

800 KILOS. of the crude grease are placed in an autoclave with 100 litres of caustic soda of  $3.25^{\circ}\text{B}$ , and boiled with live steam for three hours at a pressure of 2 atmospheres. 200 kilos. of water and 300 of acetic ether are next introduced, and the agitation is continued for eight hours at a pressure of 4 atmospheres. The whole is then allowed to rest, but until the liquids have separated, the temperature is maintained. The ethereal layer is drawn off, and washed with water, which is at first made slightly alkaline and warmed to  $60^{\circ}$ . It is finally filtered, the acetic ether distilled off, and the residue sold as "lanolin." The aqueous liquid is decomposed with sulphuric acid, the fatty acids washed and made into soap.—F. H. L.

*Olive Oils, Partial Solidification.* A. Goldberg.

Chem. Zeit. 1897, 21, 263.

THE following series of iodine numbers were obtained from the liquid (a) and semi-solid (B) portions of olive oil taken from barrels, which had for some time been stored in cold cellars. A, B, C, D, E were genuine salad oils; F, H, and I were officially denatured with orange oil, clove oil, and rosemary oil respectively. G was also denatured with rosemary oil and gave evidence by Bechli's test that it contained cottonseed oil; also 100 c.c. which had been frozen hard melted at the ordinary temperature in a much shorter time than pure olive oil under the same conditions.

### IODINE NUMBERS.

Aa .....	80.9; 81.0; 81.0.	1b .....	82.8; 82.6.
Ab .....	80.2; 80.2; 80.3.	Fa .....	81.6; 81.5.
Ba .....	82.3; 82.5; 82.3.	Fb .....	81.2; 81.3.
Bb .....	81.6; 81.5; 81.7.	Ga .....	88.1; 87.9.
Ca .....	81.9; 82.0; 82.0.	Gb .....	88.4; 88.2.
Cb .....	81.2; 81.4; 81.2.	Ha .....	81.5.
Da .....	81.0; 83.9.	Hb .....	85.6; 85.3.
Db .....	82.2; 82.4.	Ia .....	83.9; 83.8.
Ea .....	83.4; 83.6.	Ib .....	83.2; 83.0.

All the liquid fractions (a) were kept during the winter at a moderate temperature, and for the most part they set hard. On separating the liquid from the solid portions, the iodine numbers of the two fractions were about the same. The author considers it remarkable that the above iodine numbers of the fractions show such slight differences; and, as will be seen in the cases of G and H, higher values were obtained in the solid portions, although neither were pure products.—J. L. B.

*Olive Oil and Cotton-Seed Oil, On the Behaviour of Mixtures of, in the Cold.* A. Goldberg. Chem. Zeit. 1897, **21**, [31], 304—305.

OLIVE oil, when exposed to low temperatures, becomes turbid at + 2 C., and at - 6 C. deposits 28 per cent. of solid matter. Cotton-seed oil similarly treated becomes turbid at about 12 C., and completely solid at 0 to - 1 C. In order to completely melt the frozen oils, the temperature must rise a little above the respective turbidity points. Mixtures of olive oil and cotton-seed oil, however, after having been exposed to temperatures of from - 15 to - 20 C. require a much shorter time to become fluid again, and do so at a lower temperature than the individual oils. Thus pure olive oil exposed for 2½ hours at - 16 to - 20 C., and then allowed to stand at the ordinary temperature, began to melt after 55 minutes, and was completely liquid after 185 minutes, when the temperature had risen to + 11·5 C. A mixture of 95 per cent. of olive oil with 5 per cent. of cotton-seed oil began to melt after 50 minutes, and was completely fluid after 162 minutes (temperature + 12·5). A mixture of 50 per cent. of each oil showed signs of melting after 20—35 minutes, and was fluid in 95 minutes, the temperature being + 8·5 C. This behaviour is illustrated by long tables of results, and the time and temperature of melting are shown to stand in fairly constant ratio to the proportion of cotton-seed oil in the mixture. It is further shown that the results are practically the same whether the oils be exposed to the low temperature for one hour or longer.

Several determinations were made of the iodine numbers of the original mixtures, of the portions first becoming liquid, and of the more solid residue remaining in the tube, but the three results were in every case practically identical. Nor did a further fractionation by cold show any increase in the iodine number of the portion first becoming liquid.

—C. A. M.

*"Orsin Oil," A New Lubricant from Herring Fat.*

J. Laudin. Chem. Zeit. 1897, **21**, 265—266.

Up to the present, the experiments carried out to determine the value of herring oil as a lubricating agent have not been satisfactory. The author has investigated the so-called "orsin oil," which is derived from the fat of the herring. This oil has a specific gravity of 0·924 to 0·928 at 15° C., an acidity of 0·326 to 0·42 per cent. of oleic acid, and contains from a trace to 0·026 per cent. of mineral matter. Unsaponifiable oils and water were not present. The flashing point was 262 to 265 C. The new oil is satisfactory on account of its low acidity, and compares favourably in this respect with commercial olive oils, which sometimes contain as much as 30 per cent. of oleic acid. The author has further examined the so-called "refined animal oil," also said to be a lubricant, which is obtained from purified herring oil. It is said to be free from foreign matter and to have an acidity of 0·35 per cent. of oleic acid. Both these oils, it is stated, are rich in the glycerides of oleic and stearic acid and their homologues, whilst the glycerides of phytosteleic and jeoric acid were present only in small quantities. No iodine was detected in the purified oils, but traces were found in such as were unrefined. Crystals of neutral fats were deposited at 15° C., the oils resembling, in this respect, neatfoot oil. For the purpose of comparison, the viscosity numbers of these two oils were determined together with some authentic specimens of other oils.

The following values were obtained, it is said, with an Engler's viscosimeter:—Refined rape-seed oil, 14·5; "orsin oil," 14·1; olive oil from Malaga, 11·9 and 10·8; olive oil from Messina, 11·7; and "animal oil," 17·1. The determination of lubricating values was carried out with the apparatus of Ingram and Stapfer, in which a weight of 20 kilos. was used, and a speed of 1,250 revolutions per minute maintained until the temperature of the oil had risen from 20 to 70 C. The following numbers of revolutions were recorded:—Malaga Olive oil, 17,600 and 16,600; "Orsin oil," 16,000; Messina Olive oil, 15,100; "Animal oil," 15,200; Refined rape-seed oil, 15,600; and rape-seed oil, 13,000.—J. L. B.

*Egg Oil.* M. Kitt. Chem. Zeit. 1897, **21**, [31], 303—304.

By extracting with ether the yolks of 40 eggs, 130 grms. of oil were obtained—a yield of 19 per cent. on the yolks taken. The oil, when freed by filtration from some foreign suspended matters, chiefly lecithin, and dried, was of a clear orange colour, partially solidified at the ordinary temperature, and solidified in the elaidin test.

The following analytical data were obtained:—

Specific gravity at 15° C. ....	0·9144
Acidity value .....	1·2
Saponification number .....	{ 190·3 190·6
Ether value .....	189·0
Iodine value .....	{ 72·2 72·0
Hehner value .....	95·16
Melting point of fatty acids .....	33°—39° C.
Saponification number of fatty acids .....	{ 194·0 195·8
Iodine value of fatty acids .....	{ 72·9 74·6
Acetyl acid value .....	189·7
.. saponification value .....	201·6
.. value .....	11·9
Reichert-Meißl value .....	0·4
Glycerin (percent.) .....	10·4
Lecithin ..	0·2
Cholesterol ..	1·5
Mean molecular weight of fatty acids .....	285·0

By calculation from the formulæ given by Benedikt, Anal. der Fette, pp. 136, 139, and 141, the author came to the conclusion that the percentage composition of the "total fatty acids" of the oil was:—Oleic acid, 81·8; palmitic acid, 9·6; oxy acids, 6·4; stearic acid, 0·6; and cholesterol, 1·6.—C. A. M.

*Linseed Oil, Differences between Boiled and Raw.*

## PATENTS.

*Detergent, Manufacture of.* S. Wohle, London, and A. C. Irwin, Highgate, Middlesex. Eng. Pat. 1978, Jan. 28, 1896.

AN infusion of the leaves of *Albizia amara* in hot water is strained and mixed with a little glycerin, olein, paraffin, spirits of turpentine, and citric or tartaric acid, in the proportion of from  $\frac{1}{2}$  to 1 per cent. of each. This mixture is digested, at about 160° F., with the bruised fruits of *sapindacia*, or with the beans of the *Acacia concinna*, or with dried and shelled horse-chestnuts. The extract is filtered through a press, and ammonia added, but not in sufficient quantity to make the mixture alkaline, and finally mixed with an antiseptic to prevent fermentation. It is said to be specially applicable for cleansing wool and other animal fibres.—C. A. M.

*Lubricants, Impts. in or relating to the Production of.*  
P. R. de Fauchaux d'Humy, Liverpool. Eng. Pat. 5791, March 16, 1896.

ABOUT 5 parts of spermaceti and 15 parts of paraffin wax are dissolved in about 48 parts of crude petroleum heated to 250° F., and when the liquid is clear, 20 parts of pitch-pine-wood sawdust and 12 parts of soda are added. The whole is then boiled until 10 per cent. of the total mass has evaporated, when 10 per cent. of water is added and the mixture heated gently until a soft paste is formed.

—C. A. M.

*Soap, A New or Improved Manufacture of.* P. R. de Fauchaux d'Hamy, Liverpool. Eng. Pat. 5792, March 16, 1896.

THE use is claimed, in the manufacture of soap, "of celinole substances, and more especially of pitch-pine dissolved in alkali and petroleum."—C. A. M.

*Wax for Making Comb Foundation for Bee-Hives, Impt. in the Manufacture of Sheets of.* J. H. Howard, Holme, Hunts. From E. B. Wood, Medium, Ohio, U.S.A. Eng. Pat. 6297, March 21, 1896.

By subjecting the material to a high pressure after having first reduced it to a very plastic condition, the patentee claims that the sheet wax is materially altered in physical condition, becoming transparent and not getting dry and hard. The beeswax or other substance is heated to about 150° F., then cooled until plastic, and afterwards pressed. Special plant is described in which the process is carried out.—C. A. M.

*Oils and the like, Impts. in or relating to the Liberation or Recovery of.* The Fish Utilisation Syndicate, Ltd., and J. C. W. Stanley, London. Eng. Pat. 7269, April 2, 1896.

THIS invention consists in rendering animal or vegetable fats by boiling with water together with a suitable proportion of sodium silicate or other soluble silicate. The oil is subsequently well washed, to remove all traces of alkali. It is claimed that this treatment breaks open the fat-containing cells and also effects some deodorisation or purification.—C. A. M.

*Lubricant, An Improved.* C. S. Gilbert, Millersburgh, Penn., U.S.A., and J. F. Thompson, Liverpool, Penn., U.S.A. Eng. Pat. 10,221, May 13, 1896.

MINERAL oil, lime water, resin oil, sodium sulphate, black antimony, and magnesium carbonate are mixed together in prescribed proportions. It is claimed that the lubricant will not settle to the bottom of the barrel or become solidified.—C. A. M.

*Soap, Improved, for Carpets.* W. P. Thomson, London. From J. van de Bücken and S. Gattfeld, Germany. Eng. Pat. 1208, Jan. 16, 1897.

THE soap is prepared by intimately mixing 69 parts of a hot saturated solution of common soap with 12 parts of sal ammoniac and 4 parts of turpentine. To these are added 16 parts of fresh ox-gall, and afterwards 8 parts of acetic ether, 10 parts of sugar, and 3 parts of honey. Finally, the soap is scented. It is claimed that this soap, whilst cleansing the carpets, also brightens and restores colours.—C. A. M.

### XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

(A.)—PIGMENTS, PAINTS, &c.

*Verona Earth.* Ch. of Comm. J., April 1897. 89.

See under Trade Rep., page 477.

(B.)—RESINS, VARNISHES.

*Resinates, Metallic [and Coloured], Manufacture of [for Varnish Making].* P. Truchot. Rev. Chim. Ind. 1897. 8, 107.

THE resinates of the alkali metals are soluble in water, but the others are insoluble. Although the corresponding compounds of the heavy metals are less soluble in such solvents as enter into the composition of varnishes than those of the alkaline earths, yet they have the advantage of possessing the same colour as their respective hydrates. For very cheap varnish, common dark rosin may be used, but for higher-class products only the palest varieties can be employed; and it is often advisable—especially when coloured resinates are required—to first filter and bleach the colophony.

To effect this latter object the material may be either (1) distilled with superheated steam; (2) treated with chlorine, sulphuric acid, water, and finally weak nitric acid; (3) warmed with common salt and chromic acid, or a mixture of a bichromate and sulphuric acid, and washed in weak ammonia; (4) dissolved in alkali, the solution treated with chlorine, and the resin precipitated with an acid or a metallic salt; (5) heated with zinc dust, with or without the addition of sodium bisulphite or oxide of manganese and a bichromate, followed by filtration through sand; or (6) heated with sulphuric acid under a pressure of about 65 lb. for an hour, then cooled and washed in water. One of the best, but rather expensive, methods is (7) to filter the rosin, and then heat it for one or two hours with 5 per cent. of zinc chloride, afterwards adding 12 per cent. of potassium bichromate, cooling to 100° C., and filtering once more.

The hydrates of certain metals, after being dried at low temperatures, are dissolved direct on agitating them with a solution of rosin in coal-tar naphtha; but in other cases the desired resinates are obtained from the sodium compound by double decomposition. In the preparation of the latter, care must be taken only to employ the theoretical amount of alkali, and also to see that it is sufficiently free from carbonate, sulphate, silicate, &c., to prevent any contamination of the desired resinate with inorganic salts of the metal, insoluble in the volatile varnish solvent. The resinate of copper must be precipitated and dried in the cold; but in many other instances slightly warm liquids may be used, and the temperature of the drying room may be raised somewhat, except as mentioned below. The two solutions are mixed together in molecular proportions, and it is occasionally convenient to employ, as the precipitant, salts of two different metals (e.g. zinc and copper) in order to obtain double resinates at one operation. The precipitates are very bulky, and take a long time to settle; but they must be well washed in cold water, especially if they are liable to contain a deliquescent body, such as chloride of calcium or magnesium, since these would materially hinder the drying of the varnish.

The metallic resinates dissolve more readily in the light coal-tar hydrocarbons than in the corresponding petroleum products, although their solutions in the former may be diluted to the proper consistency with light petroleum spirit, as this helps them to dry more quickly. Solution is also assisted by previously dissolving in the naphtha a quantity of rosin equal in amount to that existing in the resinate—a plan which has the advantage of saturating any free hydrate or carbonate of the metallic base.

If the solution of sodium resinate is mixed with a suitable aniline dye before the addition of the other metal, on precipitation a coloured resinate is formed after the fashion of ordinary lakes. In such cases both precipitation and drying must be carried out in the cold; and it is very important to remove as much moisture as possible by means of the filter press before placing the substance in the drying chamber. The coloured resinates of magnesium dissolve very readily in methyl alcohol, while those of the other metals are preferably dissolved in naphtha as before. Generally speaking, they are soluble in spirit varnishes and in oils, &c. which contain free fatty acids.

Excepting the aluminium compound, they keep well in solution, but are decomposed above 100° C. As varnishes they yield a good film, but the latter is brittle and apt to blister unless special precautions are taken to remedy these defects.—F. H. L.

(C.)—INDIA-RUBBER, &c.

PATENTS.

*Substitute for India-Rubber, Celluloid, Leather, Oil-Cloth, Linoleum, Mother-of-Pearl, Tortoise-Shell, Amber, Ivory, and the like; An Improved Plastic and Incombustible Material to be used as a, and capable of being moulded, drawn, or made into Threads, and in the Form of Plates, Tubes, Cylinders, or Soft and Silky Threads, Resembling Silk in Appearance.* Eng. Cadoret, Paris. Eng. Pat. 12,451, June 6, 1896.

THE base of the "textiloid" is an oxidation product of oils, termed by the patentee "résinoline." This is prepared by

saponifying one part of any suitable oil with three-fourths part of a metallic carbonate, and treating the soap with one part of nitric acid (36°). After a contact of 30–25 minutes the liquid is decanted and the fatty body saponified by one part of caustic alkali. The soap is treated with acid and the liberated resinoid substance purified by solution in ether or alcohol, and evaporation of the solvent. The "résinolines" thus prepared show a great analogy in physical properties to ordinary resins. When combined with oxides or earths, natural resins, cellulose, nitro-cellulose, organic matter such as gelatin, or a mixture of these, they form the "textiloid."

For example, 100 parts of "résinoline" are mixed with 20 to 30 parts of zinc oxide, magnesia, kaolin, or the like, 60 parts of methyl alcohol are added, and the whole left for three or four hours, after which the mass is divided and passed through a rolling machine with horizontal cylinders slightly warmed (30–40°). After one or two hours' working, the paste, from which the alcohol has now evaporated off, is submitted to a pressure of from 200 to 300 atmospheres in a hydraulic press heated to 80–90°. After five or six hours the necessary consistency is attained, and the mass can be cut up, moulded, drawn, or made into threads.

In the case of organic substances such as protein, gelatin, and albumin, a preliminary treatment with glycerin and nitric acid is required before they can be incorporated with the "résinoline." In addition to the uses enumerated in the title, it is claimed that the "textiloid" can be applied to the manufacture of incandescent gas mantles.—C. A. M.

*Gutta-Percha and Caoutchouc-like Substances, Impts. in the Production of Artificial.* F. Fenton, London. Eng. Pat. 26,548, Nov. 24, 1896.

EASILY oxidisable vegetable oils, such as linseed, hempseed, nut oils, or cotton-seed, are mixed with tar or "other form of pyroligneous acid," macerated in a bath of dilute nitric acid, and, when formed into a semi-magma, roasted in hot pans or plates. The elastic mass produced, can be vulcanised and applied to the same uses as india-rubber.

For artificial gutta-percha, shellac is added in the proportion of from 1 to 20 per cent. before the nitric acid bath. If extra firmness be required, the magma is worked up with a portion of quick or caustic lime.

The proportion of tar or pitch required is from 5 to 75 per cent. of the oil taken, the lower percentages being used for the more rubber-like forms.—C. A. M.

*Compositions for Repairing Leaks in Pneumatic Tyres, Impts. in.* C. S. Howe and J. W. Langley, Cleveland, Ohio, U.S.A. Eng. Pat. 27,764, Dec. 5, 1896. (See also this Journal, 1896, 818.)

SODIUM silicate solution is mixed with thrice its volume of a solution of mucilage, starch, or dextrin, with or without glycerin, and is neutralised by an acid to form a thick jelly of silicic hydrate, which is then mixed in a churn with three additional parts of the gum or starch solution. Or, an aluminous magma may be formed by mixing a solution of alum or aluminium sulphate, or of an alkaline aluminate, with the solution of gum or starch, followed by treatment with an alkali or an acid, as the ease may be, and subsequent procedure as with the before-described silicious magma. From 4 to 6 oz. of the composition are introduced into the tyre, any small puncture in which, is automatically repaired by its action.—E. S.

#### XIV.—TANNING, LEATHER, GLUE, SIZE.

*Quebracho Tanning, Difficulties in.* W. Eitner. Der Gerber, 23, [542], 81–82.

QUEBRACHO has now taken a permanent place in tanning, and some correspondence with a sole-leather tanner using it along with oak bark, has brought to light difficulties in its use, and enabled the Versuchsstation to point out the proper method of using it. In the case in point, the tanner had extracted the quebracho with hot liquors made from oak layers. He found the leather had not the nice

white appearance of a pure oak tannage, and had a very thick grain. The extraction of quebracho with hot liquors made from old wood is quite wrong, as a great excess of colouring matter is thus dissolved out; this causes not only a bad colour, but a thick grain, owing to the layer underneath the grain absorbing the colouring matter, and causing the grain to stand out.

The proper way is to mix the quebracho with fresh oak bark and to use the combination as a layer material. Quebracho tannin extracts quite as easily as oak tannin, and, used in this way, gives a light colour. For the preparation of sour liquors, the oak and quebracho from the layers is mixed with pine bark and extracted cold.

At 88° C. all useful matter is extracted from quebracho; the warm liquor should not, however, be run direct to the pits, but first over a sour bark.—J. T. W.

*Egg-Oil.* M. Kitt. Chem. Zeit. 1897, 21, [31], 303.

See under XII., page 448.

*Leather Dyeing with Artificial Dyestuffs.* Leipziger Färber- u. Zengdrucker Zeit. 46, [4], 162.

#### PATENTS.

*Tanning Extracts and Dyestuffs, Impts. in and relating to the Manufacture of.* H. H. Lake, London. From Lepetit, Dollfus, and Gansser, of Milan and Susa (Piedmont), Italy. Eng. Pat. 8582, April 23, 1896.

See under IV., page 436.

*Horn, Impts. in the Manufacture of Artificial.* P. H. Hansen, and J. K. Westengaard, Copenhagen, Denmark. Eng. Pat. 1559, Jan. 20, 1897.

ABOUT 100 parts of separated milk are taken, and one part soda and  $\frac{1}{10}$  part pure hydrochloric acid added. After standing from one to three days, about three-fourths of the water will have separated, and the casein is removed and allowed to ferment for a few days longer. This is then pressed in linen bags and the solid portion dried at about 60° C. It is then ground, and 70 parts are mixed with about 28 parts of ground bone, kaolin, gypsum, or the like, about 2 parts of stearin or paraffin wax, and as much water as is necessary to form a stiff dough, the temperature being raised to 90° C.

The dough is placed in a hot mould and worked into sheets, a pressure of about 10 atmospheres being employed. The material is brushed over with burnt magnesite, placed in water for a few days, and dried.—A. L. S.

#### XV.—MANURES, Etc.

*Basic Slag, Chemical Composition and Agricultural Value of.* G. Patruel. Bull. Soc. Chim. 1897, 17, 319–321.

WORKING with basic slags of French origin containing 14–19 per cent. of phosphoric acid, the author confirms the view that they contain calcium tetraphosphate and silicate, with uncombined alumina, magnesia and oxides of iron and manganese. He finds that the solution of the free lime in ammonium chloride liquor (which is without effect on the phosphate and silicate) gives results in accordance with those calculated on the above supposition from the analysis of the whole sample. The solvent action of acid ammonium citrate solution on the phosphoric acid varies with the method of operation and with the proportion of free lime present. Since those samples which contain most free lime are the least soluble in the reagent, it would seem to indicate that the acid citrate was not suitable for determining the value of the slag as a fertiliser. The normal alkaline ammonium citrate made by Joulie's formula, contrary to the accepted belief, may be made to dissolve the whole of the phosphoric acid in the slag, if the latter be sufficiently finely ground and the agitation of the mixture be prolonged. Since no natural phosphate yields even a trace of its phosphoric acid to this solvent, it may be assumed that no tricalcium phosphate is present in the slag. At the same time, this reagent affords a ready means of determining the quantity of natural phosphate in an

adulterated sample. The slag exerts a profound influence upon nitrification in acid soils, and it is therefore desirable to work a considerable quantity of the slag into such soils, the proportion of possible nitrification being increased with each addition of slag. The action being due to the free lime present, it is evident that with equal phosphate contents, the slag containing most lime is the best; and the determination of the latter substance is of the highest importance from an agricultural standpoint.—W. G. M.

*Phosphates in Bone Meal, Citrate Solubility of.*

A. Keller. Chem. Zeit. 1897, **21**, 323.

SEVERAL portions of bone meal, of best quality and fineness (each 10 grms.), were placed in beakers and covered with water (5—10 mm.), which was renewed from time to time as it evaporated. The beakers were exposed for four months, some (a) to direct sunlight, the rest (b) being in the shade.

The following analytical results show the percentage composition of the original bone meal, and of the meal after decomposition:—

	Fresh Meal.	Decomposed Meal.	
		a.	b.
P <sub>2</sub> O <sub>5</sub> total.....	23.62	..	..
„ citrate-soluble.....	15.81	7.52	10.03
N total.....	5.21	4.90	5.03
N as NH <sub>3</sub> .....	0.03	1.74	1.22
Fat.....	2.06	..	..

Assuming dicalcium phosphate to be present in the meal, the results indicate that the diminished solubility is due to formation of dicalcium ammonium phosphate. This may account for the want of agreement between the results of manual experiments with bone meal and the analytical results (citrate solubility of the phosphoric acid). These, and other experiments made by the author confirm the opinion that the degree to which bones are freed from fat is often of greater influence than the quality of the bones. The percentage of fat in bone meal should therefore be determined, as well as the citrate solubility.—N. H. J. M.

PATENT.

*Artificial Manure or Fertiliser, A New or Improved, and Process for Manufacturing the same.* O. G. Blunden, London. Eng. Pat. 10,109, May 12, 1896.

CARBONISED peat, peat ash, and the liquid product of the destructive distillation of peat, are mixed with gypsum or its equivalent in suitable proportions to form a manure.

—E. S.

## XVI.—SUGAR, STARCH, GUM, Etc.

*Sugar in Water, Law of Contraction on the Solution of.*  
A. Wohl. Ber. 1897, **30**, 455—460.

FROM an investigation of the contraction which takes place when sugar is dissolved in water, the author has arrived at the following empirical laws:—

For a solution containing  $x$  parts of sugar and consequently  $1-x$  parts of water, the contraction  $d v$  referred to unit volume is given by the equation:—

$$d v = 0.00303 \frac{x(1-x)}{1-\sigma x}$$

where 0.00303 is a constant, representing the influence of sugar and water on each other, and  $\sigma = 0.35965 = 1 - \frac{1}{s}$ , where  $s$  represents the density of sugar supposed to be in the liquid state (1.56165).

The specific volume of the sugar solution is—

$$v = (1-\sigma x) - \frac{0.00303 x(1-x)}{1-\sigma x}$$

and the reciprocal of this, viz., the specific gravity of the solution, is—

$$s = \frac{1-\sigma x}{(1-\sigma x)^2 - 0.00303 x(1-x)}$$

The author claims that the specific gravity can thus be calculated correctly to the fourth or fifth decimal place.

—J. S.

*Sugar Refining, Methods of Defecation in Louisiana.*

F. C. Thiele. Chem. Zeit. **21**, [16], 136—137.

THE author discusses the relative methods of cold and hot defecation of cane juice. On most of the plantations in Louisiana, the lime is added in the form of a cream to the cold juice. In some few instances the milk of lime is poured into the defecator, and the steam turned on immediately, the juice being allowed to run on to the hot pipes; but this method is not generally practised. Experience has shown that in order to obtain a white sugar, the lime should be only added in such quantities as just to avoid the evolution of ammonia; that is, the juice must be kept slightly on the acid side. As a general rule, about 0.1 to 0.15 per cent. of lime has been found to be sufficient. If the lime be added to the previously heated juice, it is difficult to hit the exact quantity, as the colour reactions of the hot juice are not the same as those observed in the cold. An excess of lime may thus be added unawares, in which case the resulting product would be of a dark colour.—I. S.

*Cane-Sugar Juice, Carbonating of* Prinsen Geerligs.

Chem. Zeit. 1897, **21**, 241—212, 262—263.

THE author concludes from his experiments that double carbonating of cane-sugar juice is to be avoided if a product ready for direct consumption is required, because in the warming and neutralisation of the mud, some portions pass into the juice. This process also requires more lime and carbonic acid, and also time, than simple carbonating, for if the calcium gluconate is to be retained in the defecation mud, cold filtration must be adopted. Thus, the juice, which filters with difficulty in the cold, must be mixed with a considerable amount of calcium carbonate in order to start the filtration of the mass. If simple carbonating be employed, the brown colour dissolves as saturation proceeds, and the juice can then be filtered hot.—J. L. B.

*Diffusion Juice, Conditions of Inversion of the Sugar of*  
L. Jesser. Bull. de l'Assoc. des Chim. de Sucre et de Dist. 1897, **14**, 822—828. Die deutsch. Zuckerind. Jan. 2, 1897.

THE question whether there are indeterminate losses from destruction of sugar during the diffusion process and the subsequent manipulation of the juice, has not been answered categorically, although this is one of the most burning questions of the sugar manufacture.

It is well known that raw beet juice is strongly acid, but of varying amount to different indicators. This fact, and the difference of alkalinities resulting from the use of litmus and of phenolphthalein in the clarification of the juice with lime water, make it doubtful that acid salts are the sole cause of the acidity; and it is thus impossible to coincide as to the invertive power by the acidity of the juice alone.

There are three reasons for losses of sugar during diffusion, which are the consequence of some modification of the juice: loss by fermentation, loss by direct overheating, and loss by inversion of sugar caused by the non-sugar.

In the actual conditions of work, fermentation may be dismissed as non-existent, the temperature being too high to allow of the existence or the vitality of micro-organisms. An infection of diffusion juice is only possible when the works is badly served with water, or when residual waters are returned without previous purification. These being at a temperature of 50° or 60° C., and meeting cold slices, may cause destruction of sugar.

Loss by overheating may be caused by want of cleanliness, or by using direct instead of exhaust steam. Under normal conditions the indeterminate loss in diffusion may amount to from 0.3 to 0.5 per cent. of sugar per 100 kilos. of beet-roots. But it cannot be admitted that this loss is produced by

inversion. This results from the experiments of Claassen, who found the invert sugar in diffusion juice always less than that contained in the beetroot. These researches, however, are encumbered with the uncertainty of manipulations with Fehling solution.

It is of the first importance to know and prove if, in general, it be possible to attribute an invertive power to diffusion juice, and of what importance it may be from one year to another. Raw juice is known to contain a series of substances which, on boiling with bases, are converted into acids. If, on boiling the original juice, invert sugar be formed, the acid formed during subsequent treatment by alkali must be increased proportionally. This conclusion can only be drawn after having proved that the non-sugar has suffered no change on boiling. To decide this point, sugar was added to diffusion juice and the increase of acid noted in the two cases. If the increase of acid is proportional to the quantity of sugar added, it is possible to infer that the juice has an invertive action, and to measure it. The results of a number of experiments made by the author show that the indispensable conditions for inversion really exist in diffusion juice both during and after diffusion, and that it varies from one year to another. It may be said with certainty, however, that a loss greater than 0.15 per cent. is impossible under normal conditions, this figure being reached only once by boiling for an hour.—L. J. de W.

*Beetroot and Diffusion Juice, Acidity of.* L. Pannenko. Bull. de l'Assoc. des Chim. de Sucri. et de Dist. 1897, 14, 829—830.

PANNENKO carried out during a whole campaign a series of comparative tests of beetroot juice (cossettes) and corresponding diffusion juice for acidity. The acidity was expressed in c.c. of normal caustic soda per 100 c.c. of juice, and calculated to 100° Brix.

The tables given show the diffusion juice higher by 0.02 to 0.60 than that from the cossettes. The acidity of the beetroot juice during the campaign varied greatly, ranging from 5.0 to 11.2 c.c. of normal caustic soda. Healthy normal beetroots invariably yielded juice the acidity of which did not much exceed 5.0 c.c. of normal soda, and these juices worked very well in the factory. Diffusion juices which showed an acidity of 11 c.c. of normal soda, passed the filter presses very badly; in proportion as the acidity lessened, the work made better progress.

The author found but slight differences between the acidity of diffusion juice as it left the battery and that of the same juice from the measuring tank. The latter was always slightly higher. According to the author, the principal cause of this increase is to be sought in the fact that the measuring tanks are not always emptied; there remains always a portion of an older juice (the acidity of which has increased by the reason that it is older), and this mixes with the juice newly arrived. When the tanks are completely emptied and cleaned, the differences in acidity become less marked. A table given shows that, before cleaning, juices varying from 6 to 9 of acidity, increased by 0.53 to 0.91; after cleaning, the increase was only from 0.10 to 0.43.—L. J. de W.

*Sugar Solutions, Crystallisation of.* A. Herzfeld. Zeits. f. angew. Chem. 1897, 221—224.

The author reviews the theory of Wulff and the processes for crystallisation in motion, leading towards the ideal of the raw sugar manufacture—the production of a single product and molasses.

Maunoir's process for returning the whole of the syrup to the first product must eventually so increase the quantity of mother-liquor that it can no longer be worked rationally. There is more prospect of success when two qualities of sugar are made, the first syrup being incompletely exhausted, the after-product boiled to grain and then stirred for a few days to produce a second product and molasses. The author has satisfied himself of the feasibility of this process, which has been worked during the last campaign in Russia and Austria.—L. J. de W.

*Molasses [Sulphites], Process for the Purification of.* K. F. Kastengren, Stockholm. Bull. de l'Assoc. des Chim. de Sucri. et de Dist. 1897, 14, 811. (From Magyar czukoripar.)

THE object of the process is to facilitate the purification of molasses, and even to convert it into an edible product, whatever its degree of impurity may be. This result is obtained by boiling the molasses under pressure, after adding an alkaline sulphite, calcium sulphite, or even sulphurous acid in excess.

By boiling under pressure, reactions are induced in the molasses, resulting in purification and decoloration.

The excess of sulphurous anhydride may be added before boiling. If, after boiling, an excess of lime be still found, it is easily eliminated by saturating with carbonic acid.

—L. J. de W.

*Molasses, Extracting Sugar from, by Baryta.* H. R. Langen. Bull. de l'Assoc. des Chim. de Sucri. et de Dist. 1897, 14, 811—812. (From Centr. Zuckerind. d. Welt.)

LANGEN, of Euskirchen, has patented a process for the extraction of sugar from molasses by means of baryta. He employs, for the precipitation of the sugar, so-called barium hydroxysulphide, obtained as a mixture of barium hydroxide and hydrosulphide by the solution of barium sulphide. Du-brunfaut and Leplay showed that the reaction between barium sulphide and sugar in presence of water gave barium sucate; for this reason, the patentee claims only the method of regenerating the barium sulphide.

The process is relatively simple if the carbonic acid at disposal be rich. The mother-liquor, filtered from the barium sucate, contains the excess of barium and the whole of the sulphur. On treating it with carbonic acid, barium carbonate is obtained and sulphuretted hydrogen is liberated. This latter, on combustion, is converted into sulphuric acid.

The acids obtained serve to convert barium carbonate into sulphite or sulphate, and the latter, on reduction with carbon, gives rise to barium sulphide again.

Sulphuretted hydrogen, however, only enters into combination when it is relatively pure. To obtain it in this state, it is necessary to have rich carbonic acid, for gases mixed with ordinary carbonic acid likewise mix with the sulphuretted hydrogen and dilute it. Rich carbonic acid as an industrial product cannot be reckoned upon. The author has therefore sought to modify his process so as to be able to use carbonic acid of average strength.

The modification is as follows:—To the mother-liquor filtered from the sucate, magnesium sulphite is added. Insoluble barium sulphite is formed and magnesium hydroxide, while sulphuretted hydrogen is disengaged, and is converted by combustion into sulphurous acid. The precipitate formed, filters badly, on account of the gelatinous nature of the magnesium hydrate. To render it filterable, it is converted into magnesium carbonate by a current of carbonic acid gas. The mud separated from the mother-liquor is treated with sulphurous acid, converting it into magnesium sulphite, which, being soluble, is easily separated from the barium sulphite. It can thus be returned to the cycle of operations.—L. J. de W.

*Raffinose, Occurrence of, in American Sugar Beets.* W. E. Stone and W. H. Baird. J. Amer. Chem. Soc. 1897, 19, 116—124.

ATTENTION has been called to the fact that the amount of raffinose found in sugar beets is dependent on climate, soil, seed, conditions of growth, &c., and since the conditions under which beets are grown in America differ in many respects from those of Northern Europe, it might be expected that this minor constituent would be absent. The authors find, however, that raffinose occurs in the juice of American sugar beet in appreciable quantities. The circumstance that raffinose, like cane sugar, forms an insoluble compound both in hot and cold solutions with alkaline earths, accounts for the accumulation of the first-mentioned sugar in molasses and secondary products. Raffinose, to a large extent, remains uncrystallised in the presence of

considerable quantities of cane sugar, and this fact, in conjunction with its behaviour with alkaline earths, explains why nearly the whole of this sugar is found stored up at the close of the campaign in the molasses and second-grade syrups.

Unsuccessful attempts were made to detect raffinose in syrups by means of the mucic acid test, this acid being held in solution in the form of salts. Kodyl and Scheibler's methods were unsuccessfully employed for the isolation of raffinose from molasses. The authors have devised the following process, which is a combination of the preceding ones:—2,000 grms. of syrup were diluted with water and treated with a large excess of basic lead acetate. The solution was decanted from the precipitate, and, after further dilution, was treated with ammonia until strongly alkaline. After standing in a warm place a heavy precipitate settled, which was supposed to consist of 1 mol. of raffinose or cane sugar with 3 mols. of lead oxide. This was washed by decantation and treated with sodium carbonate and carbon dioxide until all the lead was removed. The filtrate obtained was concentrated to a thin syrup, and strontium oxide added in the proportion of 3 mols. to one of sugar. The mixture was maintained at the temperature of boiling water for three hours, during which time a granular precipitate was thrown down, consisting of strontium saccharate and raffinosate; the strontium compounds thus obtained were decomposed by carbon dioxide, the solution filtered and evaporated to a thick syrup. This, on standing, became solid, and after careful fractionation with methyl alcohol and water, a product was obtained having an  $[\alpha]_D^{20}$  103.7°.

It is to be noted that the influence of raffinose is manifested, not in the appearance of isolated raffinose crystals, but in a modified and abnormal appearance of all the crystals, which are similar to each other, but entirely distinct from those of cane sugar. This tendency of raffinose to modify so distinctly the crystals of cane sugar would seem, in the opinion of the authors, to afford a means of readily identifying the presence of small amounts of raffinose in cane sugar.—J. L. B.

**Beetroot Sugar Analysis.** Resolutions of the Austro-Hungarian Chemists engaged in the Sugar Industry at the Meeting at Buda-Pesth, June 22, 1896. *Zeits. angew. Chem.* 1897, 123.

See under XXIII, page 472.

**Sugar Solutions, Nitrate of Lead: The Use of, for Decolorising Various.** H. Pellet. *Bull. de l'Assoc. des Chim. de Sucre, et de Dist.* 1897, 14, 794. (This Journal, 1897, 67.)

See under XXIII., page 472.

**New German Sugar Tax, Effects of the.** Export, 19, [14], 185.

See under Trade Rep., page 477.

## PATENT.

**Adhesive Compounds, Impts. in.** A. J. Boulton, London. From C. M. Higgins, New York, U.S.A. Eng. Pat. 2746, Feb. 2, 1897.

This is a slight modification of the inventor's previous patents, 22,682 and 22,685 of 1891 (this Journal, 1892, 447), in that the borax is added to the cold solution of dextrin instead of to the hot solution.—A. L. S.

## XVII.—BREWING, WINES, SPIRITS, Etc.

**Dextrose (d-Glucose).** A. L. Stern. *J. Fed. Inst. Brewing*, 1897, 3, 179—194.

The following are given as typical analyses of commercial glucose:—

	1.	2.	3.	4.	5.
Water .....	10.5	9.9	15.7	17.8	16.0
Dextrose .....	89.0	70.6	67.4	64.9	65.3
Maltose .....	..	5.1	11.0	12.4	2.1
Dextrin .....	..	..	..	4.3	1.2
Unfermentable bodies .....	8.2	14.8	4.3	not determined.	14.3
Ash .....	1.3	0.2	1.6	0.6	1.1
	100.0	100.0	100.0	100.0	100.0

No. 1 is a very good sample, and much above the average. No. 2 is met with in large quantities at the present time, and is an excellently manufactured product; the small ash probably indicates that oxalic acid was the converting agent. No. 3 is not properly converted, and this is indicated by the amount of maltose, the low percentage of unfermentable matter, and the high percentage of water; the ash is also excessive. No. 4 shows a bad analysis, the neglect to determine the unfermentable matter making the figures valueless. No. 5 is a fairly good product, but the water and the ash are too high. In the valuation of a sample of commercial glucose, the following points have to be considered:—The colour of the solution should not be excessive; the solution should be fairly bright; the ash should not much exceed 1 per cent.; the extract should not be much under 77 lb. per 2 cwt. per barrel, and no samples should give less than 73 lb. per 2 cwt. per barrel; the fermentable matter should not be less than 70 per cent., or less than 80 per cent, if calculated on the dry matter, and there is no reason why this should not partly consist of maltose.

—A. K. M.

**Dried Yeasts, Observations on the Vitality of.** H. Will. *Zeits. f. d. ges. Brauw.* 20, [6], 91—92. (See also this Journal, 1897, 155.)

The various conserves were re-examined, at the expiration of 10½ years, for the presence of living yeast cells, those in tins being in the best condition, without any apparent smell or evolution of gas being noticed on opening. In view of the presumably small proportion of living cells still existing, larger samples (5 to 6 grms.) than before were taken for examination and sown in sterile hopped brewery wort. The bacteria present retarded the reproduction of the weakened yeast until themselves repressed by acidifying the medium, but when the cultures are left alone the bacteria entirely suppress the yeasts, and infest the dead cells of the latter. In view of the weakening of the dried yeast cells, it was deemed inadvisable to acidify the first culture, but on re-inoculation in fresh wort a little tartaric acid was found advantageous.

The results of the cultures at 25° C. demonstrated that in the asbestos conserve No. 7, wild yeasts alone were present; asbestos No. 8 containing chiefly wild, with a few culture yeasts; charcoal No. 9, mostly culture yeasts; charcoal No. 10, a predominance of wild yeasts, and wood pulp No. 13 C<sup>1</sup> (stored in ice) the same. *S. apiculatus* could not be detected in any. The wood-pulp conserve No. 13 C<sup>2</sup> (kept in a stoppered bottle in the window) and paper pulp No. 2 (top yeast) merely contained dead cells.

Bacteria (cocci and diplococci) were present in nearly all the cultures, and acetic ferments in 13 C<sup>1</sup> and 10. Nos. 8 and 10 showed brisk fermentation after 48 hours, but no living yeast cells could be identified with certainty. In Nos. 13, 9, and 7 signs of fermentation appeared only on the third, fourth, and fifth day, and new cells were discernible. The irregular development of the yeasts in parallel cultures showed that the living cells are very unevenly distributed in the conserves.

Compared with the results of the ninth year's examination, those now obtained were concordant, except with charcoal 9 and wood pulp 13 C<sup>2</sup>, in both of which the proportion of living culture yeasts was relatively greater than in the others.

A fresh proof of the unfavourable storage conditions (higher temperature, influence of light) of the wood pulp

13 C° as compared with C° was afforded by the presence of a comparatively large number of living yeast cells in the latter and their total absence in the other.—C. S.

*Yeast, Chinese (Amylomyces Rouxii). Utilisation [Spirit Manufacture] of, in European Fermentation Industries.* A. Boidin and E. Rolants. La Bière, 5, [3], 33—36.

This yeast has already been described by Calmette (Ann. Inst. Pasteur, 1892, 604). The present authors find that the organism produces less alcohol, by about 12 per cent., than is obtained from rice by the ordinary method practised in France, the shortage being due to consumption of hydrocarbons during the aerobic existence of the ferment.

Working with yeast manufacturers' wort, they find that the action of the organism is even more restricted than in the former case, ceasing when the alcohol amounts to 4 per cent. of the liquid. A study of the effect of acidification on the saccharification of rice by *Amylomyces R.* led to the conclusion that the formation of acid during the process is in inverse ratio to the amount of sulphuric acid added; that the diastase is paralysed by an excess of acid and also by a neutral condition of the paste, its activity being greatest in a faintly acid medium; that in presence of an excess of calcium carbonate the sugar and alcohol formed are rapidly eliminated; and that the sugar formed is glucose and not maltose.

When applied to the residual liquor from the distillation of the fermented wort in yeast factories—which liquor contains about 10 grms. of dextrin, 7.2 grms. of albuminoids, nearly 4 grms. of sugar, and 13 grms. of non-nitrogenous bodies per litre—and left to ferment, the *Amylomyces* produces acid in inverse proportion to the original acidity of the medium, and when the latter amounted to over 3.40 grms. (expressed as sulphuric acid) per litre, a portion is eliminated. More acid is formed by surface culture than by bottom culture, the crop of *Amylomyces* increases with the aeration, and the amount of hydrocarbons eliminated, when the medium is neutral and aerated by blowing. By prolonging the time allowed for the operation to 7 days, between 0.9 and 1 per cent. of alcohol was obtained—a result also attainable in the shorter time by fermenting at 34°—35° instead of 26°—30° C.

Further investigations pursued on a practical scale at Collette's yeast factory at Seclin, resulted in the production of some 270 litres of absolute alcohol from 300 hectolitres of the residual still-liquor and grains, the value of the product being 93 francs, at a cost, for fuel and rectification, of 22 francs, so that the net profit from 300 hectolitres of otherwise waste liquor is 71 francs, or, in an establishment producing 750 hectolitres of liquor per diem, a daily gain of 177.50 francs (7l. 2s.), which figures will give some idea of the value of *Amylomyces Rouxii* for the treatment of distillers' grains.—C. S.

*Wine Yeasts.* Kayser and Barba. Bulletin Ministère Agric. 1896; Zeits. f. d. ges. Brauw. 20, [7], 108.

PURE cultures were made of yeasts isolated from the sediment of wines from the department of Gard (France) and compared with a number of other wine yeasts. Acidity and temperature of fermentation being the two chief points of interest, were investigated, the cultures being sown in malt-germ water containing 188.76 grms. of sugar, 6.02 grms. of tartaric acid, and 223.70 grms. of total extract per litre, and allowed to ferment at 25° and 35° C. On comparing the results it appears that with the higher temperature and a medium rich in sugar and acid, the yeasts work themselves out before all the sugar is eliminated, the strongest yeast degrading only 140 out of 180 grms. of sugar per litre, and the indigenous yeasts leaving less behind than those from other districts; at the lower temperature the results were more nearly approximate. The amount of acid produced was irregular, but, as a rule, greater with the higher fermentation temperature than at 25° C., and the indigenous yeasts generally gave rise to less acidity than the others.

Cheek experiments were made to determine the influence of the percentage of sugar and acid. In the one series, with a medium containing 176.87 grms. of sugar per litre, the results obtained indicate that at 25° C. the influence of the acid is negligible, but with higher temperatures, an

increase of acid helps to restrict the elimination of the sugar, the southern yeasts being throughout more energetic than the more susceptible varieties. The latter are retarded by temperature alone, both as regards the production of alcohol, fixed acids, and yeast crop, but the formation of the volatile acids and fermentative energy are generally increased; in presence of greater acidity the results, however, vary according to the individual character of the yeast.

In the second cheek experiment, with a medium containing only 86.206 grms. of sugar and 2.22 grms. of tartaric acid per litre, similar results were obtained, both sets confirming the influence of the higher temperature on the elimination of sugar, especially in a rich and strongly acidified medium, and also that an increase of sugar, particularly in conjunction with a high temperature, retards elimination. On the other hand, the influence of acidity, apart from temperature, is much greater on the indigenous yeasts than on some of extraneous origin, which are more susceptible to temperature.—C. S.

*Beer, A hitherto undescribed Turbidity in.* H. Will. Zeits. f. d. ges. Brauw. 20, [5], 77.

THIS turbidity is caused by the presence of a number of minute pale drops, resembling, to some extent, the so-called gluten-bodies, except that they are apparently liquid, and exhibit no dark outline. Even when present in considerable numbers, they do not seem to produce more than a "haze," and the quantity is never large enough to enable their chemical nature to be ascertained. They stain slightly with aniline colours and with iodine and potassium iodide, but do not seem to store up the colouring matter, like albuminoid bodies do even when the granules are small; so that it can hardly be assumed that they consist of albuminoid matter; neither, in the author's opinion, can they be ascribed to precipitated resins or hop-constituents.

Similar drops were found by the author in the nutrient gelatin prepared from the fermented worts of old mycelium cultures of low-fermentation yeasts.—C. S.

*Beer, Yellow Foam and Ferruginous Flavour in.* J. Brand. Zeits. f. d. ges. Brauw. 20 141.

INSTANCES frequently occur wherein beer, initially good, acquires, after standing several weeks in the transport casks, an inky flavour, and exhibits a persistent yellow foam, which, on examination, is found to consist of bubbles enveloped in a strong albuminoid integument. In a sample of this kind examined by the author, the inky flavour disappeared after several days, but was succeeded by another, reminiscent of bad pitch. Iron being found present, the pitchy flavour suggested that its source was the ochre used for colouring brewers' pitch; however, several samples of these substances were tested by immersion in beer for some days, but in no case could any trace of dissolved iron be detected, either by taste or reagents. (It is finally considered inadvisable to use ochre for colouring brewers' pitch.)
